A range of scaffolds was electrospun using both artificial and natural materials (including polyurethane, poly vinyl alcohol and gelatin). Fabrication parameters were altered to produce nano- and micro-scale, aligned and non-aligned structures.

Scaffolds were characterized, using SEM and image analysis, with respect to inter-fibre separation, fibre diameter, void fraction and fibre orientation. Surface and bulk properties, including stiffness, were assessed using mechanical testing and image analysis.

Additional data was collected from existing literature.

Natural Extracellular Matrix

L929 immortalised murine fibroblasts, human Schwann cells and bovine aortic endothelial cells were cultured separately on UV-Ozone sterilised TCP discs for 7 days (seeding density of 5×10^4 cells). The extracellular matrix of each cell type was characterized through the use of cryo-SEM (no fixation or dehydration). The matrix fibres were analysed as above; additional 2- and 3-D data was again obtained from literature.

Comparison of Structural Organisation

4 repeats of each of the artificial and natural structures were examined ($n=20$ for image analysis measurements per sample). Statistical analysis was then performed to obtain mean, standard deviation, and analysis of variance (ANOVA) with post hoc testing (Tukey) values (significance tested at $P<0.05$). Structures were compared across inter- and intra-sample groupings.

RESULTS AND DISCUSSION

Differences were determined in the organisation of the fibres across all natural and artificial samples. Aligned and non-aligned samples were shown to contain inherent non-uniformity in all parameters measured, with aligned fibres demonstrating higher values of variance (for both artificial and natural samples). The exact electrospinning methodology altered the structural arrangement of the laid-down fibres, as also did the location of the natural tissue extracellular matrix.

Figure 1 shows the inherent variance of natural extracellular matrix fibres (SEM image; scale bar 2µm). The graph shows that the deviation of fibre diameters in aligned natural and artificial matrix was comparable ($P>0.05$), as was natural and artificial non-aligned matrix ($P>0.05$). There were significant differences between the uniformity of the aligned and unaligned architectures ($P<0.05$).

CONCLUSION

Electrospinning offers the capability to reproduce the range of structures and properties encompassed within natural extracellular matrix; more significantly, these artificial structures can be fabricated with similar degrees of “non-uniformity” in their organisation and fibrous architecture to the natural structures. These inherent variances in the fibres produced through the use of this technique could prove significant in the development and functionality of scaffolds that accurately mimic natural tissue through artificially creating extracellular matrix.

INTRODUCTION

We have developed a method to rapidly produce porous nanofibres by combining solution blow spinning¹ (SBS) and thermally induced phase separation² (TIPS). SBS can produce nanofibres, analogous to those electrospun from polymers dissolved in suitable solvents, yet with a production rate (per head) circa 100 times faster, and without the need for electric fields¹. In this work we freeze the nanofibres shortly after their formation, ahead of excessive solvent evaporation, causing phase separation within the nanofibres. Here we also address the challenge to produce interconnected macropores within 3-D nanofibre networks. Ice microspheres are used as *in situ* macroporosifiers, which become entangled during processing with the nanofibres. Subsequent compression of these ice/nanofibre entanglements, followed by freeze-drying, results in bioactive interconnected macroporous scaffolds, themselves formed of porous nanofibres.

EXPERIMENTAL METHODS

Amorphous polylactide (PLA) (used as a model polymer) was dissolved in dimethyl carbonate, at a polymer concentration of 15 m/v%. Up to 10 wt.% bioactive glass was added to the solution, which was then ultrasonicated to aid particle dispersion. Bioactive glass nanoparticles (20-30 nm diameter) were of the same composition as 45S5 Bioglass®. SBS was used to form nanofibres of this solution and conducted at air pressure 10-40 psi and polymer solution injection rates of 100-200 $\mu\text{L}\cdot\text{min}^{-1}$, delivered via a precision syringe driver to an inner co-axial surrounded by the higher pressure air sheath. The forming nanofibres were jetted directly into a liquid nitrogen bath, which resulted in TIPS within the nanofibres. Macroporous structures were generated by spraying water via a separate SBS head. The water formed ice microspheres proximal to the liquid nitrogen surface, measuring 300 μm – 2 mm in diameter. Different water injection rates allowed for the volume fraction of *in situ* macro-porosifiers to be controlled. The entangled ice sphere/nanofibre networks were compressed to form an interconnected network of ice. Subsequent lyophilisation resulted in macroporous scaffolds formed of bioactive porous nanofibres.

RESULTS AND DISCUSSION

Fibres of 15 m/v% had diameters 399 nm \pm 134, and exhibited a highly porous structure consisting of

elongated pores of ~50 nm by ~25 nm. Scaffolds were produced using ice microspheres at total volume fractions of between 0.4 to 0.8, resulting in interconnected macropores, themselves lined with nanofibres, as shown in Figure 1.

Figure 1. Porous bioactive nanofibres arranged into interconnected macroporous scaffolds

To the Authors' knowledge this is the first time that SBS has been used to produce porous nanofibres, as well as bioactive porous nanofibres, moreover, a method developed to form these into macroporous scaffolds via *in situ* porosifiers. These highly porous scaffolds have macroporosities of up to 76%, the nanofibres fibres themselves being up to 96% porous.

CONCLUSION

This technique provides a simple and rapid route to produce porous nanofibres, and macroporous scaffolds of controlled porosity, which can be rendered bioactive by bioactive nanoparticle inclusions.

Mechanical Properties of Zirconia 3-Unit Fixed Dental Prostheses Machined on a CAD/CAM System

Carlos Nelson Elias^{1*}, Heraldo Elias Salomão dos Santos¹ e Claudinei dos Santos²

¹Instituto Militar de Engenharia, Brazil, elias@ime.eb.br (presenting author)

²Universidade do Estado do Rio de Janeiro, Brazil

INTRODUCTION

Some works reported premature failure of femoral head alumina prostheses inside the human body¹. Biomedical zirconia was introduced to solve the problem of alumina brittleness and the potential failure of femoral ceramic prostheses², but its use in dental implants has not been thoroughly investigated.

Compared with alumina, zirconia-based ceramic used in fixed dental prostheses (FDPs) provide an adequate level of opacity, better esthetics, higher flexural strength, fracture toughness, and lower modulus of elasticity and hardness³. However, a limitation of zirconia application in FDP has been observed clinically: the degradation of zirconia when exposed to the oral environment, which may lead to a long-term decrease in strength and the possibility of failure⁴.

The manufacturing process of ceramics fixed dental prostheses (FDPs) is not the same as that of standardized samples for mechanical testing and, therefore, the surface finishing are not necessarily the same in both cases.

The purpose of this study was to compare the mechanical properties of standardized samples and FDPs before and after hydrothermal aging.

EXPERIMENTAL METHODS

Standardized samples with dimensions 43 x 3 x 4 mm were cut from commercial yttria stabilized tetragonal zirconia (3 Y₂O₃ mol%) blocks for CAD-CAM systems (ProtMat Advanced Materials, Brazil). After cut the blocks was submitted to subsequent grinding, surface polishing, and sintering in a furnace without atmosphere control (2 h at 1530°C). The flexural strength of standardized samples was measured using a 4-point bending test.

50 samples of 3-unit FDPs were machined with a CAD-CAM system from commercially ZrHP presintered blocks (Fig. 1). Samples were immersed in artificial saliva at a pressure of 2 bar for 30 h in an autoclave at 135°C. The mechanical bending tests of CAD-CAM FDPs were performed before (n=20) and after degradation (n=20).

The crystalline phases present in the presintered and sintered samples were identified by X-ray diffraction

Fig. 1. Dental prosthesis set up for 3-point bending testing.

RESULTS AND DISCUSSION

Table I shows the mean maximum force (N), flexural strength (MPa), and standard deviation for the 3-unit

FDP and standardized samples. Statistical analysis was performed.

Table I: Mechanical properties of 3-Unit FDP.

FDPs	F(N)	Stress (MPa)
Machined	740.90 ± 98.25	911.2 ± 184.1
Degraded	790.08 ± 150.18	871.9 ± 149.9
Polished	592.66 ± 101.36	573.8 ± 139.1
Standard sample		920 ± 108

The hypothesis that the CAD-CAM process changes the mechanical properties of zirconia is not confirmed. The mechanical properties of the standardized samples (920 MPa) are not statistically different from those of machined and sintered FDPs (911.2 MPa). Means comparison using Bonferroni Test, Scheffe' Test, and Tukey Test at the 0.05 level showed that the mechanical properties of the machined CAD-CAM FDPs and standard samples not significantly different (P = 0.96).

The standardized samples before sintering showed 5.8% of the tetragonal phase and 10.5% of the monoclinic phase. The content of 10.5% of the monoclinic phase is certainly related to the cutting process of the samples, which promoted phase transformation from tetragonal to monoclinic and induced residual stress.

After sintering, the standardized samples showed 98.2% of the tetragonal phase and 1.8% of the monoclinic phase. Polished FDPs have a higher percentage of monoclinic phase (14.5%) than standardized sintered samples.

CONCLUSION

1. CAD/CAM machining process introduces grooves in the surface of dental prostheses, but does not significantly change the flexural mechanical properties.
2. Hydrothermal aging does not significantly influence the mechanical properties of dental prostheses under bending, compression, and fatigue tests.

Abstract: Nowadays, TCP ($\text{Ca}_3(\text{PO}_4)_2$) that belongs to the group of calcium phosphate biomaterials as a hot topic of research for bone tissue repair applications and dentistry is studying. In this investigation, TCP powder was synthesized by mechanical activation method as a solid state process. The mixture was composed of a blend of pure calcite (CaCO_3) and silica amorphous (SiO_2) powder with 57 % wt. and 43 % wt, respectively. Then, the powder mixture milled by high energy ball mill with ball to powder ratio 10:1 and rotation speed 600 rpm for 10 h. After then, the materials milled heated at three temperatures 1100 °C, 1000 °C and 900 °C for 2 h in muffle furnace at the air atmosphere. X-ray diffraction (XRD), scanning electron microscopy (SEM) and BET technique performed on heated powders to characterize. According to XRD results, the patterns show that the phase TCP was just appeared in the mixture milled for 10 h. In addition, based on modified Scherrer calculator the TCP crystalline size was determined 37 nm. In fact, the present investigation indicated that TCP powder was composed of nano-crystallite structure, 30-40 nm, can be prepared by mechanical activation at 900 °C or 1000 °C to use as a new biomaterials for medical and dental purposes.

Hyperbranched Poly(β -Amino Ester) for High Performance Gene Delivery

Dezhong Zhou, Wenxin Wang

Charles Institute of Dermatology, University College Dublin, Dublin, Ireland

wenxin.wang@ucd.ie

INTRODUCTION

Gene therapy holds great potential for the treatment of various diseases. Although linear poly(β -amino esters) have shown great potential in a variety of cell lines, the limited functional groups hinder further improvement of their potential^{1,2}. Herein, a novel poly(β -amino ester) (HPAE) with hyperbranched structure was synthesized and used as high performance gene delivery carrier.

EXPERIMENTAL METHODS

All the chemicals were purchased from Sigma-Aldrich and used as received. Molecular weight (Mw, Mn) and polydispersity index were tested on a Varian 920-LC GPC with DMF as elution solvent. Chemical structure was confirmed by a 300 MHz Bruker NMR with chloroform as solvent.

RESULTS AND DISCUSSION

HPAE (Figure 1a) was synthesized by two steps. First trimethylolpropane triacrylate (TMTPA), bisphenol A ethoxylate diacrylate (BE) and 4-amino-1-butanol (S4) were copolymerized by Michael addition to form base polymer. And then 3-morpholinopropylamine (MPA) was used to endcap the terminal groups. Chemical structure of the synthesised HPAE was confirmed by NMR (1b). Mw, Mn and PDI of the HPAE were 8918, 3426 and 2.60, respectively. NMR and GPC results indicated that HPAE was synthesised successfully.

Figure 1 Chemical structure (a), NMR spectrum (b) and GPC curve (c) of HPAE

HPAE was used to carry out transfection in Hela, RDEBK and hADSC cell lines. As indicated by the GFP images, HPAE showed very high gene transfection efficiency in the presence of serum (Figure 2a). Gluciferase activity tests also indicated that the HPAE had much higher transfection efficiency compared to

the most widely used commercial transfection agents including superfect (SF), lipofectamine 2000 (LP), polyethylenimine (PEI) and xfect (Figure 2b), especially in RDEBK cells. Alamar Blue assay was used to test the metabolic activity of the transfected cells and the results showed that the HPAE was lowly toxic in all the three cell lines and over 80% of the transfected cells maintained good metabolic activity because of the biodegradability, which indicated that the synthesised HPAE was safe and biocompatible gene delivery carrier.

Figure 2 Fluorescence images of RDEBK cells transfected by HPAE (a), gluciferase activity (b) and cell viability (c) of cells transfected by HPAE, SF, LP, PEI and xfect after 48 hours.

CONCLUSION

Efficient and safe gene carrier is the prerequisite for successful gene therapy. In difference with the linear structured carriers, the unique hyperbranched structure of HPAE can overcome the limitation of linear counterparts by endowing multiple functional groups. HPAE was synthesised and characterized successfully. Transfection in Hela, RDEBK and hADSC cell lines indicated that the HPAE was a much more efficient and safer gene delivery carrier than all the most widely used commercial transfection agents.

Optimisation of Macromolecular Crowding Conditions for Enhanced Extracellular Matrix Deposition *in vitro*

Diana Gaspar, Abhay Pandit, Dimitrios Zeugolis

Network of Excellence for Functional Biomaterials, National University of Ireland, Galway, Ireland

dimitrios.zeugolis@nuigalway.ie

INTRODUCTION

Cell-based tissue engineering strategies have limited clinical applicability due to delayed extracellular matrix deposition and consequent prolonged production time. Scaffold-free tissue production *in vitro* can be enhanced by macromolecular crowding (MMC)¹, a biophysical phenomenon that governs the intra- and extra-cellular milieu of multicellular organisms². Enhancement of tissue production *in vitro* can greatly contribute towards the development of cell-based therapies for a variety of clinical targets. Although a number of different conditions (crowding molecules, cocktails, concentrations) have been studied, an in depth understanding and optimisation have yet to be described.

EXPERIMENTAL METHODS

Human primary dermal fibroblasts were cultured for 14 days under different concentrations of FicollTM 400 (0, 10, 50 and 100 mg/ml) and constant concentrations of FicollTM 70 (37.5 mg/ml) and FicollTM 1000 (2.25 mg/ml). These were compared with non-crowded controls and a previously described FicollTM 70 (37.5 mg/ml) and 400 (25 mg/ml) cocktail¹.

Collagen I deposition was assessed by sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS-PAGE), $\alpha 1$ bands were quantified by densitometry using ImageJ software. Cell metabolic activity was quantified by alamarBlueTM as per manufacturer's protocol.

RESULTS AND DISCUSSION

Changes in FicollTM 400 concentration while maintaining constant FicollTM 70 and 1000 caused an increase when comparing to the non-crowded control (No MMC) and the well-established cocktail (Fc 70/400), when below 10 mg/ml. Above 10 mg/ml, increasing the concentration had a deleterious effect on the collagen I deposition (Figure 1A). The same tendency was observed by increasing the concentration of FicollTM 70. Despite the negative effect on collagen deposition, cell metabolic activity was not altered significantly (Figure 1B).

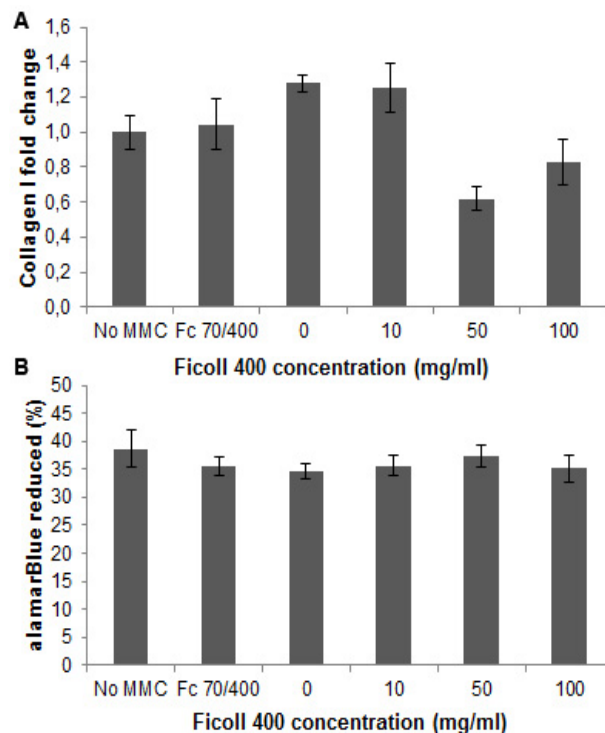

Fig. 1: Collagen I deposition (A) and metabolic activity (B) for varying concentrations of FicollTM 400 in a FicollTM 70, 400 and 1000 cocktail after 14 days in culture.

CONCLUSION

Although preliminary, these results pave the way for further understanding of macromolecular crowding and extracellular matrix deposition *in vitro*. Further characterization will be performed regarding extracellular matrix composition and concentration and excluded volume effect of these and other macromolecules.

Daniela.cigognini@nuigalway.ie

INTRODUCTION

Increasing evidence suggests that improving the accuracy of current *in vitro* microenvironment offers a better control over cell fate and subsequently can facilitate the development of clinically relevant tissue equivalents.^{1,3}

In this study we hypothesized that the synergistic application of macromolecular crowding² (MMC) and low oxygen tension,³ which represent two biologically relevant cell cues, would significantly enhance extracellular matrix (ECM) deposition in human mesenchymal stem cells (hMSC), while maintaining their undifferentiated phenotype and multipotency.

EXPERIMENTAL METHODS

First, optimal MMC conditions were identified by testing different concentrations of macromolecules (i.e. carrageenan² and a Ficoll mixture⁴) on cultured human bone marrow-derived MSCs. At four time points (2, 4, 7 and 14 days), ECM deposition, matrix metalloproteinase activity and cell viability were evaluated using SDS-PAGE and immunocytochemistry, gelatin zymography and alamarBlue® assay, respectively.

Then, the synergistic effect of low oxygen tension and MMC was investigated by culturing hMSCs under MMC at 20% O₂ or 2% O₂. ECM deposition and remodelling were assessed as described above, while hMSC phenotype and multipotency were investigated using flow cytometry, tri-lineage differentiation assays and gene expression analysis. Statistical analysis was performed using the one-way ANOVA –or the Kruskal-Wallis test for non-parametric analysis–, followed by *post hoc* tests.

RESULTS AND DISCUSSION

MMC significantly enhanced production of ECM, notably collagen I, by cultured hMSCs. MMC also increased the presence of activated metalloproteinases in the deposited ECM. Moreover, carrageenan seemed more effective than a previously published Ficoll mixture (Ficoll 70 + Ficoll 400) in inducing ECM deposition (Fig.1).

The addition of crowders on hMSCs cultured under 20% O₂ induced terminal differentiation. This MMC

effect was significantly reduced at 2% O₂, as shown by retention of hMSC surface markers and expression of stem cell transcriptional factors (e.g. Oct4). These data support previous finding and suggest that hypoxia can be used to maintain hMSC phenotype in a crowding environment.

Fig. 1. MMC increased the presence of metalloproteinases in the ECM (a), and enhanced the deposition of collagen I (b-c). Legend: CTR: control, no MMC; C: carrageenan; F: Ficoll.

CONCLUSION

Here, we report that the introduction of both hypoxia and MMC helps hMSCs to build a more biologically relevant microenvironment *in vitro*. Although this strategy needs to be further investigated, a promising application is combining it with cell-sheet technology in order to enhance the formation of cell sheets rich in ECM and multipotent human MSCs.

Synthesis and characterization of novel bioglass-ceramic $\text{CaO-Na}_2\text{O-SiO}_2\text{-P}_2\text{O}_5\text{-ZrO}_2\text{-TCP}$ by sol-gel processing

Parisa Eslami¹, Giovanni Baldi¹, Valentina Faso¹

¹Ce.Ri.Col Research Center of Colorobbia italia, Italy (FI), eslamip@colorobbia.it

INTRODUCTION

Bioactive glasses (BG) and glass ceramics (BGC) have been extensively studied for more than 30 years since Hench first invented bioglass. Because of the good bioactivity and biodegradability, BGs, as bone repair materials or fillers owing to their ability to form a bond to living bone, have been used in clinic for more than ten years¹.

Sol-gel processing, an alternative to traditional melt processing of glasses, involves the synthesis of a solution (sol), typically composed of metalorganic precursors followed by the formation of a gel by chemical reaction, and lastly thermal treatment for drying, organic removal, and sometimes crystallization. Compared with melt-processed BGs, sol-gel BGs are processed at lower temperature and have better compositional control, that leads to increase numbers of silanol groups and/or mesopores, both of which may act as nucleation sites for apatite formation². Not only silanol group provides proper sites for nucleation of hydroxyapatite (HA) but also zirconia in content of bioglass exhibits a bone bonding ability by forming an apatite layer on their surfaces in the living body when they are modified to have many Zr-OH groups on their surfaces³. In this study, we designed %23.5CaO,%4.2Na₂O,%48.6SiO₂,%12.2P₂O₅,%2.7ZrO₂,%8.8TCP BGC for the first time as a coating by sol-gel processing for Ti alloy for orthopedic disease.

EXPERIMENTAL METHODS

The glass-ceramic powders were synthesized by sol-gel process. First of all, tetraethoxysilane was mixed with 0.1M nitric acid in a breaker under vigorous stirring at r.t for 30 min. After the hydrolysis of the TEOS was completed the following reagents were added in sequence allowing 45 min for each reagent to react completely (C₂H₅)₃ PO₄, Mg(NO₃)₂, (Ca(NO₃)₂, NaNO₃, ZrO(NO₃)₂ and (Ca₃(PO₄)₂). After the reactants were stirred at r.t for 1 h, the transparent sol was formed. The sol was aged at r.t for 10 days transforming into gel and followed by being dried at 120°C for 48 h. The dried gel was ground and compacted into disk and then calcined at 750°C for 2 h to eliminate residual water and nitrates. In vitro bioactivity of the composites- as disk shaped specimens- was tested for various immersion time 1, 3, 7, 14, and 21 in Simulated Body Fluid (SBF) solution with pH=7.4 at 37 °C. The immersed materials were characterized by SEM, EDS and XRD.

RESULTS AND DISCUSSION

The in vitro bioactivity of BGC was studied by soaking BGC in SBF solution with PH=7.4 at 37 °C for 1, 3, 7, 14 and 21days. SEM and XRD (fig1) revealed the precipitation of HA on the surface of BGC after 1 day

and developing the growth of nanocrystalline HA on the surface during 3, 7, 14 and 21days. EDS analysis (table 1) clarified that a molar Ca/P ratio ranging 1.7-2.4 for BGC suggesting a thick and well-formed apatite layer on the surface of this BGC from 1 to 21 days. Therefore, the bioactivity response of the specimen BGC is rapid. Corresponding to table 1 pH variation with time increased up to 8 during first day until 21 days for BGC. As a result, more changes led to high bioactivity and this conclusion is corresponding to EDS results.

Table1

Ca/P	1 day	3 days	7 days	14 days	21 days
BG	2.03	1.73	2.42	1.81	1.81
pH=7.4	1 day	3 days	7 days	14 days	21 days
BG	7.71	7.72	8.00	8.01	8.20

Figure1

SEM of BGC

CONCLUSION

The novel bioglass-ceramic prepared by sol-gel processing showed high bioactivity. An apatite layer grew on its surface by immersion in SBF through a mechanism consisting on dissolution of ZrSiO₄, subsequent partial dissolution of ZrO₂ crystalline phases in glassy matrix and finally, nucleation and growth of a globular apatite layer on its porous surface.

Interconnected porous calcium phosphate forming cement consisting of α -TCP foam granules and calcium phosphate acidic solution

Khairul Anuar Shariff, Kanji Tsuru, Kunio Ishikawa

Department of Biomaterials, Faculty of Dental Science, Kyushu University, Japan, mppusm@gmail.com

INTRODUCTION

Interconnected porous calcium phosphate forming cement is thought to be an ideal material as artificial bone substitute and scaffold for bone tissue regeneration, since its interconnected pores offer space that allows cells' growth and penetration. Trung Kien *et al.* successfully fabricated fully interconnected porous calcium phosphate cements based on the setting reaction of α -tricalcium phosphate (α -TCP) microspheres using calcium phosphate acidic solution at 37°C for 10 minutes¹. The mechanical strength of this cement was limited when compared with powder type cement. This is due to limited contact point at interface of α -TCP microspheres². In this study, the feasibility to fabricate interconnected porous calcium phosphate forming cement was evaluated based on the setting reaction of α -TCP foam granules with calcium phosphate acidic solution.

EXPERIMENTAL METHODS

α -TCP powder was prepared by a mixture of calcium carbonate (CaCO_3) and dicalcium phosphate dihydrate (DCPD) with Ca/P ratio of 1.5. α -TCP foam was prepared using polyurethane foam as a template³. Calcium phosphate coated polyurethane foam was heated in an electronic furnace at 1500°C for 5 hours. α -TCP foam granules size were regulated from 300 μm -1000 μm by crushing and sieving. 1.0 M monocalcium phosphate monohydrate (MCPM)-1.0 M phosphoric acid (H_3PO_4) was prepared as calcium phosphate acidic solution. This solution was saturated with respect to MCPM. α -TCP foam granules were placed into 6x3 mm split stainless steel mold and then treated with calcium phosphate acidic solution at 25°C for 1 minute with L/P ratio of 1ml/g. Specimens were washed with distilled water and then immersed in acetone for 10 minutes to arrest the setting reaction process¹.

RESULTS AND DISCUSSION

Figure 1: Photographs of (a) α -TCP foam granules and (b) α -TCP foam granules after treated with 1.0 M MCPM-1.0 M H_3PO_4 solution at 25°C for 1 minute.

Figure 1 show α -TCP foam granules (a) before and (b) after being treated with 1.0 M MCPM-1.0 M H_3PO_4 solution for 1 minute at 25°C. As shown α -TCP foam granules set upon exposure to the calcium phosphate acidic solution.

The mechanism for setting reaction of interconnected porous calcium phosphate forming cement is thought to be similar with dicalcium phosphate dihydrate (DCPD) cements⁴. When α -TCP foam granules are exposed to MCPM- H_3PO_4 solution, specimens dissolve to supply Ca^{2+} and PO_4^{3-} ions as shown in equation 1⁵. This MCPM- H_3PO_4 solution would supersaturate regarding to DCPD phase. DCPD crystals would precipitate on the surface of α -TCP foam granules as shown in equation 2⁵. Precipitation of DCPD crystals from the liquid phase results in the decrease of its supersaturation and thus, α -TCP foam granules further dissolve to supply Ca^{2+} and PO_4^{3-} ions to the liquid phase. Based on this dissolution-precipitation reaction, DCPD crystals would precipitate on the surface of α -TCP foam granule with time and interlock each other to set and form interconnected porous cement.

CONCLUSION

It is concluded that this method might be useful to fabricate interconnected porous calcium phosphate for bone tissue regeneration.

INTRODUCTION

Poly(ether ether ketone) (PEEK) is a kind of superengineering plastic. PEEK exhibits high mechanical properties and heat-, chemical- and radiation-resistances. Therefore, PEEK has also employed as a biomaterials for trauma, orthopaedic and spinal implants. We thought to use PEEK in the cardiovascular devices, such as an artificial heart valve. The artificial heart valve requires high mechanical properties, antithrombogenicity and anti-infection. However, PEEK cannot satisfy those requirements. How to modify materials is changing bulk property and surface modification. In this study, we modified PEEK surface by “self-initiated photoinduced graft polymerization” for obtaining a super-functional PEEK [1]. The self-initiated photoinduced graft polymerization uses semi-benzopinacol radicals from benzophenone units in PEEK molecule structure under UV-irradiation. Advantages of this method are easy handling, well suited for application and graft polymer coating strongly binding the substrate. 2-Methacryloyloxyethyl phosphorylcholine (MPC) polymers exhibit excellent biocompatibility, that is, antithrombogenicity, anti-infection due to reduced protein adsorption. We controlled monomer concentration, polymerization temperature, UV intensity and solvent during the polymerization. Additionally, we evaluated the amount of adsorbed protein to predict antithrombogenicity.

EXPERIMENTAL METHODS

The surface of PEEK was ultrasonically cleaned in ethanol. The MPC was dissolved in degassed water and then adjusted to monomer concentration (0.25–1.0 mol/L) and temperature (25–60°C). PEEK was immersed in these solutions. Polymerization was carried out for 90 min on PEEK surface under UV (360 ± 50 nm) irradiation with intensity (2.5–9.0 mW/cm²). After polymerization, poly(MPC) (PMPC)-grafted PEEK surface was washed with clean solvent to remove monomers and free polymers. PMPC-grafted PEEK was analyzed by XPS, FT-IR/ATR, water contact angle measurement and protein adsorption by micro BCA method. Also, an artificial valve was prepared by PMPC-grafted PEEK and implanted it into pig for evaluating *in vivo* performance of the PMPC-grafted PEEK.

RESULTS AND DISCUSSION

Photoinduced graft polymerization of MPC on the PEEK proceeded well. In the XPS and FT-IR/ATR spectra and water contact angle measurement showed that the hydrophilic PMPC layer formed on the PEEK

substrate. With increasing the monomer concentration, IR intensity ratio increased. IR intensity ratio corresponds to the number of MPC units on PMPC-grafted PEEK. So the number of MPC units in the PMPC layer increased with increasing the monomer concentration. Generally, in the radical polymerization, the molecular weight of polymer increases with increasing the monomer concentration. It seemed that the PMPC layer thickness increased with increasing MPC concentration. The density of the PMPC layer increased with increasing UV intensity. The amount of adsorbed protein decreased with increasing MPC concentration in feed solution (Fig. 1). This is corresponding to the increase hydrophilic nature of the surface. The MPC polymers can inhibit blood cell adhesion and activation. Thus, we can consider that the PMPC-grafted PEEK will show both excellent antithrombogenicity and mechanical property. We have done implant experiment of artificial valve prepared with PMPC-grafted PEEK for a few weeks. It functioned well even it was *in vivo*. The fundamental results will be demonstrated.

Fig. 1. Amount of adsorbed fibrinogen and water static contact angle of PMPC-grafted PEEK prepared in water. Open marks: Untreated PEEK.

Conclusions: It was successful to provide biocompatibility to PEEK surface by self-initiated photoinduced polymerization. The new materials will be useful for developing cardiovascular devices.

Development of bioengineered designer scaffolds for full thickness skin wound healing

Naveen Kumar*

Division of Surgery, Indian Veterinary Research Institute, Izatnagar-243122, Uttar Pradesh, India
naveen.ivri1961@gmail.com

INTRODUCTION

An ideal acellular matrix should be able to provide right biological and physiological environment to ensure homologous cell and extra cellular matrix (ECM) distribution. It should also provide the right size and morphology of neo-tissue required. Collagen ranks as the most widely used matrix material for the purpose of tissue engineering in the dermis. Due to their advantageous biological properties, collagen based scaffolds are under extensive investigations and used as matrices for tissue engineering. The advantages are that natural matrix materials mimic natural ECM structure and composition; emulate native stimulating effects of ECM on cells and allows incorporation of growth factors and other matrix proteins to further enhance cell functions. ECM has an important role in providing optimal chemical and structural environment for tissue growth and regeneration.

EXPERIMENTAL METHODS

Our group has been working in this area for last one decade and we have developed protocols for preparation of acellular matrix from different organs/tissues in our Biomaterial and Bioengineering Laboratory, Division of Surgery, IVRI, Izatnagar. Bioengineered designer scaffolds has been developed using abattoir waste materials, from tissues rich in collagen. The materials used are diaphragm, pericardium, blood vessels, skin, intestines and gall bladder. The techniques have been developed for making acellular matrix from these organs/tissues. Fibroblasts/mesenchymal stem cells were seeded on these collagenous matrices to prepare 3-D biengineered designer scaffolds. These designer scaffolds were evaluated for reconstruction of full thickness skin wound defects in laboratory animal

models as well as in clinical cases requiring reconstructive surgery. These matrixes were used either without crosslinking with chemicals or they were crosslinked with some crosslinking agents to delay the resorption of these matrices in the body so that reconstruction and repair of tissue takes place.

We have also developed some protocols for de-epithelization of skin in different species of animals, viz. rabbit, sheep, goat, buffalo and pig. In these protocols enzymes have been used for de-epithelization of the skin. We have also developed some patentable protocols for acellularity of de-epithelized skin. Acellular dermal matrix has been prepared using different combinations of enzymes, anionic and non-ionic biological detergents. These acellular dermal matrices will be used for further tissue engineering and for three dimensional culture configurations to promote 3-D tissue organization. Current major research programs of the division have been directed to develop novel, biodegradable and biomimetic "designer" scaffolds for regenerative surgery. An overview of different research methodologies and techniques optimized for developing designer scaffolds and their application in tissue engineering will be discussed in details during this presentation.

INTRODUCTION

Hydroxyapatite (HA) closely resembles the mineralised phase of bone and possesses good biocompatibility, bioactivity and osteoconductivity [1]. Thus, HA has become the most widely used bioceramic in the field of bone regeneration medicine. However, resorption of HA *in vivo* is too slow to induce massive formation of a new bone tissue and HA is known to be brittle in nature. Biological apatites differ chemically from stoichiometric HA in that they contain a number of trace elements (*e.g.* CO₃, Si, Zn, Sr, Na, and Mg). Carbonate is the major substituents among the trace elements which present typically about 2-8wt% which depends on the individual age.

Therefore, simulating the chemistry of mineralised tissue in bioceramic materials may be means of improving the level of biological response of the implant to the host *in vivo*. The aim of this study is to synthesise a range of carbonated HA (CHA) that mimic the levels of carbonate present in biological apatites, followed by *in vitro* cytotoxicity assessment of the as-synthesised powders in response to MG63 cells. It is intended that this novel formulation will improve both osteogenic behaviour and mechanical properties of the resulting scaffolds.

EXPERIMENTAL METHODS

Carbonated Hydroxyapatite (CHA) powders were synthesised at room temperature using Ca(NO₃)₂·4H₂O, (NH₄)₂HPO₄, and NH₄HCO₃ (Sigma-Aldrich, Gillingham, UK) by a nanoemulsion method [2]. The amounts of carbonate ($x = 0.5, 1.0, 2.0, 3.0$ and 4.0 molar content) substituted into the HA structure were calculated based on the stoichiometry empirical formula as shown below:

The physico-chemical properties of the as-synthesised powders were investigated through XRD, FTIR, CHN and ICP. The biocompatibility of the as-synthesised powders was then tested *in vitro* cell-culture with MG63 human osteosarcoma cell line via direct contact based on ISO10993-5.

RESULTS AND DISCUSSION

At low carbonate contents, only single phase CHA pattern was detected. However, as the amount of carbonate increased the calcite (CaCO₃) phase was also observed. This formation of secondary phase was caused by the higher amount of carbonate in the apatite structure. During synthesis the carbonate that could not substitute at phosphate sites in the apatite structure, due to limited substitution, would then react with calcium and thus form calcite, CaCO₃. The FTIR analysis of the

CHA powders clearly demonstrates typical peaks of B-type CHA with the bands originating from stretching vibrations of carbonate ions at 870-875, 1410-1430, and 1450-1470 cm⁻¹. The typical peaks of the A-type CHA, which usually appear at 877-880, 1500, and 1540-1550 cm⁻¹, were not visible in the spectra [3]. These confirmed that the as-synthesised powders were B-Type CHA. However, the CaCO₃ phase as detected in XRD was not detected in the FTIR spectra. No calcite band was observed at 712cm⁻¹ due to the small amount present [4]. The marker bands of aragonite around 713 and 700 cm⁻¹ and vaterite at 745cm⁻¹ were also not observed for all samples. From CHN analysis, it is considered that 2.0CHA is an ideal composition, as it possesses levels of carbonate (2-8wt%) which are typical of biological apatites.

In vitro biological assessment demonstrated that none of the powders are toxic to MG63 cells. The 2.0CHA formulation showed the highest level of DNA and total protein production, closely followed by 1.0 and 3.0CHA.

Fig.1. Live/dead images of the CHA powders after 14 days in culture

CONCLUSION

Carbonated Hydroxyapatite (CHA) with different degrees of carbonate substitutions has been successfully synthesised by a nanoemulsion method. Chemical analysis confirmed that carbonate has been successfully substituted the phosphate groups and formed B-type CHA. The data suggest that the optimum composition is $x=2.0$ (2.0CHA) as it retained single phase with purely B-type CHA and possesses an ideal amount of carbonate. Cell growth and proliferation were also found to be faster for this formulation.

INTRODUCTION

Titanium (Ti) and its alloys are being used for production of metallic biomaterials currently because of their unique properties such as suitable mechanical properties and corrosion resistance¹. However, titanium has low wear resistance and limited osteointegration properties. Hence surface engineering studies focused on improvement of these insufficient properties of titanium alloys².

Magnesium is a biodegradable and biocompatible material with various other unique advantages. Mg²⁺ is the most abundant cation in human body and exists in natural bone structure. Furthermore, Mg²⁺ has been used to improve surface properties of Ti implant materials³. Nevertheless, usage of pure magnesium in biomaterial production or high proportional addition to alloys may cause degradation and corrosion issues³. According to a well-known phenomenon, hydrogen evolution related with magnesium biodegradation in physiological media, is one of the issues which is described as following overall stoichiometric equation⁴⁻⁷.

In this study we proposed a coating technique to obtain suitable magnesium proportions on titanium substrates via cathodic arc physical vapour deposition (PVD). It is considered that rapid corrosion of inner magnesium content from titanium substrates would be prevented by this surface modification technique.

EXPERIMENTAL METHODS

Pure Ti substrate specimens were cut in squares with ca. 1cm² surface area. The specimens were firstly chemically cleaned with acid mixture solution. Then cathodic arc PVD procedure was performed with different sputtering times and cathode current values (Table1). Etching, coating and final sputtering were carried out at bias voltages -800V, -50V and -600V respectively³.

Table 1: Process parameters of experimental coatings

Experiments	Current(A)		Coating Time(min)	Sputtering Time(min)
	Ti	Mg		
1	85	55	10	2
2	85	55	10	5
3	85	55	10	8
4	85	40	10	8
5	85	25	10	8

Surface characterization analysis were performed via electron dispersive spectroscopy (EDS), scanning

electron microscope (SEM) and X-ray diffraction (XRD).

RESULTS AND DISCUSSION

Sputtering time affected the Mg²⁺ amounts slightly after reaching a threshold (Table 2). In order to achieve lower Mg²⁺ amounts, different current values of Ti and Mg²⁺ cathodes were set under constant sputtering times.

Table 2: Approximate atomic Mg amounts of coatings by EDS analysis (kV=10kV, take-off angle 25.0°, line: Kα)

Experiments	Atomic Mg ²⁺ (%)
1	~25-28
2	~12
3	~11-12
4	~9-10
5	~3-4

Preliminary studies showed that Mg²⁺ amounts on Ti substrates could be controlled within 1 at. %. SEM micrographs, however, indicated nonuniform droplet formation on the surfaces (data not shown). Mg²⁺ corrosion mechanism and determination of different phases on modified surfaces are next steps for ongoing studies.

CONCLUSION

Sputtering process was selected to force the formation of a stable Mg²⁺ phase into Ti substrates. This approach could restrict the corrosion rate of Mg²⁺ and decrease the hydrogen evolution rate. The results are considered promising and could be a solution to lower the formation of subcutaneous hydrogen pockets after implantation operations by using magnesium based implants⁸.

INTRODUCTION

Much of research within the tissue engineering scaffold fabrication has been focused on the design of isotropic porous architectures. However, when using such scaffolds, the restriction on cell penetration and nutrient flow to the scaffold center due to rapid tissue formation on the outer edge of the scaffold generally leads to the formation of a necrotic core¹. Alternatively, scaffolds with anisotropic pore architecture improve the cell infiltration and nutrient flow thus avoiding any necrotic core formation². The unidirectional thermal induced phase separation (TIPS) process enables the fabrication of anisotropic channeled porous foams; however, the current setups are complex and limited^{3,4}. In contrast, here we demonstrate the proof-of-principle of a facile and versatile methodology based on the ideas of TIPS, termed as Dip TIPS, consisting of dipping of the template into the polymer solution followed by thermally induced phase separation to obtain anisotropic channeled porous polymer foams. The effects of polymer properties, processing conditions and template parameters on the pore architecture were investigated. The feasibility of scaffolds to provide cell infiltration and distribution within the foams in *in vivo* was tested.

EXPERIMENTAL METHODS

The setup consists of a thermally conductive template (*T*), which was fitted to the thermally conducting block (*C*). The block *C* was fitted to a non-metallic reservoir (*R*) for freezing mixtures (**Figure 1A**). The *T* bar was dipped into the polymer solution and the freezing mixture was poured into *R* to quench the polymer solution in the immediate vicinity of the *T* bar. After pre-set quenching times, the phase separated polymer was freeze-dried resulting in the 3D foam. The foam morphology was characterized by SEM and porosimetry analysis. The *in vivo* experiments were performed using male Norway brown rats (HE staining, trichrome staining, CD31 staining).

RESULTS AND DISCUSSION

The Dip TIPS follows the principles of the conventional TIPS. In contrast to the previous methods, Dip TIPS is *simple* - as it doesn't involve complex setups or procedures, *adaptable* - as it enables the preparation of tubular, open-capsular as well as flat 3D foams with variable sizes, and *scalable* - as many *T* bars can be fitted to *C* block. For example, the tubular/open-capsular foams prepared from poly(lactide-co-caprolactone) (PLA:PCL ratio of 93:7 mol/mol, $M_w = 300\,000$ g/mol, 5 % w/v in dioxane, quenched at $-80\text{ }^{\circ}\text{C}$ for 30 s) exhibit porosity of 86 %, thickness of 612 ± 22

μm , with $53 \pm 6\text{ }\mu\text{m}$ pores on the outer surface and $10 \pm 5\text{ }\mu\text{m}$ pores on the inner surface with the anisotropic and channeled structure of the pores (**Figure 1B**).

The detailed investigations revealed that (i) the pore size was inversely proportional to the applied quench depth and the polymer concentration and was directly proportional to the coarsening time (ii) the foam thickness was directly proportional to the quenching time, and (iii) the polymer type, polymer molecular weight and template dimensions also affected the pore architecture. The *in vivo* studies revealed that the foams supported the guided host cell/tissue infiltration and provided convenient conditions for the high density homogenous cell growth, without formation of fibrotic capsule or necrotic center (**Figure 1C**).

Figure 1. Schematic Dip TIPS setup (A); cross section (SEM) showing the anisotropic channeled pore architecture with a detail pore structure of outer and inner edges of the foam (B); Haematoxylin-eosin staining (pink) of 4-week old implant showing the guided host cell/tissue infiltration *in vivo* (C).

CONCLUSION

The Dip TIPS setup enabled the fabrication of anisotropic channeled porous foams in shapes such as tubular, open-capsular or flat with the foam thickness below 1 mm. The pore size was tuned by changing the polymer concentration and quenching temperature, while the thickness was regulated by altering the quenching time. The *in vivo* studies revealed the potential of these foams for guided tissue engineering applications.

Different cryogel architectures as basis for 3D cell culture of prostate cancer cells

Anne Baecker¹, Bettina Goeppert, F.J. Gruhl

¹Karlsruher Institute of Technology (KIT),
Institute of Microstructure Technology (IMT)
anne.baecker@kit.edu

INTRODUCTION

Conventional 2D cell culture affords an unnatural microenvironment for growing cells that leads to the development of cells with altered properties. The flat and rigid plastic/-glass surface affects the cells by changing the form and shape (flat cell layer), decreasing their cell-cell communication as well as their proliferation rate. Consequently this method does not reflect the in-vivo 3D microenvironment where cells grow up and are surrounded by the extracellular matrix (ECM) which is a complex network of proteins and proteoglycans. Therefore it is very significant to construct a cell scaffold which mimics the required 3D *in vivo* situation and the corresponding adhesion molecules or functional groups for cell attachment. There are multiple applications based on the existing knowledge which promise the 3D cell culture within a tissue specific architecture. The aim of the project is the establishment of an optimal 3D cell culture model system for prostate cancer cells based on the high interconnected pore network of so-called cryogels. These, which are synthesized by different polymers synthetic and/or natural origin at subzero temperature, belong to the polymeric gels, hydrogels. The polymer structures used in this work consist of the monomers hydroxyethyl methacrylate-alginate-gelatin (HAG) and poly (ethylene glycol) diacrylate (PEGda) [1]. There are some properties (e.g. porosity, pore size and distribution, swelling behaviour and elasticity) which are mandatory in general for a cell scaffold in the 3D cell culture and play a crucial role for an effective cell attachment and other biological processes. The following abstract serves as an introduction to the methods using for the physical and chemical characterization of the cryogels and shows a part of the results.

EXPERIMENTAL METHODS

Scaffold fabrication

The cryogelation technique was used for the synthesis of a blend of hydroxyethyl methacrylate-alginate-gelatin (HAG) and poly (ethylene glycol) diacrylate (PEGda).

Microstructure analysis

By the use of scanning electron microscope (SEM) and the mercury porosimeter, it is possible to get significant results of the 3D morphology (e.g. pore size, pore distribution and pore volume, average porosity). In addition the environmental scanning electron microscope (ESEM) that allows the sample detection of "wet" or uncoated material. The X-ray CT scanner is used to scan the whole scaffold and its 3D porous structure.

Swelling kinetics and scaffold degradation

The Swelling kinetics of the cryogels was performed by conventional gravimetric procedure [2]. In this method, the solvent uptake capacity (e.g. culture medium RPMI 1640) and the equilibrium state of the porous cryogel materials with respect to time at 25°C were determined.

Estimation of visco-elastic behavior by unconfined compression test

Stress was given to the cylindrical-shaped (water saturated) cryogel samples using a Zwick/Roell machine with 50 N load cell under displacement control rate.

RESULTS AND DISCUSSION

The achieved results of the characterization of distinct pHAG-PEGda cryogel compositions (all data not shown) display the influence of every single monomer of the whole structure of the polymer. Nonetheless, one thing is conspicuous that the higher the concentration of monomers and cross-linker, the lower the swelling behaviour and porosity due to the reduction of the hydrophilic groups. Depending on whether you have changed the ratio of cross-linker or corresponding components, you received a new carrier structure. All of them show a high porosity and high swelling kinetics which is an excellent starting point for the three-dimensional cell culture.

Figure 1 SEM images of two pHAG-PEGda cryogels with different initial concentration of Alginate and Gelatin (35x magnification) show obviously differences in pore size and shape as well as thickness of the pore walls. (A: 0.5% of Alginate and Gelatin; B: 2.25% of Alginate and Gelatin)

Figure 2 Swelling behaviour of the above cryogels with different initial concentration of Alginate and Gelatin. The scaffolds swollen up to six times of their initial weight and reaching equilibrium within 2 hours shows high solvent uptake capacity and interconnected morphology.

Cryogel	Average Porosity (%)	Elasticity (kPa)
pHAG(4.25%)-PEGda(5%)	31.90	41.45
pHAG(8%)-PEGda(5%)	29.40	40.16

Table 1 Comparison of the results of the porosity and elasticity of the two cryogels.

CONCLUSION

First and foremost, it was necessary to show that different pore structures of the synthesized scaffolds provide the optimal requirements for the cultured cell line. Our recent results show a stable and reproducible synthesis of the various cryogels and ideal prerequisites for future investigations.

Rapid screening of potential biomedical zirconium alloys with 1 wt. % alloy additions

F.Y. Zhou¹, Y.F. Zheng^{1, 2*}

¹Center for Biomedical Materials and Engineering, Harbin Engineering University, China

^{2*}Department of Materials Science and Engineering, College of Engineering, Peking University, China,
yfzheng@pku.edu.cn

INTRODUCTION

Nowadays, magnetic resonance imaging (MRI) has wide applications in clinic diagnosis, such as dentistry, orthopedics and brain surgery, and its use is on the rise. However, MRI diagnosis is inhibited when there are some metallic implants in body. Because they can be magnetized in the intense magnetic field of the MRI instrument, which may produce image artifacts and therefore prevent exact diagnosis¹. To reduce the artifacts, medical devices with low magnetic susceptibility are required. Zirconium is biocompatible and it has lower magnetic susceptibility than stainless steel, Co–Cr alloys and titanium alloys². Therefore, developing novel Zr alloys with excellent biocompatibility and MRI compatibility are highly interesting. In this study, various Zr–1X (X=Ti, Nb, Mo, Cu, Au, Pd, Ru, Ag, Hf and Bi) alloys were designed and fabricated in order to screen the optimum alloy element(s) for novel biomedical Zr alloys with sufficient mechanical properties, improved corrosion resistance, excellent biocompatibility and low magnetic susceptibility. Besides, proper heat treatment was taken into consideration, for as-cast ingots, cold deformation and annealing were performed to obtain plate samples with high strength and good ductility.

EXPERIMENTAL METHODS

The binary Zr–1wt. % X alloys were prepared in a non-consumable arc melting furnace. The obtained ingots were hot-rolled to 3 mm thick sheets and then cold-rolled for a total reduction of 50%. The rolled samples were annealed at 600°C for 2 hours. The microstructure, mechanical properties, corrosion resistance and in vitro cytocompatibility of Zr–1X alloys were investigated by X-ray diffraction analysis, optical microscopy, uniaxial tensile test, microhardness test, electrochemical measurements, cytotoxicity test and ALP activity assay, respectively. The magnetic properties of Zr–1X alloys were investigated using a SQUID-VSM at room temperature. The magnetization (M) of sample against applied magnetic field (H) was measured and recorded, and its magnetic susceptibility, $\chi = M/H$, was obtained from the slope through linear fitting of the data.

RESULTS AND DISCUSSION

It was found that the annealed Zr–1X alloys consisted entirely or primarily of α phase. After annealing, a typical recrystallized structure was observed in pure Zr and Zr–1X alloys. All alloying elements significantly increased the strength and hardness of pure Zr. Among these Zr–1X alloys, Zr–1Ru alloy exhibited an optimum combination of strength and ductility, and both were the highest levels. The result of electrochemical corrosion measurements in Hank's indicated that adding various

elements into Zr improved its corrosion resistance and passivity, as indicated by the reduced corrosion current density and passive current density, respectively. Besides, the extracts of Zr–1X alloys did not produce any significant deleterious effect on inhibiting notably the proliferation and weakening differentiated function of osteoblast-like cells (MG 63), indicating good in vitro cytocompatibility. As shown in Fig. 1, all except for Zr–1Ag alloy showed decreased magnetic susceptibility compared to pure Zr and Zr–1Ru alloy had the lowest value. The magnetic susceptibility of Zr–1Ru alloy was comparable to those of α' -phase Zr–Mo alloys² and Zr–Nb alloys³, which was nearly one-seventh that of Co–Cr alloy and one-third that of Ti–6Al–4V alloy², indicating a better MRI compatibility.

Fig. 1 The magnetic susceptibility of pure Zr and Zr–1X alloys. * indicates $p < 0.05$ when comparing with pure Zr while # indicates $p < 0.01$ when comparing with pure Zr.

CONCLUSION

Among these designed Zr–1X alloys, Zr–1Ru alloy had excellent mechanical properties, high corrosion resistance, good cytocompatibility and lowest magnetic susceptibility, and it may be a promising candidate for implant devices in an MRI environment, such as the encasing material of a pacemaker.

INTRODUCTION

Hyperthermia is an old technique which is recognized as a possible treatment option for cancer.¹ Cancer is a severe disease and currently is one of the leading causes of morbidity and mortality in the world, while chemo- and radiotherapy present several side effects due to their lack of specificity to the cancer type and the development of drug resistance.^{1,2}

Iron oxide nanoparticles are having been extensively investigated for several biomedical applications such as hyperthermia and magnetic resonance imaging for cancer treatment.^{3,4} In this context, a work was performed comparing the effect of surfactants on the stability and the heating ability of iron oxide colloids.

EXPERIMENTAL METHODS

Iron oxide nanoparticles were synthesized through chemical precipitation and stabilized using two surfactants: sodium citrate and oleic acid. The as-prepared nanoparticles were characterized by several techniques and their heating ability was evaluated using different sample concentrations and field intensities.

RESULTS AND DISCUSSION

Figure 1 - Magnetization vs. applied magnetic field for Iron oxide nanoparticles coated with sodium citrate (a) and oleic acid (b).⁴

Figure 2 – Specific power absorption (SPA) vs. Surfactant concentration (left image – Oleic acid, Right image – Sodium

citrate) for three field intensities with a frequency of 418.5 kHz.

The hysteresis loops measured at temperatures 10 and 320 K for coated iron oxide nanoparticles are shown in Fig. 1. Comparing the effect of sodium citrate and oleic acid it is possible to observe that oleic acid is reducing the magnetic moments at the surface of the nanoparticles probably due to the diamagnetic contribution of the surfactant volume. For higher concentrations of oleic acid it seems to be an increase in the SPA values.

The hyperthermia results (Fig. 2) show a drastic reduction on the SPA value when oleic acid is added to the colloids, while for sodium citrate this reduction is not so pronounced.

CONCLUSION

These results show that oleic acid has a more severe effect on the magnetic properties and heating ability of the nanoparticles. This effect is probably due to the surfactant viscosity and the size of the molecule that is higher than sodium citrate.

INTRODUCTION

One million people: the number of deaths worldwide caused each year by liver cancer, the 3rd leading cause of cancer death¹. Although surgical removal of liver tumors offers the best chance for a cure, more than 70% of the liver cancer patients are inoperable and are treated with palliative transarterial chemoembolization (TACE). In TACE, the hepatic artery is embolized following delivery of the chemotherapeutic agents into the artery. Usually, repeat procedures are common so patency of the hepatic arteries need to be restored before the next TACE can be performed. Currently, Gelfoam, a gelatin sponge, is typically used for embolization². However, it is required to cut into small pledgets and delivered as a particulate, resulting in an unpredictable occlusion level due to their variability in size and uncontrollable target embolization. While Gelfoam is degradable, its degradation period cannot be strictly controlled. Furthermore, it is also not visible under fluoroscopy. One solution to this is to develop a biodegradable shape memory embolic plug, which would address the shortcoming of the existing embolic agents.

Shape memory polymer represents promising candidate material for embolization, since it can be stored in a temporary compressed shape and deployed via a catheterization process until it is actuated on demand via external stimulus. In this work, we investigated the thermomechanical property of biomaterial, poly(D,L lactide-co-glycolide) (PLGA), and the effect of the incorporation of radio-opaque particles, barium sulphate (BaSO₄) on the thermal, mechanical and shape memory properties of PLGA composites.

EXPERIMENTAL METHODS

Material and Sample Preparations

PLGA (M_w = 9x10⁴) and BaSO₄ were purchased from Purac and Sigma Aldrich, respectively. Film samples were prepared by casting from a polymeric solution of PLGA in dichloromethane. For polymer composite samples, various fraction of BaSO₄ (10-50 wt%) was mixed into the PLGA solution. Solution was casted onto glass plates using an automatic film applicator and then dried in oven for 2 weeks at 60°C.

Material Characterisation

Glass transition temperature (T_g) was measured using TA Instruments MDSC 7 at a heating rate of 10°C/min under nitrogen medium from -20 to 150°C. Uniaxial tensile tests were performed with an Instron 5548 and the film samples were cut according to ASTM D638-V. Tensile experiments were conducted at temperature of

37°C with crosshead speed of 10mm/min. Shape recovery tests were performed in tensile mode. The specimen was stretched to 200% strain (ϵ_0) at 37°C and then cooled down to room temperature with the external force to maintain the deformation (ϵ_i). During the recovery process, the deformed specimen was immersed into 37°C water bath for 4 minutes and the change of specimen length (ϵ_r) was recorded. The recovery ratio R_r was defined as $(\epsilon_i - \epsilon_r)/\epsilon_i$. All tests were performed in triplicate and statistical analysis was performed using ANOVA, with significance level $p = 0.05$.

RESULTS AND DISCUSSION

Table 1 summarizes the thermal, mechanical and shape memory properties of PLGA and its composites.

	T _g (°C)	E Modulus (MPa)	Elongation to break (%)	R _r (%)
PLGA	44	736	901	94
PLGA/10%BaSO ₄	43	771	900	98
PLGA/30%BaSO ₄	43	1084	893	99
PLGA/50%BaSO ₄	45	1213	20	-

As shown in Table 1, PLGA is an amorphous polymer having a glass transition of 44°C and the addition of BaSO₄ into PLGA has very little effect on the T_g. On the contrary, the modulus is increased with addition of BaSO₄ when the BaSO₄ content is above 30 wt%. This is expected since rigid filler usually increases the modulus in a composite system. PLGA and its composites achieved high elongation to break of ~900%, except for PLGA/50%BaSO₄. The elongation to break for PLGA/50%BaSO₄ is 20%, which makes the composite too brittle for shape memory test and actual clinical application. In term of shape recovery, R_r is higher than 90%, indicating the PLGA and its composites exhibit good shape memory property. Interestingly, with the addition of BaSO₄, it enhances the shape memory effect of PLGA from R_r of 94% to 98% ($p < 0.05$).

CONCLUSION

PLGA/30%BaSO₄ composite exhibit enhanced mechanical and shape memory properties and it can be a promising candidate material for biodegradable shape memory embolic plug.

Analysis of PVA- hydrogels loaded with propolis for burn healing application

Renata N. Oliveira^{1*}, Regis Rouze³, Brid Quilty³, Gloria D.A. Soares¹, Rossana M.S.M. Thiré¹ and Garrett B. McGuinness²

^{1*}Department of Materials and Metallurgical Engineering, Federal University of Rio de Janeiro, Brazil, nunes@metalmat.ufrj.br

³ School of Biotechnology, Dublin City University, Ireland

INTRODUCTION

PVA hydrogels are well established materials for dressings, since they have several characteristics of the ideal dressing, i.e. transparency and high swelling capacity in aqueous fluids^{1,2}. However, these gels do not have antimicrobial effects. Among the antimicrobial agents, bee propolis is a natural product used in folk medicine and it has been officially used in wounds healing since World War II³. The propolis properties vary with the propolis source⁴. Recently, gels loaded with propolis for wound healing application have been studied with promising results⁵⁻⁷. Since PVA gels loaded with propolis have not been reported, the goal of this work is to produce and characterize PVA-propolis gels intended for dressings.

EXPERIMENTAL METHODS

Aqueous solution of 10% w/v PVA was prepared (90°C, 4h, stirring) and different amounts of propolis were added (room temperature, stirring). Regular amounts of solution were poured in Petri dishes; they were freeze-thawed, dried and sterilized, resulting in samples with 0% ("PVA"), 0.075%, 0.15%, 0.45% and 0.90% propolis. Microstructural (XRD), thermal (DSC), and mechanical (tensile tests of the samples swollen in PBS) characterization as well as antimicrobial tests were performed.

RESULTS AND DISCUSSION

It could be observed that the propolis interferes with the polymer crystallization and that high amounts of propolis (> 0.15%) resulted in low crystallinity. The DSC results corroborated the XRD results, Table 1. The T_g decreased with propolis addition until 0.15%, then there is an increase in the T_g values with the propolis content. The X_c diminished for amounts of propolis > 0.15%. Higher amounts of propolis led to lower T_m values. The propolis interferes with the amorphous chains mobility, altering the T_g, and also with the PVA crystallization. Propolis could be located not only in the gels interstices, but also between the PVA crystal planes⁵. Propolis could lead to the formation of less and more imperfect crystals, lowering the T_m.

Table 1 – DSC results, crystallinity degree (X_c), melting temperature (T_m) and glass transition temperature (T_g)

	T _g (°C)	T _m (°C)	X _c (%)
PVA	71	222	36
0.075%	68	218	35
0.15%	62	215	37
0.45%	73	207	29
0.90%	118	201	0

The equilibrium of the swelling degree was established in 1 day of immersion, Figure 1 (a), where all the samples swelled at least ~300%. The tensile tests of the samples immersed in PBS for 1 day, Figure 1 (b), revealed that higher amounts of propolis led to higher secant modulus and failure strengths, an exception being the 0.90% propolis sample which presented the lowest values of the secant modulus and of the failure strength. Nonetheless, all samples presented adequate mechanical properties, failure strengths of > 0.13 MPa⁸.

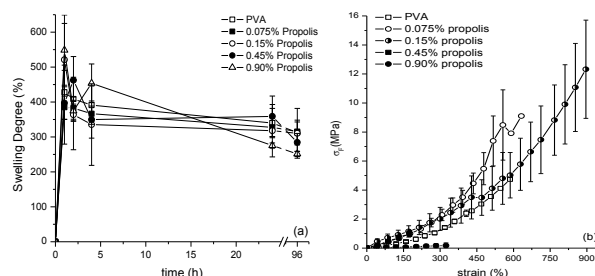

Figure 1 – (a) swelling degree of the samples and (b) tensile tests of the samples immersed in PBS.

The antimicrobial tests revealed the propolis was not active against *E. Coli* and *C. Albicans*. Nonetheless, the propolis used in this work was active against *S. aureus* for amounts of propolis ≥ 0.15% (inhibition zone of ~1000mm²), the most common bacteria in wounds⁹.

CONCLUSION

The presence of propolis interfered with the PVA crystallization and the highest amount of propolis used in this work had the poorest mechanical properties. Nonetheless, all samples presented adequate mechanical properties and high swelling degree. Propolis samples (propolis ≥ 0.15%) were active against *S. aureus*.

INTRODUCTION

Synthetic octacalcium phosphate (OCP) has become recognized as a highly osteoconductive bone substitute material based on *in vitro* and *vivo* studies ^{1, 2}. OCP enhances osteoblastic cell differentiation *in vitro* in a dose-dependent manner ³. Furthermore, the dose-dependent stimulatory capacity of OCP was confirmed in *vivo* implantation with collagen matrix in rat critical sized calvaria defect ⁴. OCP has higher solubility than be-ta tricalcium phosphate (be-ta TCP) therefore more resorbable than be-ta TCP *in vivo* ⁵. It has been shown that OCP combined with collagen (OCP/Collagen) facilitates bone regeneration in comparison with OCP itself ⁶. The osteoconductivity of OCP/Collagen has been demonstrated also in critical-sized bone defect of dog ⁷. After that, we examined the effect of OCP/Collagen on alveolar bone regeneration in human small bone defect and confirmed the healing at the defect ⁸. In this study, we attempted to know about mandibular bone regeneration in larger bone defect of human by OCP/Collagen.

EXPERIMENTAL METHODS

OCP was prepared according to a method of synthesis by mixing calcium and phosphate solution ¹. Particle size of OCP was 300 – 500 µm in diameter. OCP/Collagen was prepared from pepsin-digested atelocollagen isolated from the porcine dermis and OCP. OCP/Collagen was molded in the shape of a disc, 9 mm diameter, and 1 mm thick. The protocol of the clinical trial was submitted and approved by the research ethics committee of the Tohoku University Graduate School of Dentistry. The patients were healthy men or women from 20 to 65 years old. The defect of longer axes was less than 50 mm. In this study, a 42 years old man, that diagnosis was a residual cyst at right mandibular the second premolar region and apical periodontitis at the first and second molars, consented to our investigation with enough explanation. We performed cystectomy or tooth extraction and implantation of OCP/Collagen in the bone defect that longer axes was 40 mm. We observed the healing at operative region and confirmed having infection or allergy, or not and radiographic examination or CT scan was performed until 1 year

after operation. Then, CT value was measured at bone defect.

RESULTS AND DISCUSSION

There was no abnormality for healing, no infection and no allergic reaction for the entire period. OCP or OCP/Collagen does not have radiopacity under normal X-ray condition. However, radiopacity of OCP/Collagen implanted in bone defect increased with time. CT scan showed radiopacities at 3 months after implantation. At 6 or 12 months, the radiopacity of bone defect was almost same as surrounding bone. CT value of bone defect increased significantly at 3 months, and at 6 months. CT value was almost same as surrounding bone of that in cancellous bone. In radiographic examination or CT scan, the radiopacities of implanted OCP/Collagen increased with time. The results suggest that OCP/Collagen itself may convert to hard tissue. At 6 months, CT value was almost same as surrounding bone. It is considered that OCP/Collagen enhances bone regeneration enough by 6 months.

CONCLUSION

This study revealed that OCP/Collagen may enhance bone regeneration in large bone defect of human. OCP/Collagen could be a good bone substitute material.

INTRODUCTION

We have found first that octacalcium phosphate (OCP), synthesized in a specified condition, enhances bone formation more than hydroxyapatite (HA) materials, including a Ca-deficient HA obtained from the original OCP through its hydrolysis reaction, if placed onto cortex or implanted in defect of murine calvaria, during its progressive physicochemical conversion from OCP to HA¹⁻³. OCP enhances osteoblastic cell differentiation of stromal cells^{2,4} and osteoclast formation from its precursor cells⁵ dose-dependently^{4,5}. However, OCP cannot be sintered with keeping its original crystal phase because OCP includes a large amount of water molecules in the structure. We have reported that if OCP is combined with hyaluronic acids (HyAs), having various molecular weights (MWs), then the composites of OCP/HyAs acquire not only a better handling property, including the moldability and injectability⁶, even in a granule form of OCP with several hundreds of micrometer, but also increase the osteoconductivity more than that of OCP alone^{6,7}. However, it is not clear that the addition of HyAs to OCP affects the biological performance in particular the osteoconductivity and the biodegradability of OCP with the prolonged implantation. The present study was designed to investigate about the long term performance of OCP/HyA composites if they were implanted in subperiosteal region of mouse calvaria with prolonged implantation (9 weeks) beyond the previous study (6 weeks)⁷.

EXPERIMENTAL METHODS

OCP was prepared by a direct precipitation under a supersaturated condition with respect to OCP and HA¹. Three sodium hyaluronic acids with different molecular weights, ranging from 90×10^4 , 190×10^4 and 600×10^4 (a chemically-modified sodium hyaluronate derivative), were used as source HyAs. OCP granules (300 to 500µm diameters) were obtained and mixed with HyAs at room temperature. The composites were hereafter referred to as OCP/HyA90, OCP/HyA190 and OCP/HyA600, respectively. These composites were implanted independently in polytetrafluoroethylene (PTFE) rings (OD 8 mm, ID 6 mm, 1 mm thickness) placed onto eight-week old ICR mice in comparison with OCP and HyA alone until 9 weeks. The rate of newly formed bone and the remaining implants was histomorphometrically estimated after the decalcification and the hematoxylin and eosin staining. The capability to form osteoclast-like cells was examined by inoculating macrophage RAW264 cells with RANKL, an osteoclast differentiation factor, in the presence or absence of HyAs. Number of tartrate-resistant acid phosphatase (TRAP)-positive

multinucleated giant cells was then evaluated to know the effect of the HyAs.

RESULTS AND DISCUSSION

The viscosity of OCP/HyA increased with increasing the MW of HyA used. However, all HyAs exhibited fluidity so that they were injectable the inside of PTFE ring at the surgical operation. Although the previous study⁷ showed that HyA90 and HyA600 worked as a stimulant for bone formation by OCP until 6 weeks, HyA190 also became increasing the positive role on new bone formation until 9 weeks as well as other two HyAs. The capacity to form new bone by OCP/HyAs finally became compatible to that by OCP alone, suggesting that HyAs in particular HyA190 and HyA600 have positive roles to activate new bone formation in the early stage of bone formation by OCP. OCP biodegradation progressively advanced until 9 weeks but the degradation rate at 9 weeks was similar between OCP/HyAs and OCP alone. In vitro study confirmed that TRAP-positive osteoclast-like cells from RAW264 cells with RANKL were formed more in the addition of HyA90 and HyA600 than that of HyA190. These results suggest that the observed early enhancement of bone formation by OCP/HyA90 and OCP/HyA600 may be stemmed from the stimulatory capacity of these HyAs on osteoclast formation, resulting in the enhancement of biodegradation of OCP followed by new bone formation.

CONCLUSION

The present study confirmed that the injectable OCP/HyAs provide a better handling property and that HyAs support the osteoconductivity of OCP most probably through modulating osteoclastic activity to biodegrade OCP in particular at the early stage of bone formation. Further study is underway to establish the molecular mechanism of HyAs on bone formation enhanced by OCP.

INTRODUCTION: Boron (B) based glasses have variable degradation characteristics and are attractive for a diverse range of biomedical applications. B is associated with a variety of roles, from embryogenesis and bone growth, to enhanced immune functionality. It is also known as a potent antimicrobial agent against pseudomonas, enteric bacteria, and staphylococci, thus offering potential for engineered infection control properties in biomaterials [1]. Consequently, and based on nascent data in the literature, B-Ge based glasses may provide a suitable strategy for developing non-classical formulations of GICs [2], which consolidate a variety of fundamental design attributes (*i.e. suitable for multiple hard tissue applications*) into a single material formulation (*e.g. design attributes include intrinsic infection control bioactivity, and biodegradation characteristics*). The objective of this study was to utilize a combination of Mixture-Design (DOM) and experimental evaluations to permit composition-property modelling based on variable compositions of B-Ge based GICs based on infection control characteristics and degradation.

EXPERIMENTAL METHODS: A series of glasses (n=10) of formulation $x\text{ZnO}-y\text{B}_2\text{O}_3-(0.8-x-y)\text{GeO}_2-0.15\text{CaO}-0.05\text{ZrO}_2$ ($0.21 \leq x \leq 0.36$ mol. fraction) were designed via DOM, melt-quenched and ground to $\leq 45\mu\text{m}$. Each glass was utilized to form a contiguous GIC (n=10 GICs), with 55wt% polyacrylic acid ($M_w=37,700$) at a glass to acid ratio (P:L) of 3:2. Cement specimens $\varnothing 6\text{mm} \times 1\text{mm}$, (n=3 for each cement) were incubated at 37°C in 2mL tissue culture water for 24hrs. After incubation, cement specimens were placed in direct contact with *Lactobacillus casei* (L. casei) for a further 24h. In addition, filtered extracts were evaluated *via* indirect contact using L. casei. Tissue culture water and Fuji IX (GC Corp) were used as controls. B^{3+} , Ge^{4+} , Ca^{2+} , and Zn^{2+} levels were determined via inductively coupled plasma atomic emission spectroscopy. An optimized glass formulation for GIC synthesis (*based on maximum antibacterial efficacy*) was identified using Scheffe equation analysis.

RESULTS AND DISCUSSION:

Figure 1: L-Casei viability (%) after 24h direct contact with cement specimens (based on B_2O_3 mol. fraction).

Figure 2: L-casei viability (%) after 24h indirect contact with filtered extract versus Ca^{2+} concentration.

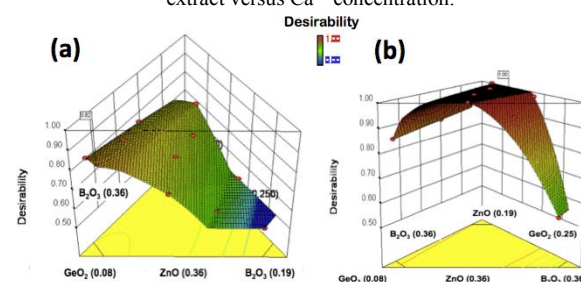

Figure 3: 3-D contour of optimal design formulations from: (a) direct contact, (b) indirect contact assays.

Of all compositional variables examined, the antibacterial efficacy of cements only *increased linearly with increased B_2O_3 content* in the glass (Fig 1). Total ion release ranged from 1142-2830ppm, 202-1243ppm, 75-222ppm, and 15-55ppm for B^{3+} , Ge^{4+} , Ca^{2+} , and Zn^{2+} , respectively; no direct mathematical relationship could be established for ion release *vs.* composition. Antibacterial efficacy appeared independent of the ions released, with the exception of Ca^{2+} ; where *increased Ca^{2+} release levels were directly related to increased bacterial viability* (Fig. 2) - an important finding given the inclusion of Ca in the formulation of many conventional bioglasses. Regression analysis relating to composition-property relationships (Fig. 3) indicates that *formulations comprising $0.275 \leq \text{B}_2\text{O}_3 \leq 0.33$ provide maximum antibacterial efficacy* for the GICs.

CONCLUSION: Mathematical design of biomaterial compositions, with a view to establishing composition-property relationships, is a valuable tool toward rational design and optimization of medical materials. Utilizing this approach, this data shows that the mol. fraction of boron directly increases the antibacterial efficacy of the novel GICs and that Ca, a common 'bioactive' additive in biomaterials promoted bacterial cell viability.

Pre-osteoblast cell responses on phosphate and calcium co-immobilized titanium

Sunarso, Riki Toita, Kanji Tsuru, Kunio Ishikawa

Department of Biomaterials, Faculty of Dental Science, Kyushu University, Japan, sunarso_chemugm@yahoo.com

INTRODUCTION

Titanium (Ti) has been widely used for dental and orthopaedic implants due to its excellent biocompatibility and mechanical properties [1]. However, improve osteoconductivity is desired for strong clinical use. Surface modification is one of the most promising methods to increase the osteoconductivity of Ti.

Phosphate (P) and calcium (Ca) are known to play important roles in the osteoblast cell responses such as proliferation and differentiation (*e.g.*, increase of alkaline phosphatase (ALP) activity and mineral deposition) [2, 3]. Thus, the existence of P and Ca on the surface of Ti was expected to increase the cell response significantly.

In this present paper, we introduced a new technique to improve osteoconductivity of Ti implant by co-immobilizing phosphate and calcium on its surface. Both P and Ca can be easily immobilized on Ti surface by NaH_2PO_4 treatment and subsequent CaCl_2 treatment. Effect of P and Ca immobilization on cell responses was investigated using pre-osteoblast cells.

EXPERIMENTAL METHODS

Mirror polished pure Ti disks (14.5 mm $\phi \times 1$ mm) were used in this study. The Ti was washed with ultrapure water, ethanol and acetone, and then dried. The Ti specimen was treated with 30 mL of 100 mM NaH_2PO_4 aqueous solution at 80°C for 24h, followed by washing with ultrapure water, ethanol and acetone ultrasonically. The phosphate treated Ti specimen was then treated with 10 mM CaCl_2 aqueous solution at 80°C for 1h. The surface of the specimens was analyzed by X-ray photoelectron spectrometer (XPS). The non-treated and treated Ti were symbolized as Ti and Ca-P-Ti, respectively.

The MC3T3-E1 cell line (mouse pre-osteoblast cells) was used for *in vitro* study. The cells were differentiated in alpha minimal essential medium (α -MEM) containing 10% fetal bovine serum, 10 mM Na- β -glycerophosphate, 10 nM dexamethasone and 1% antibiotics under humidified atmosphere containing 5% CO_2 at 37°C. The cells were seeded at the initial density of 1×10^4 cell/cm² for cell proliferation, and 4×10^4 cell/cm² for ALP activity and Ca quantification on test substrates in 24-well culture plate. The medium was changed every 2 days.

RESULTS AND DISCUSSION

Figure 1 is the XPS spectra of the Ti surface after NaH_2PO_4 and CaCl_2 treatment. The original Ti showed Ti2p and O1s peaks, but did not show P2p and Ca2p peaks. In contrast, the P2p and Ca2p peaks were detected after NaH_2PO_4 and CaCl_2 treatment, indicating that both P and Ca were successfully immobilized on

the surface of Ti. Atomic percent of P and Ca were determined as 14.76% and 7.91%, respectively.

Figure 1. XPS spectra of Ti and Ca-P-Ti

The number of proliferated cells on Ca-P-Ti surface was higher when compared with that on the Ti. The ALP activities of cells on Ca-P-Ti were higher when compared with those on Ti at day 8, and tend to decrease after 16 days of culture. Meanwhile, the ALP activity on the Ti surface showed tendency to increase during 16 days of culture. The decrease of ALP activity at day 16 indicated that the cells were in the progress of maturation, which attributed with the production of mineralized matrix at the later. Mature osteoblast cells can form mineralized matrix consisted of apatite. The quantification of Ca amount thus can be used to indicate the mineralization process. Ca content of the cultures on Ca-P-Ti surface was two times higher than that on the Ti after 20 days, showing that more apatite deposition on Ca-P-Ti surface. These results clearly showed that co-immobilization of P and Ca facilitated proliferation and differentiation of pre-osteoblast cells.

CONCLUSION

The Ca-P-Ti surface showed higher proliferation, ALP activity and mineralization compared to the Ti surface. Co-immobilization of P and Ca on Ti could improve the osteoconductivity of Ti.

Nanohybrid Approach to Create Cell-Compatible Degradable Copolymer Thermogels as Cell Delivery Carriers

Naho Oyama and Koji Nagahama*

Department of Nanobiochemistry, Konan University, Japan, nagahama@center.konan-u.ac.jp

INTRODUCTION

In situ forming hydrogels have been attracted much attention as injectable cell delivery carriers for tissue engineering. Injectable gels currently studied are covalently cross-linked networks of synthetic- or biopolymers via click chemistry and enzymatic reactions¹. Although these methods allow forming ideal mechanically-stable hydrogels *in situ*, complicated chemistry are required for preparing gel precursors and harmful reagents/catalysts/substrates for preparing gels caused a decrease in cell viability¹. Thus there is a need to have alternative strategy for making cell-compatible injectable gels. Here we present a novel strategy to make physically cross-linked injectable gels having excellent cell-compatibility by means of nanohybrid technique using biodegradable poly(lactide-co-glycolide)-*b*-poly(ethylene glycol)-*b*-poly(lactide-co-glycolide) (PLGA-PEG-PLGA) and clay nanosheets.

EXPERIMENTAL METHODS

PLGA-PEG-PLGA copolymers were synthesized through ring-opening polymerization of DL-lactide and glycolide in the presence of PEG (M_w : 1.5k and 3.0k). Thermo-responsive behaviour of mixed aqueous solutions of PLGA-PEG-PLGA and clay nanosheets was examined by test tube inverting method. Degradation profiles of hybrid gels in PBS at 37°C and the molecular weight reduction was analyzed by GPC. Calcein-labelled L929 cells (1.0×10^5 cells) were dispersed in hybrid solutions and then incubated at 37°C to form cell loading hybrid gels. Live/Dead staining and confocal laser scanning microscopic observations of loaded cells were carried out to examine the cell viability and cell proliferation in the hydrogels.

RESULTS AND DISCUSSION

PLGA-PEG-PLGA copolymers, called as $P_{1.5k}$ and P_{3k} , were synthesized and the molecular compositions were determined by ¹H-NMR and gel permeation chromatography analyses. Although thermo-gelling property of PLGA-PEG-PLGA is useful for injectable cell delivery, these aqueous solutions indeed exhibit strong cytotoxicity against loaded cells, because PLGA segments are released from the destabilized micelle core by thermal stimulus and directly disrupt the cytomembranes of loaded cells. Here, in order to produce PLGA-PEG-PLGA based cell-compatible thermogels, we attempted to quench the cytotoxicity via preventing the release of PLGA segments by capping PEG loop located on the micelle surfaces using clay nanosheets (Laponite: LP) as nano-stabilizer. Peak intensity of PEG in ¹H-NMR spectrum of P_{3k} /LP hybrids measured in D₂O significantly lower than that of P_{3k} . Hydrodynamic diameter (averaged value) of P_{3k} /LP hybrid micelles and P_{3k} micelles was 44 nm and 33 nm, respectively. These results suggest that PEG loops located on the micelle surfaces are capped with

Figure 1 (a) Cell viability of L929 cells encapsulated in $P_{3k}5L1.1$ gels (●) and $P_{1.5k}$ gels (●) after 1 hour incubation. (b) Live/Dead staining of L929 cells encapsulated in $P_{3k}5L1.1$ gel (upper) and 15 wt% of $P_{1.5k}$ gel (lower) after 4 hours incubation.

LPs. We therefore investigated the influences of the capping micelle structures on their thermo-gelation. $P_{1.5k}$ aqueous solutions exhibited temperature-responsive gelation at above 5 wt% in reversible manner. P_{3k} /LP solutions with certain mixing ratios exhibited thermo-gelation at lower concentration (1 wt%) in irreversible manner, while P_{3k} solutions never exhibit thermo-gelation even at high concentration, suggesting that LPs located on micelle surfaces possess an ability to promote gel network formation.

Cell viability in $P_{1.5k}$ gels and P_{3k} /LP hybrid gels was examined by Live/Dead staining assay. L929 cells encapsulated in P_{3k} /LP gels (e.g., $P_{3k}5L1.1$ indicates hybrid of 5 wt% P_{3k} and 1.1 wt% LP) were completely alive (Figure 1a), whereas $P_{1.5k}$ gels exhibited cytotoxicity in dose dependent manner, moreover L929 cells encapsulated in $P_{1.5k}$ 15 wt% gels were completely dead after 4 hours (Figure 1b), meaning the excellent cell-compatibility of P_{3k} /LP thermogels and the compatibility should be owing to the capping micelle structures. Importantly, P_{3k} /LP hybrid gels achieved significantly high cell encapsulation ability by utilizing its thermo-gelling property (maximum cell number: 5×10^6 cells per 100 μ L of gel) because of their rich inner space derived from the low gelation concentrations. These results prove that this original nanohybrid strategy is useful to quench a cytotoxicity of PLGA-PEG-PLGA thermogels.

CONCLUSION

Since LP is known to absorb various kinds of proteins including growth factors, the nanohybrid thermogels could be applied as injectable cell delivery carries for various types of cells. In addition, the nanocomposite thermogels would have a potential as injectable scaffolds having sufficient space for cell migration, cell growth, and cell 3D organization in the hydrogels.

Self-assembly of PEI Modified Biodegradable Complex Micelles as Gene Transfer Vector for Proliferation of ECs

Juan Lv, Jing Yang, Xuefang Hao and Yakai Feng*

School of Chemical Engineering and Technology, Tianjin University, Weijin Road 92, Tianjin 300072, China
yakaifeng@tju.edu.cn

INTRODUCTION

Gene therapy is an attractive alternative to realize rapid endothelialization of artificial vascular grafts in current clinical treatments of coronary bypass surgery. Poly(ethylene imine) (PEI) has been widely used to deliver plasmid DNA¹. PEI with high molecular weight has perfect transfection efficiencies but high cytotoxicity². Low molecular weight PEI has been demonstrated a low toxicity³ but its transfection efficiency needs to improve. It is reported that PEI modified with other polymers showed high transfection efficiencies⁴, and grafting low molecular weight PEI onto biodegradable backbone is of intriguing interest. Herein, low molecular weight PEI ($M_w = 1800\text{Da}$) was used, and a complex micellar system with a biodegradable PLGA core and a mixed mPEG / PEI shell which was prepared by self-assembly of methoxy-poly(ethylene glycol)-*b*-poly(lactide-co-glycolide) (mPEG-*b*-PLGA) and poly(ethylene imine)-*b*-poly(lactide-co-glycolide) (PEI-*b*-PLGA) in aqueous solution. Then, a novel ZNF580 gene (plasmid fused to green fluorescence protein, pEGFP-ZNF580), which has the ability of enhancing the proliferation of vascular endothelial cells, was encapsulated onto the micelle core (Scheme 1). The aim of this work is to design a novel gene vector to adjust the cytotoxicity and the transfection efficiencies through easily changing the ratio of mPEG/PEI of the micelles.

Scheme 1 Schematic illustration of self-assembly mechanism of blank and gene-loaded micelles.

EXPERIMENTAL METHODS

PEI was grafted onto PLGA according to the literatures⁵. mPEG-*b*-PLGA and PEI-*b*-PLGA were dissolved in DMF. Then the solution was added dropwise into PBS (50 mL) under stirring to induce micellization. The mixture was dialyzed for 24 h to remove DMF. The ZNF580 gene was added into micelles solution, and the complexes were gently vortexed and incubated for 30 min at room temperature.

RESULTS AND DISCUSSION

The polymer micelles were prepared from the polymers with mass ratio of PEG/PEI = 3/1, 2/2, 1/3 and 0/4. The gene-loaded micelles were formed at N/P 5, 10, 15, and

20. The hydrodynamic diameter of the blank and gene-loaded micelles estimated by dynamic light scattering (DLS) was between 90 to 160 nm, which could be in favor with cellular uptake. When the ratio of PEG/PEI was 3/1 or 2/2, the gene-loaded micelles at different N/P ratios showed smaller size than the blank micelles, while the hydrodynamic size of micelles at PEG/PEI = 1/3 or 0/4 became larger after loading pEGFP-ZNF580. The decrease content of PEG in shell could lead to unstability of the gene-loaded micelles which may result in aggregation of these micelles. The zeta potential of gene-loaded micelles was reduced with decreasing N/P ratios.

Figure 1 Zeta potential of blank and gene-loaded micelles at different PEG/PEI and N/P ratios.

CONCLUSION

A complex micellar gene delivery system with a biodegradable core and a mixed shell was prepared using grafting low molecular weight PEI onto biodegradable PLGA backbone. The hydrodynamic size and zeta potential of blank and gene-loaded micelles indicated that they were feasible to cellular uptake and gene transfection. These complex micelles could change the ratio of mPEG/PEI easily to adjust the cytotoxicity and the transfection efficiencies.

Ultrasonic non-invasive monitoring of the mechanical properties of collagen vascular scaffolds in bioreactors

Bernard Drouin^{1,2}, Ramiro M. Irastorza³ and Diego Mantovani¹

¹ Laboratory for Biomaterials and Bioengineering, Department of Materials Engineering and Research Center of CHU de Québec, Laval University, Quebec City (Qc), (Canada), E-mail: Bernard.drouin@sympatico.ca

² Physics Dept., Cegep Garneau, Quebec City, Canada

³ Instituto de Física de Líquidos y Sistemas Biológicos (IFLYSIB), CONICET, La Plata, Argentina

INTRODUCTION

One of the main challenges that Tissue Engineering faces today is to have bioreactors that reliably and reproducibly allow cells to expand while forming tissues that can sustain physiological functions in vivo. One key factor in achieving this objective is to monitor the mechanical properties by non-invasive evaluation techniques¹. This will require substantial design features to be included into the bioreactor for constructs that have to provide an important mechanical function, such as blood vessels².

Ultrasonography imaging is widely used in medicine. In this application, the only direct measurement is the time delay between the emission and reception of a pulse. To assess distances, one must presume a mean speed of sound identical for all tissues. On the contrary, within a bioreactor, distances are known and the time delay between emission and reception of a pulse is determined with very high precision. This allows one to determine very accurate speed of sound (SOS) which is related to the ratio of Bulk Modulus to Density in the case of hydrogels.

$SOS^2 = K/\rho$; K = Bulk Modulus; ρ = density

EXPERIMENTAL METHODS

Mechanical behaviour of collagen gels has been investigated using unconfined compression. To assess SOS within disk-shaped gels made from Type-I collagen obtained from rat tail tendons, the upper moving plate attached to a 10 N Load Cell had an embedded ultrasonic probe. Newly formed collagen hydrogels have been submitted to relaxation, creep and cyclic tests similar to those encountered in bioreactors.

RESULTS AND DISCUSSION

This work is focused on the ongoing effort done in our lab to propose a global strategy to attain reliable and reproducible vascular tissue constructs. First part of this strategy is to gain an in-depth understanding of collagen hydrogels mechanical properties and in particular of the visco-elastic linear as well as non-linear models³ applicable in the various parts of the maturation process. Second part of the strategy is the necessity to rely on a non-invasive technique to assess the properties during the maturation process. Third part of the strategy is to develop an easy to use simulation tool in order to reproduce and predict the behaviour of these hydrogels in dynamic solicitation as encountered in bioreactors and, more generally, in experiments related to mechanobiology.

All relaxation tests indicate that a viscoelastic model based on two Maxwell bodies can satisfactorily reproduce relaxation load curves. Cyclic tests similar to the one reproduced in Figure 1, show steep variations whenever a change in the movement direction of the compression plate occurs. Moreover, the Load relaxation and the SOS relaxation do not exhibit the same behaviour. Load resume to the initial value while the SOS final value is much higher.

Fig.1. Load (Green), Speed of Sound (Blue) and extension (red) recorded during a compression test of a Collagen hydrogel sample.

This kind of tests has been made on a great number of samples. The results of these tests will be presented and discussed.

CONCLUSION

Results permit us to conclude that the overall objective of assessing mechanical properties of the construct with non-invasive ultrasonic techniques is feasible and attainable.

Scaffold and tissue engineering by self-assembly therapies for tendon repair

Zeugolis, Dimitrios

Network of Excellence for Functional Biomaterials (NFB), National University of Ireland, Galway (NUI Galway), Galway, Ireland; dimitrios.zeugolis@nuigalway.ie

INTRODUCTION

Tendon and ligament injuries constitute an unmet clinical need with approximately 100,000 new cases annually in US alone [1]. Tissue grafts are considered the gold standard in clinical practice. However, allografts and xenografts can lead to disease transmission, whilst the limited supply of autografts restricts their use. To this end, scaffold and scaffold-free therapies are under development to address the tissue grafts shortage [2]. Herein, we describe biophysical, biochemical and biological methods to maintain tendon derived cell phenotype; development of tendon-equivalent facsimiles; and ultimately functional neotendon formation.

EXPERIMENTAL METHODS

Growth factor supplementation was assessed as means to maintain tendon derived stem cell phenotype. Biophysical and biochemical/biological features were assessed as means to maintain tendon derived cell phenotype and directional neotissue formation in rat patellar tendon model. Rich in tendon-specific extracellular matrix cell sheets were produced by appropriate modulation of the in vitro microenvironment [3].

RESULTS AND DISCUSSION

Fig. 1 indicates that after 28 days in culture, tendon stem cells (TSCs) treated with IGF-1 were positive for CD90 and CD44; negative for CD31 and CD34; and maintained similar expression level of extracellular matrix molecules, such as Tenascin C (TEN-C); Collagen I (Col I), Decorin (DCN) and Scleraxis (SCX), as TSCs at day 0 without IGF

Fig. 2 shows that tenocytes seeded on low stiffness align electro-spun PCL films and hierarchically assembled collagen fibres were positive for CD90 (green) and negative for Tenascin C (red) similar to native tendon tissues, whilst on smooth rigid tissue culture plastic expressed far from physiological Tenascin C and CD90.

CONCLUSION

Treatment with IGF-1 preserved tendon stem cell multipotency for up to 28 days in culture and minimised changes in marker expression and extracellular matrix molecules production. Hierarchically assembled collagen scaffolds and anisotropically ordered polymeric substrates of rigidity similar to native tendons facilitate tenocyte phenotype maintenance in vitro. Modulation of the in vitro microenvironment of tenocytes with macromolecules enhances tendon specific extracellular matrix deposition within 6 days in culture, facilitating that way clinical translation of cell-sheets.

Characterization of PCL based nano/micro fibrous scaffold for Bone Tissue Engineering

Izabella Rajzer^{1*}, Elżbieta Menaszek²

^{1*} Department of Mechanical Engineering Fundamentals, ATH - University of Bielsko-Biała, Poland
irajze@ath.bielsko.pl

² Department of Cytobiology, Collegium Medicum, UJ Jagiellonian University, Poland

INTRODUCTION

Nano/micro-fiber combined scaffold have an innovative structure, inspired by extracellular matrix that combines a nano-network, aimed to promote cell adhesion with a micro-fiber mesh that provides the mechanical support¹. The main objective of this work was to obtain new hybrid nano-/micro- fibrous materials which could be prospectively applied as a three-dimensional porous scaffold for bone tissue engineering purposes. In this study, it was found that the combined use of two techniques namely electrospinning and needle-punching processes, could be beneficial for the fabrication of 3D bioactive scaffolds with a desired pore size and a final nano-/micro- fibrous structure.

EXPERIMENTAL METHODS

Hybrid scaffolds were obtain by a combination of electrospinning method and the conventional needle-punching process. The properties of composite nano/micro fibrous scaffolds were investigated using the methods of: DSC, TGA, FTIR, SEM, EDX, WAXD and mechanical tests. Bioactivity was determined by assessing the formation of crystalline apatite on the surface of scaffolds upon immersion in Simulated Body Fluid (SBF). NHOst cells were seeded onto scaffolds to evaluate cell viability and morphology. Cell differentiation ability on the scaffolds was evaluated by measuring the activity of ALP. The mineralization was assessed by OsteoImage mineralization test (Lonza, USA).

RESULTS AND DISCUSSION

In this study, bioactive hybrid scaffolds were fabricated by direct spinning of nanofibers on micro-fibrous nonwovens. Both scaffold layers were modified with nano-hydroxyapatite in order to ensure the bioactive character of final hybrid scaffold. The presence of n-HAp was confirmed by FTIR and SEM studies. The macroscopic images of nano/micro fibrous scaffold are shown in Fig. 1. After immersion in SBF bone-like crystalline apatite layers completely covered the surface of samples, as shown in Fig. 2.

Fig. 1. SEM micrographs of hybrid scaffold (a) before and (b) after immersion in SBF.

The ability of cells differentiation was demonstrated in their morphology (Fig. 3), activity of the enzyme -

alkaline phosphatase, and the production of hydroxyapatites.

Fig. 2. SEM micrographs of hybrid scaffold after immersion in SBF.

Fig. 3. Morphology of NHOst cells on hybrid scaffold.

The materials usually proposed for bone tissue engineering made of ECM-mimicking nanofibrous electrospun mats cannot be used as 3D scaffolds due to their very small pore size. It is well known that pore size distribution, porosity and pore interconnectivity are crucial parameters for tissue engineering scaffolds, as they provide the optimal spatial and nutritional conditions for the cells and determine the successful integration of the natural bone tissue and the material as well as enabling neovascularization and cell attachment.

CONCLUSION

By combining nano-fibers with micro-fibers, a new scaffold material with 3D structure and different pore size ranges was obtained. The bioactive character of these hybrid scaffolds was confirmed by an SBF mineralization study. Already after 7 days, the hybrid scaffold surface was totally covered by apatite deposits.

Mechanism of Electrodeposition of Poly(Ethylene Glycol) to Titanium Surface

Takao Hanawa¹, Osamu Fukushima¹, Yusuke Tsutsumi¹, Hisashi Doi¹ and Maki Ashida¹

¹Institute of Biomaterials and Bioengineering, Tokyo Medical and Dental University, Japan
hanawa.met@tmd.ac.jp

INTRODUCTION

Immobilization of poly(ethylene glycol) (PEG) to titanium (Ti) surface has been attempted by electrodeposition technique. Both terminals of PEG are terminated with -NH_2 ($\text{NH}_2\text{-PEG-NH}_2$) and cathodic potential was charged to Ti. During charging, the $\text{NH}_2\text{-PEG-NH}_2$ electrically migrates to and is deposited on the Ti cathode^{1,2}. The amounts of the PEG layer immobilized onto the metals are governed by the concentrations of the active hydroxyl groups on each surface oxide in the case of electrodeposition³. The PEG-immobilized surface inhibits the adsorption of proteins and cells, as well as the adhesion of platelets⁴ and bacteria⁵, indicating that this electrodeposition technique is useful for the biofunctionalization of metal surfaces. However, the electrodeposition mechanism is still unclear. In this study, electrodeposition phenomena were investigated using a quartz crystal microbalance (QCM), an ellipsometer, and a potentiostat. This research will enhance to elucidate the mechanism of electrodeposition of other biofunctional molecules to metal surface.

EXPERIMENTAL METHODS

The following experiments were performed: (1) measurement of mass change to characterize the adsorption behaviour of $\text{NH}_2\text{-PEG-NH}_2$ to Ti (QCM), (2) injection of $\text{NH}_2\text{-PEG-NH}_2$ solution into NaCl solution where Ti was immersed and cathodic potential was charged, followed by measurement of mass change to characterize the electrodeposition behaviour of $\text{NH}_2\text{-PEG-NH}_2$ to Ti (QCM), (3) measurement of the thickness of immobilization layer of $\text{NH}_2\text{-PEG-NH}_2$ during cathodic polarization of Ti (ellipsometer), (4) measurement of mass change and current change of Ti during cyclic voltammetry (QCM and potentiostat).

RESULTS AND DISCUSSION

(1) $\text{NH}_2\text{-PEG-NH}_2$ adsorbed to Ti when Ti was immersed, while less unmodified PEG adsorbed to Ti, as shown in Fig. 1. Therefore, $\text{NH}_2\text{-PEG-NH}_2$ molecules immediately adsorbed to Ti by electrostatic force. (2) Injection of $\text{NH}_2\text{-PEG-NH}_2$ solution after immersion of Ti in NaCl solution increases the mass of Ti as shown in Fig. 2, indicating the electrostatic adsorption of $\text{NH}_2\text{-PEG-NH}_2$ occurred. When cathodic potential was charged to Ti, the frequency in QCM was disturbed by the evolution of H_2 and the mass increased. More $\text{NH}_2\text{-PEG-NH}_2$ molecules were immobilized by the charge of cathodic potential. The adsorbed $\text{NH}_2\text{-PEG-NH}_2$ attracted to Ti surface and the layer was condensed during cathodic charge. (3) When the potential charge was stopped, the thickness of $\text{NH}_2\text{-PEG-NH}_2$ layer increased again. Even anodic potential was charging, $\text{NH}_2\text{-PEG-NH}_2$ molecules did not desorb

from Ti and remained on Ti. (4) When cyclic voltammetry of Ti was performed, polarization curves showed difference between with and without $\text{NH}_2\text{-PEG-NH}_2$ molecules and the respond current showed hysteresis in the case of $\text{NH}_2\text{-PEG-NH}_2$ solution. This quantity of electricity was used for electrodeposition.

Fig. 1 Time transient of the frequency shift after the injection of each $\text{NH}_2\text{-PEG-NH}_2$ solution measured by QCM. The decreasing frequency shift indicates the increase of PEG molecules adsorbed on the Ti surface.

Fig. 2 Mass shift of the PEG layer on a Ti surface by QCM measurement. -3 V vs. SCE potential applied after $\text{NH}_2\text{-PEG-NH}_2$ injection.

CONCLUSION

$\text{NH}_2\text{-PEG-NH}_2$ immediately adsorbed to Ti surface by electrostatic force, but the bonding is weak and random. During cathodic charge of Ti, $\text{NH}_2\text{-PEG-NH}_2$ molecules rearranged and condensed to Ti surface with electrochemical reactions of the molecules and Ti surface.

INTRODUCTION

Biphasic calcium phosphate (BCP) as bone grafting component confirmed bioactivity of synthetic hydroxyapatite (HAP) in activation of endogenous growth factors, remineralisation of atrophic host bone and integration in natural remodelling of bone¹. However, the results obtained by various researchers appear to differ² and to depend on different stimulatory factors. One of such factor is implantation of mesenchymal stem cells (MSC) that is known to increase biocompatibility and bioactivity of the implants and newly formed bones³. Objective of this study was to evaluate the tissue reactions after implantation of BCP ceramic granules with HAP/tricalcium phosphate (TCP) ratio of 90/10 in combination with injection of MSC in hard and soft tissues of experimental animal.

EXPERIMENTAL METHODS

We used 6 experimental New Zealand rabbits who underwent ovariectomy to develop experimental osteoporosis⁴, 1.5 months later the HAP/TCP and MSC was implanted into the hip bone and into the soft tissue, but animals were euthanized 5 months later. Blocks with implants were proceeded for BMP2/4, osteopontin (OP), osteocalcin (OC), tumour necrosis factor (TNF α) and IL1/IL10 immunohistochemically. Controls were developed by four animals with osteoporosis who received implants of bioceramic only in hard and soft tissue.

RESULTS AND DISCUSSION

Partially reabsorbed granuli enrolled by osteoclasts and distinct connective tissue capsule were detected in both – experimental and control animals. Bone with bioceramic and MSC demonstrated equal to the control side osteocalcin expression while osteopontin-containing cell number was moderate in comparison to the occasional cells found in control. These data suggest not only about active bone mineralization and/or growth, but also about possible ability of MSC to stimulate renovation of ground substance proteins. This our suggestion is proved by other authors observing the OP expression among those first factors which are secreted by differentiating into the osteoblasts MSC⁵. From other side, the increase of OP stimulates MSC migration⁶.

Soft tissue in control rabbits showed numerous IL1- and TNF α -containing cells, mainly they were fibroblasts and macrophages in the connective tissue capsule. Experimental animals demonstrated only occasional

TNF α positive connective tissue cells, but IL1 positivity was absent. Also there was a lack of IL10 immunoreactive cells in both – control and experimental animals. These data suggest about the presence of inflammatory and anti-inflammatory cytokines in tissue with implants which is diminished by MSC injections. Interestingly, proliferation marker Ki67 marked fibroblasts and macrophages in the connective tissue capsule, but selectively - only in control side. It is showed that rabbit dermal fibroblasts under the influence of MSC could show proliferation potential during chronic wound healing⁷. So, we speculate that this stimulation could persist also after biomaterial implants with following suppression of proliferation potential under the influence of MSC in our animals. This indirectly is proved also by other authors⁸ who revealed decrease of cellular proliferation via prostoglandin E2 depression in experimental osteoblast culture treated by MSC.

CONCLUSIONS

HAP/TCP and MSC implantation renovates stable expression of bone mineralization regulating protein osteocalcin and proves the combined influence of MSC and osteopontin in bone regeneration still 5 months after implantation.

The “hidden” inflammation characterizes soft tissue around biomaterial implants still 5 months after the implantation, but is notably decreased together with cellular proliferation under the combined treatment of tissue with bioceramic and MSC implants.

INTRODUCTION

Delivering an effective dose to ocular tissues can be a challenge. The bioavailability of most topical ophthalmic medications is surprisingly limited. The major obstacle to targeting the eye with therapeutics in general, is the presence of various barriers which control the concentration and entry of solutes into the eye¹. Contact lenses used as drug delivery devices could minimize the drug loss and side effects^{2,3}. The duration of drug delivery and solubility of hydrophobic drugs can be increased if the drug is first entrapped in vesicles such as polymer-phospholipid complexes, which can be dispersed on very thin contact lens coatings to immobilize the drug on their surface. The properties of such vesicles would increase the bioavailability and therapeutic effects of the drugs on the eye. When hydrophobically associating polymers, such as poly(styrene-maleic acid) (PSMA) are combined with film-forming lipids, such as the phospholipid dimyristoylphosphatidylcholine (DMPC), they form lipid-polymer nanostructures analogous to lipoprotein micellar assemblies found in nature⁴. In this study, two types of complexes, stable at different pH values where synthesized and loaded with drugs of different hydrophilicities during their formation process. The controlled drug release was studied in vitro and compared to the release of the free drugs.

EXPERIMENTAL METHODS

Synthesis of drug-loaded PSMA-DMPC vesicles

Model molecules and drugs were encapsulated individually in the vesicles. Briefly, the phospholipid and the drug were homogenised in organic solvent that was subsequently evaporated. Then, 3 % (w/w) PSMA aqueous solution was homogenized with the lipid-drug mixture, in relative amount 3 to 1, for several minutes in a high speed homogenizer combined with a sonicating bath. When non-esterified PSMA was used, the vesicles were formed after decreasing the pH to their hypercoiling point (close to pH 5), the vesicles with esterified PSMA, however, were formed at neutral pH.

Physical characterisation of the vesicles

PSMA-DMPC vesicles were characterised by means of SEM, particle size distribution, polydispersity index, and Zeta potential (ZSizer).

RESULTS AND DISCUSSION

In Figure 1 a monodisperse particle size distribution characteristic of these nanometric vesicles can be observed; Table 2 shows the different sizes and surface charges of vesicles made from different PSMA samples.

Figure 1. Particle size distribution of a vesicles sample.

Table 1. Particle size, PDI and Z potential of vesicles

Sample	size	PDI	Zpot.
AS(average of 7 samples)	48±11	0.23±0.03	-13.6±8.6
EAS (average of 3 samples)	434±8	0.37±0.01	-41.7±2.8

*AS=vesicles from PSMA 1600; EAS= from esterified PSMA 1600

Figure 2 shows how the free Rose Bengal kinetics profile is much higher than the Rose Bengal release from the vesicles.

Figure 2. Cumulative percentage release profiles of free Rose Bengal (blue) and Rose Bengal from vesicles (red)

Depending on the PSMA used to form the vesicles, the pH stability, surface charge and average sizes can be tuned to encapsulate molecules of different natures and to achieve different drug loads and release profiles. The initial “burst” effect of the free drug can be avoided.

CONCLUSION

The nanoparticles synthesis can be tuned to achieve high encapsulation efficiency. This study is the starting point for the development of a more complex delivery system. An controlled delivery was observed in the release profile especially in the case of hydrophobic drugs, avoiding initial “burst” and with total drug released being moderated by the interaction of the drug with the phospholipid core.

Modification of PVC catheters with a binary graft of PEGMA and AAc to improve their biocompatibility

L. Islas, G. Burillo

Instituto de Ciencias Nucleares, Universidad Nacional Autonoma de México, leislas@gmail.com

INTRODUCTION

Healthcare associated infections (HCAs) continue to be a problem for healthcare facilities, costing both lives and money¹. In the US, urinary tract infections (UTIs) account for 70% of HCAs, with 95% of those due to urinary catheters². A catheter associated UTI (CAUTI) begins with contamination of the catheter's surface by bacteria, leading to the formation of a biofilm². One way of preventing CAUTIs is to modify the surface of the catheter to make it unfavourable for bacterial attachment. In this study, through the use of ionizing gamma radiation, we investigated the kinetics of the surface modification of poly(vinyl chloride) urinary catheters with a binary graft of poly(ethylene glycol) methacrylate, to prevent the formation of biofilm^{3,4}, and acrylic acid, a smart pH-sensitive polymer that will give the catheter the ability to retain and release biocides⁴.

EXPERIMENTAL METHODS

Materials Medical grade poly(vinyl chloride) (PVC) catheters were cut into 2 cm samples, washed with MeOH for 24 h, and dried for 8 h in a vacuum oven at 40°C. Acrylic acid (AAc) and poly(ethylene glycol) methacrylate (PEGMA) were distilled and washed before being used. The ionizing radiation comes from ⁶⁰Co (Gammabeam 650T). **Method** A PVC sample, in a glass ampoule, is pre-irradiated in the presence of oxygen to create active sites. Once irradiated, the sample is put in contact with a 5 mL solution of AAc or PEGMA. The ampoule is then bubbled with argon for 10 min and sealed. Afterwards, the ampoule is heated to initiate grafting. To graft the second monomer/polymer, the modified PVC catheter repeats the aforementioned cycle. Once grafted, the samples are removed from the ampoule and washed with distilled water. The samples are then dried and the grafted percent (%G) is calculated with the following formula,

$$\%G = \frac{W_g - W_o}{W_o} \times 100$$

where W_g is the final weight and W_o is the initial weight.

RESULTS AND DISCUSSION

Table 1 shows the amount of PEGMA grafted on PVC.

Sample	%G
1	14.63
2	13.69
3	14.27
4	14.58

Table 1: % PEGMA grafted on PVC at 60 kGy, 70°C, 8% (v/v) PEGMA in H₂O, and 5 h reaction time.

Figure 1 shows that in PVC-g-AAc more PEGMA is grafted than on PVC alone (table 1).

Figure 1: PEGMA graft on PVC-g-AAc at 60 kGy, 70°C, 8% (v/v) PEGMA in H₂O, and 5 h reaction time.

Figure 2 shows that more AAc is grafted on PVC-g-PEGMA than on PVC alone.

Figure 2: % AAc grafted on PVC (□) and PVC-g-PEGMA (◇) at 5 kGy, 80°C, 50% (v/v) AAc in H₂O

Figure 3 shows that grafted PVC catheters (AAc and AAc/PEGMA) present a critical pH response to changes in pH when swelling.

Figure 3: Maximum swelling as a function of pH for PVC-g-AAc(25%) (●) and [PVC-g-AAc(27%)]-g-PEGMA(28%) (◇)

CONCLUSION

The binary graft of PVC catheters is possible through the use of ionizing radiation, giving the catheter the ability to respond to changes in pH. The grafting of PVC is significantly higher when previously grafted with PEGMA or AAc.

christophe.helary@upmc.fr

INTRODUCTION

Cutaneous chronic wounds are characterized by an impaired wound healing after 6 weeks. In some cases, the absence of wound closure leads to infection and amputation. Current treatments are negative pressure therapy or application of wound dressings¹. To date, no ideal treatment is available. Nowadays, research orientation is towards medicated dressings for drug delivery of biomolecules. Collagen-based biomaterials are broadly used to treat chronic wounds as collagen is biocompatible, biodegradable and favors wound healing. Nevertheless, collagen hydrogels are poor drug delivery systems since the drug content is usually released within a few minutes². Hence, the combination of collagen with a drug delivery system is required to control and delay the release. In this study, silica nanoparticles/collagen nanocomposites have been evaluated as novel drug delivery systems for controlled release of antibiotics.

EXPERIMENTAL METHODS

Gentamycin, an antibiotic targeting gram positive and gram negative bacteria, has been encapsulated within plain silica nanoparticles (SiNPs) of various sizes (100, 300 and 500 nm) using a single step procedure. Particles presenting the best loading ability were selected. Subsequently, increasing doses of loaded SiNPs were immobilized within concentrated collagen hydrogels at 5 mg/mL. Structure was analyzed by scanning (SEM) and transmission electronic microscopy (TEM), mechanical properties of composites were assessed by rheological measurements. Biological activity of gentamycin, released from nanocomposites, was evaluated on *Pseudomonas Auriginosa*. Using a standard curve, antibiograms allowed for the quantification of released doses of gentamycin from materials. In parallel, cytotoxicity of nanocomposites was studied over 7 days using Alamar blue test.

RESULTS AND DISCUSSION

Fig1: Structure of SiNP/collagen nanocomposites with 250 mM SiNP observed in SEM (A) and TEM (B).

Silica nanoparticles of 500 nm in diameter presented the best loading capacity with 600 μg of gentamycin per SiNPs gram. Gentamycin-loaded 500 nm particles could be immobilized at high silica dose (from 250 mM to 1M) in concentrated collagen hydrogels without modifying their fibrillar structure (Figure 1) or impacting on their biomechanical behavior. Gentamycin release from the nanocomposites was sustained over 7 days, offering an unparalleled prolonged antibacterial activity on *Pseudomonas aeruginosa* (Figure 2). The drug release kinetic exhibited a linear profile without any initial burst. Particles immobilization within collagen hydrogels was not associated with any toxicity towards fibroblasts as cell viability was maximal despite the high SiNPs doses used. The drug release seemed to rely on the slow and low dissolution of SiNP, this avoids toxic effects.

Fig2: Cumulative doses of gentamycin released from collagen/ silica nanocomposites at different SiNP concentrations.

CONCLUSION

Our study shows that collagen/SiNP nanocomposites allow for the sustained release of gentamycin over one week. Hence, these materials could be used as medicated wound dressing to prevent infection in the wound bed of chronic wounds. Nanocomposites associate a drug delivery system with a collagen bulk which has interesting properties in wound healing.

Fibroin reinforced calcium phosphate cement

Martha Geffers, Jürgen Groll, Uwe Gbureck

Department of Functional Materials in Medicine and Dentistry, University of Würzburg, Germany

martha.geffers@fmz-uni.wuerzburg.de

INTRODUCTION

The major advantage of brushite ($\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$) forming calcium phosphate cement is the high solubility under physiological conditions. This results in a rapid resorption and bone remodeling *in vivo*.¹ One disadvantage of this system is their brittle character. An opportunity to solve this problem is the combination of the CPC and a second material with better fracture behaviour properties such as polymers with a higher elasticity and fracture toughness. For example the work of fracture could be improved by more than one order of magnitude for a hydroxyapatite (HA)/2-hydroxyethylmethacrylate (HEMA) composite.² Since HEMA could not be resorbed *in vivo*, the reinforcement of brushite forming CPC was done in this study with the resorbable biopolymer fibroin, which is the main compound of the silk spun by the silk worm *Bombyx mori*.³

EXPERIMENTAL METHODS

Brushite cements were produced by mixing β -tricalcium phosphate (TCP) powder in an equimolar ratio with dicalcium phosphate anhydrous ($\text{Ca}(\text{H}_2\text{PO}_4)_2$, MCPM).¹ Fibroin was incorporated in the CPC/fibroin composite as non-woven or aqueous solution. First the silk cocoons were boiled in alkaline solution (0.02 M Na_2CO_3) to remove the sericin coating. For the non-woven the washed fibroin fibres were pulled in one direction to get an isotropic orientation. Subsequently the non-woven was embedded in the CPC paste. The aqueous solution was done by dissolving the washed fibres in 9 M lithium bromide and dialyzed against water. Afterwards the solution was added to the CPC powder as the liquid cement phase in a powder to liquid ratio of 1 g/ml. The fibroin concentration within the aqueous solution was analyzed by UV/Vis at 280 nm (approx. 4 w/v-%). The mechanical properties were measured by 4 point bending and compressive test. The morphology was analyzed by scanning electron microscopy (SEM). The phase composition was identified by Fourier transform infrared spectroscopy (FTIR) and X-ray diffraction (XRD).

RESULTS AND DISCUSSION

By the reinforcement of brushite cement with a non-woven fibroin fibre the bending strength could be doubled (Figure 1a). According to the test set up these composites could not load until their total fracture (Figure 1c) and the broken cement fractures were hold together by the fibres. These are promising results for *in vivo* studies since the cracks provide channels in the implant where angiogenesis and bone remodelling may take place.

The combination of the CPC raw powder and the aqueous fibroin solution results in a dual setting system

with both setting reactions running parallel and building up interconnective matrices (Figure 1f). The FT-IR and XRD measurements indicate that the water in the fibroin solution dissolves the CPC raw powder, meanwhile the released phosphates induce the β -sheet formation and gelation of the fibroin solution.

Figure 1: Stress-strain-diagram of exemplary brushite reference and fibroin fibre reinforced brushite (a) or brushite/aq. fibroin solution composites (b); image of these samples after their testing (c & d) and SEM images of their fracture surfaces (e & f).

During the mechanical test the composite samples are compressed until ~50 % without any cracking (Figure 1b & d).

CONCLUSION

The combination of two resorbable material show promising results for CPCs with improved fracture behaviour. For further enhancement the fibroin solution might be higher concentrated and a higher PLR could be used. Additionally other parameters are supposable for prospective new application fields: For example the encapsulation of biological agents or even cells in the fibroin solution to protect them during the acid setting reaction of brushite.

Influence of heat treatment and additives of alkali substituted calcium phosphate cements on their properties

Martha Geffers, Laura Straub, Jürgen Groll, Uwe Gbureck

Department of Functional Materials in Medicine and Dentistry, University of Würzburg, Germany

martha.geffers@fmz-uni.wuerzburg.de

INTRODUCTION

Alkali substituted calcium phosphate cements like calcium potassium sodium phosphate ($\text{Ca}_2\text{KNa}(\text{PO}_4)_2$) are of high interest as bone substitutes due to their higher solubility and hence resorption ability compared to normal apatites.¹ According to previous studies, they show better osteoconductivity² as well as antibacterial potency³. However, there are many differences published in the properties of these cement types like the phase composition after setting and the mechanical properties. Berger *et al.* observed no hydroxyapatite (HA) formation by cement setting⁴, whereby Gbureck *et al.* identified HA by X-ray diffraction (XRD) measurements³. One main difference of the cement manufacturing is the temperature treatment of the cement raw powders. Berger *et al.* processed molten powders above 1550 °C⁵. In contrast Gbureck *et al.* sintered it at 1050 °C³. Furthermore Berger *et al.* used additives like SiO_2 and MgO. In this study we analyzed in a systematically way the influence of the heat treatment and the additives on the cement properties of alkali substituted calcium phosphates.

EXPERIMENTAL METHODS

The $\text{Ca}_2\text{KNa}(\text{PO}_4)_2$ powders were synthesized by heating a mixture of monetite, potassium carbonate and sodium carbonate in a molar ratio of 4:1:1 with the addition of 3 – 12 wt.-% silicon dioxide or 3 – 6 wt.-% magnesium oxide for 24 h to 1050 °C or for 2 h above 1550 °C. The received powder cake was crushed and milled for 24 h. The particle size was measured by laser light scattering. The powders were mixed with water, 2.5 wt.-% Na_2HPO_4 solution or monocalcium phosphate (MCPA) and 0.1 M citric acid. Setting pH and time were studied. XRD-measurements were done with raw powders and set cements. The mechanical properties were analysed by compressive test. For visual observation SEM images were taken.

RESULTS AND DISCUSSION

The particle sizes for all raw powders were about $1.5 \pm 0.3 \mu\text{m}$ after mechanical activation by milling. $\text{Ca}_2\text{KNa}(\text{PO}_4)_2$ showed the typically XRD-pattern, which is known from literature⁵ (Figure 1: 0 % MgO). HA is formed with water or 2.5 wt.-% Na_2HPO_4 solution at low additive concentrations independent on the process temperature (Figure 1: 0 & 3 % MgO). This is in contrast to the observations of Berger *et al.*⁴. Interestingly all raw powders show a shift to β -tricalcium phosphate (β -TCP) with an increasing additive content (Figure 1: 3 & 6 % MgO). These cements set with 0.1 M citric acid and MCPA under acid conditions and transform into brushite. With an increasing additive content the setting time increased, whereas SiO_2 and MgO worked as a retarding agent in the setting reaction. Furthermore the conversion rate

decreased and the raw powders were still present in a high amount.

Figure 1: XRD-Pattern of $\text{Ca}_2\text{KNa}(\text{PO}_4)_2 + 0, 3, 6 \text{ wt.}\% \text{ MgO}$: sintered at 1050 °C (a) and set with 2.5 wt.-% Na_2HPO_4 solution (b) or melt at 1550 °C (c) and set with 2.5 wt.-% Na_2HPO_4 solution (d).

$\text{Ca}_2\text{KNa}(\text{PO}_4)_2$ set at an alkaline pH value, whereby the setting pH is highly influenced by the liquid cement phase. All cements showed low compressive strength values in a range between 0.3 and 3.7 MPa after 24 h setting, whereby the strength decreased with increasing additive concentration. This could be related to the decreasing conversion rate. There is no significant difference between the 1050 °C and the 1500 °C cements.

CONCLUSION

All measurements did not show significant differences between the results of the sintering at 1050 °C and melting at 1550 °C. This indicates that the discrepancy in the published results must be influenced by other parameters for example the sample preparation conditions. A promising observation is the phase composition change of the raw powders with an increasing content of SiO_2 or MgO. Here it would be very interesting to rise up the additive concentration for further experiments.

Development of an in situ culture-free screening test for the rapid detection of *Staphylococcus aureus* within healthcare environments

Adam Le Gresley¹, Alex Sinclair¹, Lauren E. Mulcahy², Lynsey Geldeard¹, Samerah Malik¹ and Mark D. Fielder²

¹Pharmacy and Chemistry, SEC, Kingston University, UK a.legresley@kingston.ac.uk

²Life Sciences, SEC, Kingston University, UK,

INTRODUCTION

Staphylococcus aureus (SA) infections are a significant problem within hospitals worldwide. In Europe alone, around 7% of all patients develop healthcare acquired infections and this is estimated to cost up to £11bn annually to diagnose and treat. Epidemiology suggests that up to 30% of the UK population are carriers of SA, currently UK hospitals only screen surgical patients.¹ It has been predicted that for an in-patient cohort of 70 000, cost savings of ~£600k could be achieved; along with the potential avoidance of 840 hospital acquired infections through the use of a routine pre-screen and treat strategy.² Current clinical detection methods for SA are limited by sensitivity. In all current detection methods, amplification of bacterial numbers via culturing or amplification of characteristic DNA via PCR are utilised for the detection of SA.²

EXPERIMENTAL METHODS

1. Synthesis of prototype fluorescent probe LGX (3)

Scheme 1 (a) HO-Arg(Cbz)₂NHBoc, EDCl, pyridine, DMF, 18%. (b) TFA, DCM, 94%. (c) HO-Pro-Val-NHBoc, COMU, NEt₃, DMF, 14%. (d) H₂, Pd/C, MeOH, DMF, 77%.

2. Biological Testing of LGX

Screening was carried out involving 15 clinical isolates of MRSA. These were cultured on nutrient agar overnight at 37 °C. Discrete colonies of each isolate were tested for coagulase activity using a staphylase test kit (Oxoid), and each MRSA isolate was shown to be coagulase positive. Following this, an inoculum of each respective sample was cultured overnight in nutrient broth under aerobic, shaking conditions at 37 °C. Each sample was washed in sterile 1 × phosphate buffered saline (PBS) and varying concentrations of bacterial suspension, ranging from 10⁰ to 10⁶ colony forming units per mL (CFU mL⁻¹) were generated by serial dilution in 1 × PBS. Solutions of 50 µM and 100 µM LGX were prepared aseptically. In order to detect the presence of staphylocoagulase and thus the efficacy of LGX, varying cell concentrations (10⁰–10⁶ CFU mL⁻¹) (50 µM LGX) and 10⁰–10⁴ CFU mL⁻¹ (100 µM LGX) were added to a microtitre plate (Nunc 96 well plates) in a 1 : 1 ratio with either 50 µM or 100 µM of LGX solution. This provided a final LGX concentration of 25 µM or 50 µM, respectively.

RESULTS AND DISCUSSION

Fig. 1 demonstrates the efficacy of LGX as both a selective and sensitive means of determining the presence of coagulase positive bacteria. As previously described, all bacterial strains were assessed for coagulase activity, and the coagulase status of each bacterium juxtaposed with the results demonstrated in this experiment

Figure 1. The efficacy of 50 µM LGX in demonstrating both selectivity and sensitivity in detecting coagulase positive MRSA and MSSA, compared to coagulase negative *S. epidermidis* and *E. coli* at concentrations of 10³ CFU mL⁻¹. Average of fifteen bacterial strains (n = 3). Error bars represent standard deviation.

CONCLUSION

We have developed a novel, selective fluorogenic assay, which obviates the need for time consuming culturing or genetic amplification, currently core to most hospital SA tests. Our test has proved itself to be rapid, presently giving a preliminary positive/ negative result within 30 minutes for bacterial concentrations commonly found on skin (>10² CFU mL⁻¹). The testing methodology described within this paper is currently undergoing further biological screening within our labs and work is ongoing towards the development of a rapid point-of-care testkit.³

INTRODUCTION

The anti-microbial properties of noble metals have been known since ancient times. The new technology allows obtaining metal particles with programmed size and shape. Gold and silver nanoparticles have been employed for various bio-medical applications (1, 2, 3). In our study we developed the method of obtaining gold and silver nanoparticles with different shape. The nanoparticles are to be incorporated into the cryogel, which provides an ideal antimicrobial micro-environment for effective wound healing.

EXPERIMENTAL METHODS

Silver nanoparticles have been synthesized using sodium borohydride reduction of silver nitrate. The synthesis of gold nanoparticles for this method has been realized through Turkevich method (4). Turkevich method has been known as one of the oldest and most popular procedures for obtaining gold nanoparticles of 10-15 nm diameters in the water. Produced silver nanoparticles and gold nanoparticles were imaged by Tunnelling Electron Microscopy (TEM) and Scanning Electron Microscopy (SEM).

RESULTS AND DISCUSSION

Initially we have developed several methods for synthesizing gold and silver nanoparticles of varying shapes and sizes. We have achieved production of triangular and circular nanostructures made of noble metals. We do hypothesize that shape of the particle affects its anti-microbial properties.

As a second step, experiments for conjugating the metal nanoparticles to the surface of cryogel have been conducted. It has been achieved through formation of strong covalent bonding between gold nanoparticles and cysteamine. By following cysteamine functionalization to gold nanoparticles surface, we were able to form NH₂ bond sticking out of the surface. This was done in order to make sure that the nanoparticles are well attached and do not get detached from the surface.

Figure 1. SEM image Attached gold nanoparticles on the surface of a cryogel.

Figure 2. SEM image Aggregated gold nanoparticles on the surface of a cryogel.

CONCLUSION

The manufacturing of several types of nanoparticles with programmed shape and size (made of noble metals) has been established. The form of particles has been confirmed by SEM and TEM imaging. Produced nanoparticles were attached to the surface of cryogel by forming bonds between cysteamine and noble metals. The obtained composition ‘metal-cryogel’ provides a perfect foundation for developing new type of wound dressings. The noble metals ensure an anti-microbial effect, whilst macro- and mesoporous structures of the cryogel provide an optimal environment for the process of wound healing by absorbing exudate and debriding the wound.

Precision patterning of gelatin protein fibrils was achieved using near-field electrospinning (NFES). These fibrils were employed as an image cytometry assay testing the drug effectiveness against early stages of endothelial capillary formation.

INTRODUCTION

Cellular behavior is strongly influenced by the architecture and pattern of its interfacing extracellular matrix (ECM). For an artificial culture system which could eventually benefit the translation of scientific findings into therapeutic development, the system should capture the key characteristics of a physiological microenvironment. At the same time, it should also enable standardized, high throughput data acquisition. Since an ECM is composed of different fibrous proteins, studying cellular interaction with individual fibrils will be of physiological relevance.

EXPERIMENTAL METHODS

We employ near-field electrospinning^{1,2} to create ordered patterns of collagenous fibrils of gelatin, based on an acetic acid and ethyl acetate aqueous co-solvent system. Using these fibril constructs as cellular assays, we study EA.hy926 endothelial cells' response to ROCK inhibition (H1152)², because of ROCK's key role in the regulation of cell shape.

RESULTS AND DISCUSSION

Tunable conformations of micro-fibrils were directly deposited onto soft polymeric substrates in a single step. We observe that global topographical features of straight lines, beads-on-strings, and curls are dictated by solution conductivity (see Figure 1); whereas the finer details such as the fiber cross-sectional profile are tuned by solution viscosity.

The fibril array was shown to modulate the cellular morphology towards a pre-capillary cord-like phenotype, which was otherwise not observed on a flat 2-D substrate. Further facilitated by quantitative analysis of morphological parameters, the fibril platform also provides better dissection in the cells' response to a H1152 ROCK inhibitor.

Figure1

CONCLUSION

In conclusion, the near-field electrospun fibril constructs provide a more physiologically-relevant platform compared to a featureless 2-D surface, and simultaneously permit statistical single-cell image cytometry using conventional microscopy systems. The patterning approach described here is also expected to form the basics for depositing other protein fibrils, seen among potential applications as culture platforms for drug screening.

INTRODUCTION

Titanium and its alloys have been used widely as biomaterials for orthopaedic implants because of their excellent mechanical properties and biocompatibility. Despite the major research efforts in the field of osseointegrative materials, there are situations where this effect should be suppressed, for example when these alloys are employed in bone plates/screws which are removed after recovery. The purpose of the present study was to synthesise bioactive TiO₂ film and bioinert TiO₂-ZrO₂ film on pure Ti surfaces by a combined chemical-hydrothermal treatment¹. In addition, *in vivo* bone conduction in the tibiae of rats was also investigated.

EXPERIMENTAL METHODS

Commercial purity (CP-) Ti rods, 2 mm in diameter and 5 mm in height, were chemically treated with aqueous 5 M H₂O₂/0.1 M HNO₃ at 353 K for 20 min. The rods were hydrothermally treated with 1M NH₃ or 100 mM ZrOCl₂/5 M NH₃/400 mM C₆H₈O₇ (citric acid) aqueous solution in a Teflon-lined autoclave at 453 K for 12 h. The rods were implanted into tibiae of eight-week-old rats. After two weeks, the peripheral sections were extracted. Tissues embedded in polymer were cut and polished and the contact ratio between bone and implant was measured by using optical microscopy. The interfaces between the implants and cured bone were observed by transmission electron microscope (TEM).

RESULTS AND DISCUSSION

The Ti is uniformly covered by a film showing a sponge-like morphology after chemical treatment with aqueous H₂O₂/HNO₃¹. The film is anatase-type TiO₂ with very low crystallinity (TiO₂ gel)¹. The morphology of film changed dramatically as a result of the hydrothermal treatments. The surfaces of Ti were covered with cube crystals and the average sizes were measured to be 40 nm and 10 nm or less in the treatments with NH₃ and ZrOCl₂/NH₃/C₆H₈O₇ aqueous solution, respectively. Both films were anatase-type TiO₂ but the latter included a small amount of ZrO₂.

In the animal test, the bone-implant contact ratio, R_{B-I} , was calculated by following equation in order to evaluate bone conductivity.

$$R_{B-I}(\%) = \frac{\text{total length of hard tissue formation on implant}}{\text{total length of implant}} \times 100$$

Figure 1 shows contact ratios for cortical bone in the surface modified implants. Bone conduction was drastically improved on the TiO₂ film from that on the CP-Ti. In contrast, it was suppressed on the TiO₂-ZrO₂ film from the TiO₂. Apatite formation in simulated body

fluid was also reported to be promoted on TiO₂¹ but suppressed on TiO₂-ZrO₂². In addition, the TiO₂ film showed an adhesive interface to living bone (Fig. 2), but the TiO₂-ZrO₂ film always separated from it. Therefore, the present surface modifications have considerable potential for controlling direct bonding to living bone.

Fig.1 Contact ratios for cortical bone on the surface modified implants.

Fig. 2 TEM image of the interface between TiO₂ coated implant and living bone.

CONCLUSION

1. TiO₂ film or TiO₂-ZrO₂ composite film could be synthesised on CP-Ti surfaces by the hydrothermal treatment with NH₃ or ZrOCl₂/NH₃/C₆H₈O₇ (citric acid) aqueous solution, respectively.
2. Bone conduction was promoted on TiO₂ film but suppressed on TiO₂-ZrO₂ film. Therefore, this method has a potential for Ti alloys to control bone conduction and adherence to living bone.

INTRODUCTION

Electrospinning as well as inkjet printing has emerged as a useful tools for creating spatially organized materials for tissue engineering¹. Electrospun nanofibrous scaffolds are aimed to mimic the architecture and biological functions of the extra-cellular matrix (ECM). By incorporating conductive material (PANi) and bioactive particles (HAp) into an electrospun scaffold we have formed a bioactive, hybrid scaffold system, which provides an electrically conductive environment. Combination of electrospun, biodegradable scaffolds with conductive polymers in the future would enable us (by the use of controlled electrochemical signals) to stimulate a multitude of cellular functions.

The aim of this work was to investigate the effect of inkjet printing on the properties of obtained scaffolds but also the effect of deposited conductive polymer on the attachment, proliferation, migration, and differentiation of bone cells.

EXPERIMENTAL METHODS

Electrospinning was carried out using custom-made apparatus consisting of a power supply, syringe and electrodes. The solution were placed in a 20 ml plastic syringe with a stainless-steel blunt needle of 0.7 mm in diameter. The solutions were spun at a working distance of 20 cm with a driving force of 30 kV. Conductive polymers were deposited on the surface of electrospun membranes using piezoelectric material printer DMP-2831. The complex structure of the scaffolds and their chemistry were characterized using SEM, FTIR, and WAXD. The nanocomposite scaffolds were also characterized in terms of their porosity, mechanical properties and bioactivity, and by in-vitro cellular tests using NHOst cells. Mineralization process and ALP activity were studied to estimate the cells differentiation.

RESULTS AND DISCUSSION

Ink-jet printing enables to obtain regular patterns on the fibrous support (Fig 1). We have noticed that due to the hydrophobic nature of electrospun material the printing was limited to the outer layer of nonwoven support.

Fig. 1. (a) Piezoelectric material printer DMP-2831; (b-c) pattern printed on the electrospun material;

Our experimental data demonstrate that electrospun PCL/nHAp/PANi scaffolds are biocompatible, supporting attachment, migration, and proliferation of NHOst cells (Fig. 2 and 3).

Fig. 2. Morphology of cells cultured on PCL/n-HAp/PANi scaffolds.

Fig. 3. SEM images of NHOst cells cultured on the PCL/n-HAp/PANi scaffolds.

CONCLUSION

PANi micropatterns were successfully inkjet printed on PCL/n-HAp membranes; Presence of PANi did not affect cell proliferation; Further studies will focus on cell stimulation by controlled electrochemical signals. The greater cell proliferation upon electrical stimulation is expected.

Chelate Bonding Mechanism of a Novel Magnesium Phosphate Bone Cement

Theresa Christel¹, Martha Geffers¹, Susanne Christ¹, Jürgen Groll¹ and Uwe Gbureck^{1*}

¹Department for Functional Materials in Medicine and Dentistry, University of Würzburg, Germany

*uwe.gbureck@fmz.uni-wuerzburg.de

INTRODUCTION

Magnesium phosphates have comparable characteristics to calcium phosphate bone substitutes, but degrade faster under physiological conditions. Farringtonite ($\text{Mg}_3(\text{PO})_4$), for example, is known to set with an aqueous $(\text{NH}_4)_2\text{HPO}_4$ solution to form struvite ($\text{MgNH}_4\text{HPO}_4 \cdot 6\text{H}_2\text{O}$) monolith which is naturally found in the calcifications of kidney stones¹. In the present study, an alternative setting mechanism of this magnesium phosphate cement was tested by replacing $(\text{NH}_4)_2\text{HPO}_4$ with phytic acid ($\text{C}_6\text{H}_{18}\text{O}_{24}\text{P}_6$). The latter is a strong chelating agent for Mg^{2+} and Ca^{2+} ions and is assumed to form stable complexes with the cement raw material.

EXPERIMENTAL METHODS

0.6 mol $\text{MgHPO}_4 \cdot 3\text{H}_2\text{O}$ and 0.3 mol $\text{Mg}(\text{OH})_2$ were sintered for 5 h at 1050 °C in a sintering furnace. The resulting $\text{Mg}_3(\text{PO})_4$ was sieved < 355 µm and milled in a planetary ball mill for 1 h at 200 rpm. $\text{Mg}_3(\text{PO})_4$ was mixed with 10, 20 or 30 % phytic acid in a powder-to-liquid-ratio (PLR) of 3.0 g/mL. The paste was transferred into silicon rubber molds (12x6x6 mm) and stored for 24 h at 100 % humidity and 37 °C. The compressive strength of these cuboids was measured by universal testing machine using a crosshead speed of 1 mm/min. The fractions were crushed and analyzed by X-ray diffractometry and infrared spectrometry. Furthermore, the development of the pH of the cement paste was analyzed during the first half hour of setting. Analysis of variance was examined by applying the Dunett's test by means of the excel sheet inerSTAT-a (M.H.Vargas, Instituto Nacional de Enfermedades, Mexico).

RESULTS AND DISCUSSION

The hardened cements had a compressive strength up to 64 ± 9 MPa (Fig. 1a). Infrared spectra showed a slight shift of the P=O valence vibration from 1635 to at least 1650 cm^{-1} (Fig. 1b) which implies a successful chelation. In addition, a little phase transformation took place from struvite to newberyite ($\text{MgHPO}_4 \cdot 3\text{H}_2\text{O}$) according to the recorded X-ray diffractometry spectra. The cement paste had a pH minimum of about 3.7 for 30 % phytic acid during the examined time period.

The performance of this chelating process by means of phytic acid was earlier approved on calcium containing phosphate formulations². The high compressive strength values in this study are comparable to those of the conventional magnesium phosphate cement setting reaction¹ and are not affected by the chelation mechanism. The novel cement system even combines the conventional cement setting with the novel

approach. The formation of newberyite out of farringtonite is already shown in literature and results from the acidic conditions, but those harden with worse mechanical properties³. As expected, the pH of the cement paste was low during setting reaction, but comparable to that of brushite cements ($\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$)⁴. However, the latter is already commercially available for bone substitution applications⁵.

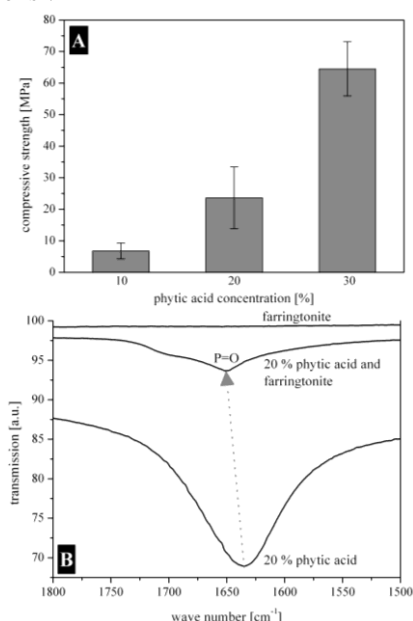

Fig. 1: Compressive strength of hardened samples with $\text{Mg}_3(\text{PO})_4$ and differently concentrated phytic acid solutions in a PLR of 3.0 g/mL after 24 h of setting. All the results differ significantly ($p < 0.01$) (a). Infrared spectra of $\text{Mg}_3(\text{PO})_4$, 20 % phytic acid and a mixture of both (b).

CONCLUSION

A novel approach to harden magnesium phosphate cements was successfully presented by combining chelation with a conventional setting reaction. Further characterization showed that this material composition development seems to be promising.

INTRODUCTION

Magnesium phosphate compounds, as for example struvite ($\text{MgNH}_4\text{HPO}_4 \cdot 6\text{H}_2\text{O}$), are comparable to calcium phosphate bone substitutes, but degrade faster under physiological conditions. In the present work, we used a calcium doped magnesium phosphate with the general formula $\text{Ca}_x\text{Mg}_{(3-x)}(\text{PO}_4)_2$ ($x=0.75, 1.0$ or 1.5) to set with $(\text{NH}_4)\text{HPO}_4$ solution and form struvite¹. The paste can be dispersed in a hydrophobic phase and stabilized as small droplets by surfactants until it hardens by cement setting. The resulting spherical granules (Fig. 1a) are suitable for applications in maxillofacial surgery (e.g. sinus floor augmentation). The problem with hydraulic cement pastes to form granules <1 mm by emulsification is their tendency to coalesce². The present study was aimed to fabricate small granules by the right choice of composition of the $(\text{NH}_4)\text{HPO}_4$ containing solution in the struvite forming cement paste and to show their biological properties.

EXPERIMENTAL METHODS

$\text{Ca}_x\text{Mg}_{(3-x)}(\text{PO}_4)_2$ was prepared by sintering $\text{MgHPO}_4 \cdot 3\text{H}_2\text{O}$, $\text{Mg}(\text{OH})_2$, CaHPO_4 and CaCO_3 for 5 h at 1100 °C in a furnace. The product (< 355 µm) was milled in a planetary ball mill for 4 h at 200 rpm. The powder was mixed with a 2.0 M $(\text{NH}_4)\text{HPO}_4/1.5$ M $\text{NH}_4\text{H}_2\text{PO}_4$ solution in a powder-to-liquid-ratio of 2.0 g/mL. This paste formed small granules < 1 mm via emulsification process. The paste was transferred into disc-shaped silicon rubber molds (15x2 mm) and stored for 24 h at 100 % humidity and 37 °C, washed in phosphate buffered solution for 14 d and disinfected in 70 % ethanol. Human fetal osteoblast cell line (hFOB) was seeded on the cement samples with a density of 100,000 cells/mL. After 4, 6 and 10 d, the cells were counted by means of Trypan blue and their activity was determined by the cell proliferation agent WST-1. Reference surfaces were both polystyrene (PS) and hydroxyapatite (HA). To analyze their passive solubility, the samples were also put in cell culture medium without hFOB and incubated for 10 d. The accumulated PO_4^{3-} , Mg^{2+} and Ca^{2+} content of the used media was measured by mass spectrometry.

RESULTS AND DISCUSSION

The cell activity of hFOB on the cement composition leading to an optimum granule size is exemplarily shown with the $\text{Ca}_{0.75}\text{Mg}_{2.25}(\text{PO}_4)_2$ formulation (Fig. 1b). The normalized activity per cell for the struvite samples remained constant during the culture period of 10 d. Cell activities were comparable to those on PS on day 4 and 6 and partially even higher than

those on HA. During the same period, a more than three times higher PO_4^{3-} content was detected in the medium released by struvite compared to HA. Simultaneously, no Mg^{2+} ions were released by HA, but more Ca^{2+} ions were detracted by the latter material.

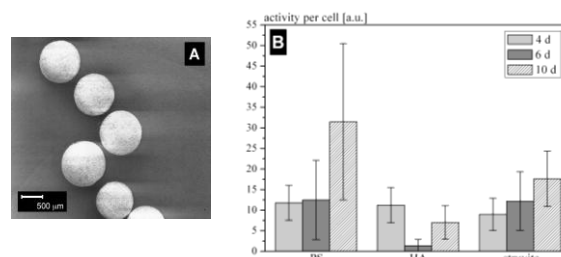

Fig. 1: Scanning electron micrograph of granules prepared by emulsification (a) and activity per cell on different surfaces for 4, 6 and 10 d. Struvite samples were made of $\text{Ca}_{0.75}\text{Mg}_{2.25}(\text{PO}_4)_2$ and 2.0 M $(\text{NH}_4)\text{HPO}_4/1.5$ M $\text{NH}_4\text{H}_2\text{PO}_4$ solution (b).

Both Mg^{2+} and Ca^{2+} promote proliferation and differentiation of osteoblasts and play an important role concerning bone deposition and mineralization³. The analyzed struvite samples favor the presence of both ion types in the cellular environment. The biocompatibility of struvite based mineral systems is already proved *in vitro*¹ and *in vivo*⁴, but the additional benefit of our system is its ability to be granulated via emulsification process and to build granules <1 mm.

CONCLUSION

We found an effective method to granulate a struvite based cement paste and verified the biocompatibility of the used formulation. Further experiments will focus on detailed bio(-chemical) studies concerning both the expression of genes and proteins and the active resorption of our surfaces by osteoclastic cells.

Study and design of RGD-Self-assembling peptide hydrogels

Deidda Graziano,^{1,2} Mitraki Anna,^{1,2}
Graziano Deidda: grazianodeidda@gmail.com,

¹Materials Science Department, University of Crete, Heraklion, Crete, Greece,

²Institute of Electronic Structures and Lasers, Foundation for Research and Technology-Hellas (IESL-FORTH), Heraklion, Crete, Greece

INTRODUCTION

In the last decade, the development of peptide-derived 3D hydrogels and their use as scaffolds for cell attachment and proliferation has attracted lots of attention.³ In this work, we designed and characterized peptides comprising a natural self-assembling peptide building block together with a RGD integrin-binding motif. Moreover, we designed bifunctional building blocks carrying cysteine residues, a central self-assembling core, and an RGD motif. We have been evaluating the structure and self-assembly propensity of these peptides. These self assembling peptide materials will be targeted as scaffolds for angiogenesis in ischemic *in vitro* models.

EXPERIMENTAL METHODS

Six different RGD self-assembling peptides were tested for the ability to self-assemble in physiological solvents. Different microscopy techniques were utilized to monitor the kinetics of assembly and morphology of the assembled fibrils: Transmission Electron Microscopy (JEOL JEM-2100 TEM), Scanning Electron Microscopy (Field Emission JEOL JSM 7000F SEM) and Atomic Force Microscopy (AFM).

RESULTS AND DISCUSSION

The images collected from the aforementioned techniques (Fig. 1,2 and 3) demonstrated that all the designed RGD self-assembling peptides showed a distinct tendency to form porous networks of interconnected fibrils. Most of them form self-supporting hydrogels. The position of the RGD motif at the C-terminus or at the N-terminus and the presence or the absence of a cysteine residue seems to play an important role in self-assembly. Future experiments will focus on the identification of the most suitable candidate peptides for developing cell-recruiting fibrils.

Figure 1: TEM analysis highlighted how thin fibers could form spontaneously after being suspended for 6 hours.

Figure 2: AFM analysis showed clearly fibril formation in most of the peptides.

Figure 3: SEM images showed that most of the peptides could afford a dense, interconnected 3D web of fibers.

CONCLUSION

All the designed peptides are appropriate building blocks for the construction of higher order biological structures. Our long-term goal is to develop bifunctional scaffolds that will allow cell attachment and proliferation and could be simultaneously functionalized with angiogenesis signalling molecules through the cysteine residues. Such functionalized scaffolds will be tested for angiogenesis in ischemic *in vitro* models. The RGD-exposure geometry will also play a crucial role to guarantee these features.⁴

Structure and Properties Study of Calcium Apatites

Y. Gao¹, R.V. Law^{1*}, N. Karpukhina², R.G. Hill²

¹Department of Chemistry, Imperial College London, UK

²Dental Physical Sciences/Institute of Dentistry, Queen Mary University of London, UK

yajie.gao11@imperial.ac.uk

INTRODUCTION

Calcium apatite is the basis for a multiplicity of inorganic solids important in geology and materials science[1]. As we know, hydroxyapatite (HA; $\text{Ca}_5(\text{PO}_4)_3\text{OH}$) is the main mineral component of human dental enamel and bone, and can react readily undergo fluoride substitution from solutions to form fluoride-substituted hydroxyapatite or hydroxyfluorapatite (HFA) $\text{Ca}_{10}(\text{PO}_4)_6\text{F}_{2x}(\text{OH})_{2-2x}$ ($0 < x < 1$). However, the different proportions of fluoride in fluoride-substituted hydroxyapatite may cause difference solubility and thermal stability. It is difficult to quantify fluoride substitution in hydroxyapatites using X-ray diffraction; this is because the patterns are very similar, as these apatites are isostructural [2]. High-resolution solid state nuclear magnetic resonance (NMR) is a sensitive local probe of atomic and molecular structure, which can be used to determine oxygen/fluorine ordering in the structure of calcium apatite. The quantitative and qualitative structural information of calcium apatites can be obtained by ^1H , ^{19}F and ^{31}P NMR spectra[3]. Lots of efforts and achievements have been made in apatite science[4]; however, the fine structural details are still not available.

EXPERIMENTAL METHODS

Various calcium apatites, HA and HFA, have been synthesised by both solution route and solid-state reaction methods[5] followed by heating in air at different temperatures. The various experimental techniques, like solid-state nuclear magnetic resonance (NMR), X-ray diffraction (XRD), differential scanning calorimetry (DSC), Fourier transform infrared spectroscopy (FTIR) and Scanning electron microscopy with energy dispersive X-ray spectroscopy (SEM/EDX), were used to characterise the synthesised powder samples

RESULTS AND DISCUSSION

FTIR spectra show PO_4 ν_4 , PO_4 ν_1 and PO_4 ν_3 bands in all of the samples; wet and dried samples contained a CO_3 ν_3 band, which disappeared after heat treatment. The XRD pattern indicates that two phases are formed

in HFA heat treatment samples. All of the samples have single ^{31}P resonance at 2.8ppm corresponding to phosphorus in an orthophosphate environment (PO_4^{3-}). From ^{19}F NMR spectra, the signals are observed in the range from -102ppm to -106ppm depending on degree of the fluoride substitution in HFA and water absorbed by the sample. The implications of these multiple ^{19}F NMR signals and how it can be related to the apatite structure will be discussed.

CONCLUSION

Experimental data suggest that synthetic apatite contains a small amount of carbonate which can be removed by heating samples above 873K in air. There are two phases in hydroxyfluorapatite heat treated at high temperature: tricalcium phosphate and apatite. The quantitative and qualitative structural information of calcium apatites were obtained by ^1H , ^{19}F and ^{31}P MAS NMR spectroscopy. The ^{19}F NMR results show two resonances at -104ppm and -102ppm, corresponding to the two F environments in the apatite structure after heat treatment at 1173K.

Development and study of poly(butylene succinate)/chitosan/hemp fiber fully biodegradable composites

Z. Terzopoulou¹, V. Nikolaidis¹, D. Bikiaris¹, E. Athanassiadou², E. Papadopoulou²

¹Department of Chemistry, Aristotle University of Thessaloniki, Greece

²CHIMAR HELLAS SA, Sofouli 88, 55131 Thessaloniki, Greece, terzoe@gmail.com

INTRODUCTION

The use of natural fibers to reinforce polymers is an established practice, and biocomposites have gained an increased interest in areas such as automotive, construction and agriculture¹. The purpose of the present work was the preparation and study of fully biodegradable ("green") composite materials using poly(butylene succinate) (PBSu) as polymeric matrix with hemp fibers (HF) and chitosan as fillers.

EXPERIMENTAL METHODS

Poly(butylene succinate) (PBSu)/Chitosan 90/10 and 80/20 w/w blends containing 10, 20, 35, 50 and 65wt% hemp fibers of 0.5cm length respectively were prepared by melt mixing in a Haake-Buchler Reomixer at 190°C and 35 rpm for 5 min. The polyester and the fillers were dried under vacuum prior to the melt mixing. Films of the samples were received using a hydraulic press, set at 190°C. Mechanical properties including tensile strength, elongation at break and impact strength were studied. Enzymatic degradation took place in aqueous solution in the presence of *R. Oryzae* and lysozyme in pH=7.2, at 50°C and soil degradation took place in conventional leaf soil, for 30 days. The effect of both enzymatic and soil degradation on the polymeric matrix was studied with SEM and weight loss measurements.

RESULTS AND DISCUSSION

SEM images of the composite materials revealed poor interfacial adhesion in general, though better coverage of the hemp fibers with chitosan for the PBSu/Chitosan 80/20 w/w composites. The addition of hemp fibers reduced the mechanical properties of the materials due to the fact that the natural fibers and chitosan are hydrophilic materials whereas the polyester has a hydrophobic character, which results in poor interaction between them². The better coverage of the hemp fibers in the materials with chitosan 20 wt%, as observed in Fig. 1, lead to better mechanical properties compared to the materials with chitosan 10 wt%, including tensile and impact strength.

Figure 1: SEM micrograph of PBSu/Chitosan 80/20 w/w with hemp fiber 65 wt%.

The rate of both enzymatic and soil degradation was found to be greater for the composite materials compared to neat PBSu. While neat PBSu lost only the 1.5% of its initial mass after one month, the enzymes caused greater weight loss of up to 22% for the PBSu/Chitosan 90/10 w/w HF 65wt % composite. As the concentration of the hemp fibers increases, there is an increase in the biodegradation rate. The higher degradation in the composites, in comparison with neat PBSu, can be explained by the increase of the free surface of PBSu because of the gaps between the contact surfaces of the polymer and the fillers. The higher the concentration of the hydrophilic additive, the greater the moisture absorption and swelling, which results in increasing the rate of degradation of composites. SEM micrographs revealed that as the enzymatic degradation progresses, bigger parts of the fibers are revealed due to the biodegradation of PBSu and chitosan.

PBSu lost 5% of its weight while buried in soil for one month. The composite materials showed again greater degradation rates and mass losses (up to 27%) for the same reasons mentioned above for the enzymatic degradation, plus the rich population of microorganisms in the soil that can degrade our materials. In this case though, the final weight losses for all the composites was higher compared to the hydrolysed by enzymes materials. The water intake promoted the entrance of microorganisms present in soil due to the high hydrophilicity of the composites. SEM micrographs of the soil degraded samples confirmed the results from the weight loss.

CONCLUSION

Although the addition of both Hemp fibers and chitosan in PBSu resulted in decreased mechanical properties, they accelerated the degradation rate. Larger proportion of chitosan may have caused the creation of hydrogen bonds with the polymeric matrix and the fibres, resulting in a slight enhancement of the mechanical properties in comparison with the composites with 10 wt% chitosan.

INTRODUCTION

Osteoconductivity is the ability of biomaterials to support bone formation and chemically bond to bone. Hydroxyapatite (HAp) and alpha-type alumina (α -Al₂O₃) are typical osteoconductive and non-osteoconductive biomaterials, respectively. Post-implantation, the biomaterials are immediately coated with, and subsequently adsorb, layers of proteins from blood and tissue fluids¹. Importantly, all subsequent cellular responses are dependent on the implants' ability to adsorb protein at early time points. However, a detailed mechanism of the osteoconductive process is not yet clear.

In this study, we investigated adhesion, spreading, and proliferation in response to and bovine serum albumin (BSA)-adsorbed disc of HAp or α -Al₂O₃ using MC3T3-E1 osteoblastic cells and mouse RAW264.7 macrophages.

EXPERIMENTAL METHODS

Original discs were autoclaved at 121 °C for 20 min and adsorbed with BSA at 8.0 mg/mL in 2 mL of saline at 4 °C for 24 h. Following BSA adsorption, the samples were transferred to a 24-well culture plate. Each disc was seeded with 1x10⁴ MC3T3-E1 osteoblast-like cells or RAW264.7 monocytic cells in 1 mL of DMEM supplemented with 20% FBS and penicillin / streptomycin. For experiments, the cells were cultured for various periods of time ranging from 1 h to 14 days at 37 °C and 5% CO₂. For cell adhesion and spreading assays, cells adhered to discs were stained with fluorescein diacetate, and the number of adhered cells were counted and the maximum cell length was determined using an inverted fluorescent microscope. To determine cell proliferation, we isolated DNA from viable cells adhered to discs at 2, 7, and 14 days after incubation by using the AllPrep DNA/RNA/Protein Mini Kit and QIA Shredder columns, according to the manufacturer's protocol. Cell extraction was performed using cell scrapers and DNA was quantified by measuring absorbance at 260 nm by using a spectrophotometer.

RESULTS AND DISCUSSION

Effects of adsorbed BSA on MC3T3-E1 cell response are summarized in Table 1. Adsorbed BSA inhibited adhesion and spreading of MC3T3-E1 cells but it hardly affects MC3T3-E1 cell proliferation, no matter the substrate type. However, for HAp, we suggest that the inhibition effect of BSA is decreased because MC3T3-E1 cells adhered to HAp before sufficient adsorption of

BSA. This can be elucidated from the results regarding time-dependent adsorption of protein and MC3T3-E1 cell on HAp. These data suggest that the quick adherence of osteoblast cells might play an important role HA osteoconductivity.

Table 1 Effects of BSA adsorption on MC3T3-E1 cell response to HAp and α -Al₂O₃.

	Adhesion	Spreading	Proliferation
HAp	Inhibited	Inhibited	Not affected
α -Al ₂ O ₃	Inhibited	Inhibited	Not affected

The effects of adsorbed BSA on the RAW264.7 cell response are summarized in Table 2. Adsorbed BSA inhibits adhesion of RAW264.7 cells on α -Al₂O₃ but not on HA, whereas it hardly affected the spreading and proliferation of RAW264.7 cells on both HA and α -Al₂O₃ substrates. These results indicate that the initial adhesion of monocyte-macrophage lineage cells is inhibited by BSA adsorbed on α -Al₂O₃ but not by BSA adsorbed on HA. While a detail mechanism remains unclear, we speculate that the adsorption of BSA on HA plays some role in the cell response.

Table 2 Effects of BSA adsorption on RAW264.7 cell response to HAp and α -Al₂O₃.

	Adhesion	Spreading	Proliferation
HAp	Not affected	Not affected	Not affected
α -Al ₂ O ₃	Inhibited	Not affected	Not affected

SUMMARY

We investigated effect of adsorbed BSA on responses of osteoblast-like MC3T3-E1 cells and RAW264.7 macrophages. The adsorbed BSA inhibited adhesion and spreading of MC3T3-E1 cells, but it hardly affected the proliferation of MC3T3-E1 cells on both HAp and α -Al₂O₃. This suggests that MC3T3-E1 cells quickly adhered to original HAp before sufficient adsorption of BSA. The adsorbed BSA also inhibits adhesion of RAW264.7 cells on α -Al₂O₃ but not on HAp, whereas it does not affected the spreading and proliferation of RAW264.7 cells on both HAp and α -Al₂O₃ substrates. These results indicate that BSA adsorbed on HAp induces a different cell response than α -Al₂O₃. Moreover, the quick adherence of osteoblast cells and monocyte-macrophage lineage cell likely plays a role in HAp osteoconductivity.

New Insights into the Control of 3D Architecture and Porosity in Collagen Scaffolds for Tissue Engineering

K. M. Pawelec¹, A. Husmann¹, S. Best¹, R. Cameron¹

¹Cambridge Centre for Medical Materials, University of Cambridge, UK, ah492@cam.ac.uk

INTRODUCTION

Ice-templated collagen scaffolds are a powerful tool of regenerative medicine. Scaffold structure is formed during freezing, when ice nucleates and grows, pushing collagen to the space between the ice crystals. Once removed via sublimation, the porous structure is a mirror image of the ice, and can influence the biological response of the scaffold¹. Many different factors have been used to control ice structure including collagen weight percentage, mould design, and freezing protocols²⁻³. Given the close relationship between ice crystallization and the final scaffold structure, we hypothesized that by understanding the physics of crystal growth, scaffold structure could be predicted, regardless of the processing.

EXPERIMENTAL METHODS

Collagen slurry (1 wt%) was frozen in a Perspex mould. The set freezing temperature ranged from -20 to -40 °C. A protocol with a thermal hold at -14 °C was also used. Thermal profiles were recorded with thermocouples at the slurry top and base; from these, the nucleation temperature, slurry cooling rate, freezing time and “time at equilibrium” were quantified, Figure 1. The time at equilibrium was defined, with differential scanning calorimetry, as the time the slurry spent above -1.5°C; within this range most active crystal growth and annealing occurs within the slurry. Pore size was determined using micro-computed tomography (25 kV, 132 µA). All data was analysed using a Mann-Whitney test, with a confidence interval of 95%.

RESULTS AND DISCUSSION

Changes to the set final freezing temperature significantly affected the entire freezing process, altering all thermal parameters. Adding a thermal hold only affected the freezing time and the time at equilibrium. The resulting pore size at the scaffold top changed significantly as the freezing protocol varied.

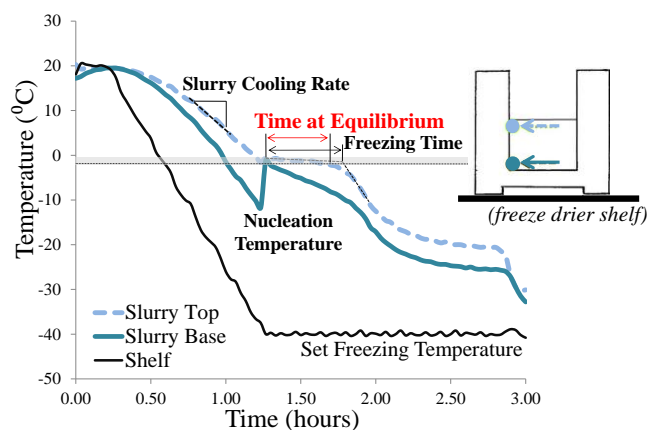

Figure 1. Description of thermal parameters quantified from a thermal profile recorded during freezing.

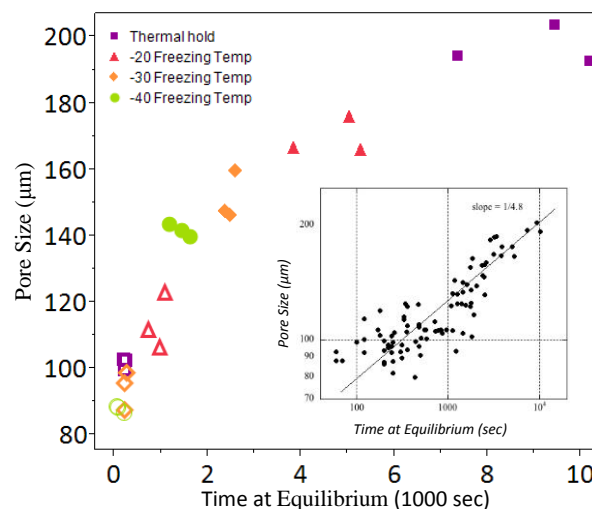

Figure 2. Relationship between time at equilibrium and pore size in collagen scaffolds (open marker: scaffold base, closed marker: top). *Inset: the slope of the curve was 1/4.8; fit with linear regression ($p < 0.05$, $R^2 = 0.8$)³.*

It was found that a strong relationship existed between the pore size and the time at equilibrium, Figure 2. The “time at equilibrium”, defined in the current study, is a measure of the efficiency of latent heat removal from the slurry, and is related to ice crystal growth. At the base of the slurry, which was close to the heat sink, heat removal occurred rapidly, despite changes to the freezing protocol, and the pore size remained constant. At the top of the mould, however, heat removal from the slurry was heavily dependent on the freezing protocol. With high set freezing temperatures or the addition of a thermal hold, the slurry at the scaffold top remained near equilibrium for longer periods, allowing the ice crystals to grow and anneal.

CONCLUSION

A fundamental relationship was revealed between the time at equilibrium and the final pore structure of tissue engineering scaffolds. By relating pore structure to the underlying physics of solidification, the curve should be robust regardless of processing changes. A predictive tool for tailoring scaffold architecture will be useful for future tissue engineering efforts.

Characterization and cytocompatibility of nanocellulose films

K.Hua, D.O.Carlsson, M.Strømme, A.Mihranyan, N.Ferraz

Nanotechnology and Functional Materials, Department of Engineering Sciences, Uppsala University, Sweden
kai.hua@angstrom.uu.se

INTRODUCTION

Characterized by exceptionally high degree of crystallinity, large surface area and broad chemical modifying capacity, nanocellulose deriving from the green algae *Cladophora sp.algae* has a great potential as a natural biomaterial for the development of medical devices and applications in healthcare ^[1]. In this study, we characterized pristine, cationic and anionic *Cladophora* nanocellulose in terms of surface charge, surface topography and specific surface area. The cytocompatibility of the nanomaterial was investigated by studying the behaviour of fibroblasts cultured on the *Cladophora* nanocellulose films.

EXPERIMENTAL METHODS

Cladophora nanocellulose (CC) was modified through glycidyltrimethylammonium chloride (EPTMAC) condensation and TEMPO mediated oxidation to obtain cationic and anionic CC respectively. Films of unmodified, anionic and cationic CC were prepared by vacuum filtration and characterized by measuring their ζ -potential and specific surface area. The surface topographies of the different CC films were observed under scanning electron microscopy (SEM).

In vitro cytocompatibility was investigated by assessing cell adhesion and proliferation on the nanocellulose films. Human dermal fibroblasts (hDF) were cultured on the surface of anionic, cationic and unmodified CC films for 24 h. Cell cultured on thermanox (TMX) served as positive control and cells cultured on TMX in the presence of 5 % DMSO were used as negative control. Cell viability was determined by the Alamar blue assay. Cell adhesion to the cellulose surfaces was studied in terms of cell number and morphology by SEM.

RESULTS AND DISCUSSION

The ζ -potential measurements at pH 7 showed that the surface charge of unmodified, anionic and cationic CC were -12, -41 and 31 mV, respectively. These results confirm that a significant number of negatively and positively charged groups have been introduced to the nanofibers by TEMPO oxidation and EPTMAC condensation respectively.

The specific surface areas of the different CC films were found to be 102 m²/g for unmodified CC (u-CC), 77 m²/g for anionic CC (a-CC) and 70 m²/g for cationic CC (c-CC), showing that the presence of charges resulted in a decrease in specific surface area. SEM micrographs of the CC films revealed that fibers of a-CC have aggregated, featuring co-axially aligned fibers rather than the randomly oriented fibers observed in u-CC and c-CC films (Fig. 1).

The Alamar blue assay showed that cell viability on the a-CC films was not significantly different from the

results of the positive control TMX. However, cells cultured on u-CC and c-CC showed poor cell viability, comparable to the values found for the negative control. SEM micrographs showed that a great number of fibroblasts adhered to the surface of a-CC films and showed typical fibroblast morphology. On the contrary, fewer and mainly round-shaped cells were observed on the c-CC and u-CC films (Fig. 2).

Fig. 1: SEM micrographs of a) unmodified, b) anionic, and c) cationic *Cladophora* nanocellulose films. Note the co-axial alignment of nanofibers in the anionic *Cladophora* nanocellulose film (panel b) compared with the random orientation of the fibers in the unmodified and cationic nanocellulose samples (panels a and c)

Fig. 2: SEM micrographs of hDF adhered on surfaces of a) unmodified, b), anionic, c) cationic *Cladophora* nanocellulose films, d) Thermanox in the presence of 5% DMSO and e) Thermanox, after 24 hours culture.

CONCLUSION

In this work, we found that a-CC promoted fibroblast adhesion and presented cell viability comparable to the results obtained with the tissue culture material thermanox. However, hDF cultured on u-CC and c-CC showed poor viability. We hypothesize that the distinct aligned nanofiber structure present in the a-CC films is responsible for the improved cell adhesion and viability. The results presented in this work suggest that TEMPO modified *Cladophora* nanocellulose (a-CC) is a good candidate to be further explored in tissue engineering. Other material properties like porosity and degree of crystallinity will be further investigated to relate such physicochemical properties with cell behaviour on the different cellulose materials.

INTRODUCTION

Angiogenesis is the physiological process involving the growth of new blood vessels from pre-existing ones. It is a critical process not only during normal development, but also in pathologic situations, where inadequate vascular evolution contributes to health complications. Angiogenesis is predominantly regulated by local factors that promote or inhibit neovascularization like e.g. AcSDKP (N-acetyl-seryl-aspartyl-lysyl-proline, acetyl-N-Ser-Asp-Lys-Pro)¹ isolated originally from fetal calf bone marrow.

Figure 1. Structure of N-acetyl-Ser-Asp-Lys-Pro

It has been shown that AcSDKP acts as a mediator of angiogenesis which occurs both during embryonic development and in postnatal life. AcSDKP can be used as biologically active supplement in number of different biomaterials². That is why its support in angiogenesis process has been investigated. Because of using ionizing radiation as a method of choice for sterilization, its influence on tetrapeptide has been also studied.

EXPERIMENTAL METHODS

In this work hydrogel matrixes containing polyvinylpyrrolidone – PVP, poly(ethylene glycol) – PEG, agar and tetrapeptide were synthesized using EB-irradiation (25 kGy, 4μs, 50 Hz). Release kinetics of active substance from the hydrogel dressings by high performance liquid chromatography – HPLC and gel swelling kinetics by the gravimetric method were

investigated. The equilibrium swelling degree of hydrogels and gel fraction content were determined. Changes in gene expression of human endothelial cells EA.hy926 (CRL-2922™ ATCC) induced by hydrogel matrix containing AcSDKP were studied using Human Angiogenesis Oligo GEArray System (SABiosciences). Cells were grown, in the presence of hydrogel with AcSDKP, to 80% of confluence. Total RNA was then isolated from the cells. cRNA was obtained in PCR reaction, then it was amplified and labeled with biotin-16-dUTP. The synthesized molecular probe (biotined cRNA) was used for 12 hours of hybridization with oligonucleotide fragments immobilized on microarrays. Chemiluminescent reaction was triggered by an addition of CDP-Star (1,2-dioxetane). Gene expression was determined by the spot darkness analysis on X-ray film (Kodak) by using ImageQuant 300 and ImageQuant TL 8.0 software (GE Healthcare).

RESULTS AND DISCUSSION

It was observed that the amount of active substance released from hydrogel matrix into water at 25 °C reaches the level of 55 - 80% after 6 h. Furthermore, swelling degree of hydrogel matrix in water rises with the amount of active substance and achieves the equilibrium after 160 h swelling. Gel fraction of matrix decreases with increasing amount of AcSDKP. Contact of endothelial cells with hydrogel matrix containing AcSDKP results in a higher level of changes in expression of genes responsible for angiogenesis.

CONCLUSION

Hydrogel based matrix containing acetyl-N-Ser-Asp-Lys-Pro activating angiogenesis process can be synthesized using EB-irradiation technique.

INTRODUCTION

Environmentally sensitive materials have recently attracted considerable attention due to their biomedical application owing to the reversible responses to external stimuli, such as temperature, pH, ionic strength, electric field, magnetic field, light, etc. Poly (N-isopropylacrylamide) (*p*-NIPAAm) and their copolymers are the most well-known thermoresponsive polymers and have been extensively studied for biomedical applications owing to the reversible thermoresponsive phase transition from a hydrated random coil (or a swelled globule) to a deswelled compact globule at the lower critical solution temperature. However, they have limited applicability as a drug delivery system due to the too low LCST (below body temperature), a tedious drug-releasing profile in a wide temperature range (affected by encapsulated drugs and surrounding pH), or too low drug-carrying ability (about <0.35 mg drug per 1.0 mg polymer).

EXPERIMENTAL METHODS

Ionic Liquid (IL)-doping on the temperature responsive *p*-NIPAAm was achieved by radical copolymerization of N-isopropyl acryl amide (NIPAAm; 90 mol%) and 1-butyl-3-vinylimidazolium bromide ([BVIIm]Br; 10 mol%) to give a new temperature responsive copolymer (*p*-NIBIm).

RESULTS AND DISCUSSION

The as-prepared *p*-NIBIm copolymer showed the highly increased Zeta potential value and the optimal LCST (lower critical solution temperatures) value, respectively, +9.8 mV at pH=7 and 38.2 °C, compared to those (+0.3 mV at pH=7 and 32.1 °C) of *p*-NIPAAm. The temperature-dependent size change of the *p*-NIBIm micelles was determined in the range from 25 to 45 °C by SEM under dry condition and by Zeta Sizer under wet condition, showing a certain size contraction from 253±12.1 to 90.5±7.8 nm in diameter (about 95.4 % of volume contraction).

Figure 1. LCST determination of a) *p*-NIPAAm and b) IL-doped *p*-NIBIm using DSC scan.

The thermo-sensitive behaviors to entrap BSA protein at body temperature (37 °C) and to release the protein between 38-42 °C (near the LCST) also were tested by sizing of the complexes of *p*-NIBIm/BSA using Zeta Sizer and also by a colorimetric assay (Bio-Rad DC Protein Assay), resulting in a maximum entrapment of 1.02 mg BSA for 1.0 mg of the polymer at body temperature (37 °C) and in a maximum release of 0.73 mg BSA for 1.0 mg of the polymer (about 73% releasing of the entrapped amount) at the temperature range of 38-42 °C.

Figure 2. SEM microscopic images of the *p*-NIBIm copolymer and the *p*-NIBIm/BSA complex micelles.

Figure 3. The BSA loading and releasing behavior of the *p*-NIBIm copolymer.

CONCLUSION

These results revealed the IL-doped and temperature responsive co-polymeric system has high applicability as a novel delivery system for negatively charged molecules as a natural (or synthetic) drug and DNA.

INTRODUCTION

A long-term antibacterial ability of a biomaterial is desirable in order to prevent implant associated infection. Therefore, modification of implant surfaces is in the focus of many scientists worldwide [1]. The present study is directed towards the modification of metal implant properties to produce predictable clinical results of implant osseointegration by developing of a biocomposite ensuring both a higher bioactivity and prolonged antibacterial activity. Through the use of nanofabrication techniques a multifunctional biocomposite containing hydroxyapatite (HA) and silver nanoparticles (AgNPs) has been fabricated.

EXPERIMENTAL METHODS

PVP-coated silver nanoparticles were synthesized by a wet chemical reduction method of silver nitrate using glucose as a reductant and polyvinylpyrrolidone as a stabilizer [2]. AgNPs were deposited onto titanium substrate via dripping/drying technique and were further covered with CaP coating by means of RF-magnetron sputtering [3, 4]. A commercially available installation with a RF-magnetron source (COMDEL, 13.56 MHz) was used. The coating was deposited at an RF-power level of 500 W in Ar atmosphere at grounded substrate holder for 180 min. A target for sputtering was prepared from hydroxyapatite ($\text{Ca}_{10}(\text{PO}_4)_6\text{OH}_2$, HA). The morphology and composition of the samples on each preparation stage were estimated by SEM using an ESEM Quanta 400 FEG instrument equipped with EDX (Genesis 4000, SUTW-Si(Li) detector) operating in a high vacuum with gold/palladium-sputtered samples. To determine the internal structure and phase composition of studied thin films the Grazing-incidence small-angle X-ray scattering (GISAXS) was used.

RESULTS AND DISCUSSION

The negatively charged silver nanoparticles (zeta potential -21 mV) with a spherical shape and a diameter of the metallic core 50 ± 20 nm were coated with dense, nanocrystalline CaP film. X-ray diffraction studies showed that the synthesized HA film was nanocrystalline with hexagonal structure. The diffraction patterns of the formed coatings showed peaks corresponding to HA: 25.8° (002), 31.7° (211), 32.2° (112). Three peaks attributable to metallic silver low intensity at 46.3° (200), 64.5° (220) and 81.5° (222) are also observed. Meanwhile, the most intense Ag x-ray emission line at 38° (111) is overlapped by the line of Ti (002). SEM of the cross section in backscattering mode showed the layer of silver nanoparticles below the CaP layer (Fig.1). The release of Ag ions from the developed biocomposite in phosphate buffer was

evaluated via Atomic Adsorption Spectroscopy (AAS). The cumulative concentration of Ag^+ within 7 days of immersion was 0.27 ± 0.02 $\mu\text{g/mL}$, which is below the cytotoxic level of Ag ions found in the literature [5].

Fig. 1. SEM images of the composite cross-section representing the superposition of the images obtained in a second electron beam and backscattering reflections.

CONCLUSION

We suppose that the release behavior of Ag ions from the developed biocomposite could be adjusted by controlling the initial concentration of AgNPs on the substrate surface and HA coating structure. So, proposed approach seems to be promising to design a novel tunable antimicrobial biocomposite.

INTRODUCTION

3-D printed hydroxyapatite (HA) scaffolds with defined macro porosity have emerged as attractive biomaterials in tissue engineering. In order to reinforce their compressive strength (CS) and change their properties, a combination of additives like biocompatible synthetic or natural (bio)polymers during the printing process, and extracellular matrix (ECM) generated by osteoblast-like cells, have been investigated. Osteoblasts are specialised fibroblasts that secrete and mineralise the bone matrix by regulating calcium deposition and mineralization. In our study, a human preosteoblast cell line (MG-63) was used as a model. Some preliminary experiments have been investigated *in vitro* to characterize the MG-63 differentiation on HA scaffolds by (a) cell proliferation, (b) matrix maturation and (c) matrix mineralisation studies.

EXPERIMENTAL METHODS

Scanning electron microscopy (SEM), MTT assay and Confocal Laser scanning microscopy (CLSM) were used to evaluate cell adhesion on HA scaffolds. Osteoblast differentiation was evaluated by determining alkaline phosphatase (ALP) activity at day 1, 3, 5, 14, 21. To quantify osteoblast differentiation, the mRNA expression of several osteoblast marker genes (ALP, OC, COL and Runx2) was assessed by a quantitative real-time polymerase chain reaction (qRT-PCR).

RESULTS AND DISCUSSION

When 10^5 cells per scaffold were seeded, cell number gradually increased with 7-fold higher after 14 days in comparison with day 1. After induction of ECM production with osteoblast stimulators (OS), qRT-PCR analysis showed a significant 9-fold increased for ALP expression (early differentiation marker) at day 3 in comparison with day 1. The matrix maturation was observed by SEM analysis (Fig 1) from day 5 to 21, and osteocalcin (mineralisation marker) was detected by immunofluorescence staining after 24 days (Fig 2B). Our preliminary studies demonstrated that MG-63 cells attached and proliferated as a monolayer over time on HA scaffolds (Fig. 2A). Our work proved also the ability of these cells to produce visible ECM after 14 days and, exhibit some mineralization indicator by the presence of osteocalcin after 24 days.

Fig. 1: SEM images of 3D-printed HA scaffolds without MG-63 cells A), and with MG-63 after 5 days B), after 14 days C), and after 21 days D) of differentiation.

Fig 2: Immunofluorescence staining of MG-63 on HA scaffolds. Cytoskeleton (red) and nuclei (blue) showed the distribution of the cells after 10 days of differentiation A), and Osteocalcin (green) expression was observed after 24 days of differentiation B).

CONCLUSION

After these preliminary results with a cell model, long-term mineralization studies *in vitro* will be performed with stem cells under “dynamic” conditions (Perfusion Bioreactor) to get homogeneous cell distribution and higher level of mineralization.

Protein Adsorption onto Polymer-based Nanocarriers for Vaccine Delivery

Nitesh Kunda*, Gillian Hutcheon and Imran Saleem

School of Pharmacy and Biomolecular Sciences, Liverpool John Moores University, Liverpool, UK,
N.K.Kunda@2011.ljmu.ac.uk

INTRODUCTION

Progress in the vaccine technology has been to deliver the antigens by micro or nanoparticles (NPs). Particulate systems utilising polymers such as polylactic acid (PLA), polylactic-co-glycolic acid (PLGA), chitosan, alginate, polyanhydride, poly(glycerol adipate-co- ω -pentadecalactone) (PGA-co-PDL) etc. have been widely investigated^{1,2}. In addition, the biodegradable polymeric NPs offer numerous advantages such as controlled or sustained drug release, biocompatibility with the surrounding tissues and cells, lower toxicity compared to non-biodegradable polymers, are non-thrombogenic, act as adjuvants and are more stable in blood³.

The pulmonary route for vaccine delivery has gained significant attention due to an abundance of antigen presenting cells (such as macrophages, dendritic cells (DCs)) for targeting antigens⁴.

In this study, we adsorbed a model protein, bovine serum albumin (BSA), onto PGA-co-PDL NPs, and formulate into nanocomposite microparticles (NCMPs) for pulmonary vaccine delivery via dry powder inhalation.

EXPERIMENTAL METHODS

NPs were prepared by a modified oil-in-water (O/W) single emulsion solvent evaporation method. Particle size, polydispersity index (PDI) and zeta-potential were characterised using laser diffraction. The NPs were centrifuged and BSA was adsorbed onto NPs at different ratios from 100: 4 to 100: 20 (NPs: BSA) for 1 h. The effect of time on adsorption was evaluated using 100: 20 (NPs: BSA) for 30 min, 1, 2 and 24 h. The protein adsorbed was evaluated using micro BCA protein assay kit. The BSA adsorbed NPs were spray-dried using L-leucine (1: 1.5, NPs: L-leu) for pulmonary delivery. The resultant nanocomposite microparticles (NCMPs) were characterised for protein stability using SDS-PAGE and *in vitro* toxicity (MTT assay, A549 cell line).

RESULTS AND DISCUSSION

NPs of size 128.50 ± 6.57 nm, PDI 0.07 ± 0.03 and zeta-potential -24.56 ± 0.50 mV were produced indicating its suitability for targeting lung DCs.

The adsorption of BSA, μ g per mg of NPs, increased significantly from 100:4 (NP:BSA) loading concentration (4.75 ± 0.39) to 100: 20 (10.23 ± 1.87) (Fig 1). In addition, for 100: 20 (NP: BSA) loading concentration, the average adsorption increased significantly from 30 min (1.84 ± 0.82) to 1 h

(10.23 ± 1.87) with no significant difference beyond 1 h compared to that of 2 and 24 h indicating maximum adsorption at 1 h.

Fig 1: Amount of BSA adsorbed per mg of NPs at different concentrations (NP: BSA) (Mean \pm SD, n=3)

Langmuir (LM) and Freundlich (FM) models have been employed to study the relation between the amount of protein adsorbed effectively onto the NPs and the protein concentration in the solution at equilibrium. The regression coefficient (r^2 , LM ≥ 0.93 ; FM ≥ 0.98) was obtained for LM (C_e/Q_e vs C_e), FM ($\log C_e$ vs $\log Q_e$) where Q_e is the amount of protein adsorbed (μ g/mg) and C_e is the concentration in equilibrium (μ g/ml). The data fits the FM suggesting multilayer type of protein deposition onto PGA-co-PDL NPs surface, resulting from the competition of protein molecules to the particle surface. The LM does not consider the multiple sites available for adsorption nor the protein-protein interactions⁵.

The BSA adsorbed PGA-co-PDL NPs were spray-dried with L-leu resulting in NCMPs. The released BSA from NCMPs was analysed for stability using SDS-PAGE and the bands for released BSA were identical to the standard BSA indicating that the stability not affected by formulation processes. MTT assay showed cell-viability of $87.01 \pm 14.11\%$ at 1.25 mg/ml concentration after 24 h exposure indicating a good toxicity profile.

CONCLUSION

The results indicate effective BSA adsorption onto the surface of PGA-co-PDL NPs with BSA stable after spray-drying. In addition, the NCMPs displayed a good toxicity profile. This provides an indication about the feasibility of using PGA-co-PDL polymers as safe carriers for pulmonary vaccine delivery.

Surface functionalization of electro-spun Poly(L)Lactic Acid scaffolds with heparin to induce angiogenesis

Giulia Gigliobianco*, Sabiniano Roman, Chuh K. Chong and Sheila MacNeil

Kroto Research Institute, University of Sheffield, Sheffield, S3 7HQ, UK, email: dtp11gg@sheffield.ac.uk

INTRODUCTION

Delays in new blood vessel formation after implantation of a tissue-engineered construct within the host is a major limiting factor for the long survival of the constructs [1]. Smarter biomaterials are needed to be able to induce angiogenesis post-implantation and keep the newly formed tissue alive. Hence, biomaterials can be designed to be specifically functionalised for this purpose. The aim of this study is to develop a versatile approach to modifying scaffolds to induce angiogenesis once implanted.

EXPERIMENTAL METHODS

Electrospun PLA scaffolds were plasma polymerized with PolyAcrylic Acid (PAA) and coated with alternative layers of PolyEthyleneImine (PEI) and PAA or PEI and Heparin for a total of seven layers, in a layer-by-layer (LBL) coating approach. Coated scaffolds were then dipped in heparin solution, dried and immersed in Vascular Endothelial Growth Factor (VEGF) solution. Surface chemistry was verified by X-Ray Photon Electron Spectroscopy. An ELISA was used to quantify the amount of VEGF bound to the scaffolds. The Chick Chorionic Allantoic Membrane (CAM) assay was used to assess *in-vivo* the angiogenic potential of the scaffolds over a period of 7 days.

RESULTS AND DISCUSSION

XPS showed that plasma polymerization of the scaffolds with PAA was successful as the presence of S indicates Heparin is present. Heparin bound well to LBL-coated scaffolds, compared to non-functionalised scaffolds, and showed an increase in VEGF binding. The CAM assay showed that the functionalized scaffolds induced blood vessel formation compared to non-functionalised scaffolds.

Table 1. Atomic ratios of elements present on the surface of different scaffolds, normalized by the amount of carbon atoms present (C= carbon, N=Nitrogen, S=Sulphur, O=Oxygen).

Type of Scaffold	Atomic Ratios		
	O/C	N/C	S/C
Not-functionalized PLLA	0.375	0.011	0.000
1 layer functionalized PLLA	0.468	0.128	0.052
5 layers functionalized PLLA	0.542	0.155	0.076
7 layers functionalized PLLA	0.546	0.149	0.082

CONCLUSION

The LBL functionalization we describe allows heparin to be bound to the surface of the scaffold which can in turn bind VEGF. The CAM assay demonstrated that this bound VEGF is functional inducing directed neovascularisation. We conclude that this protocol (which can be applied to a range of scaffolds) offers a new approach to tackling the problems of delayed angiogenesis for tissue engineering. can liberate us by displaying our authenticity.”

NTT Basic Research Laboratories/NTT Corporation, Atsugi, Japan
kasai.nahoko@lab.ntt.co.jp

INTRODUCTION

An artificial synapse is a nano-micro-meter scale nano-biodevice that mimics neuronal synaptic functions (Figure 1). With the aim of realizing an artificial synapse, we have succeeded in forming a suspended lipid bilayer on a well [1] and examined the activity of an ion channel reconstituted in the lipid [2]. We have used scanning electron microscopy (SEM) to observe neurons and their interface with substrates to examine the optimal conditions for neuronal growth, and we have also observed the morphological changes in neurons induced by cell death [3].

In this study, we used the above SEM technique combined with nano-meter-scale fabrication technology to examine neuronal growth on a glass substrate consisting of nano-pillars. We employed this approach to investigate neuronal preferences, which determine the growing direction. This study will contribute to the control of neuronal growth when implementing artificial synapses.

EXPERIMENTAL METHODS

Amorphous silicon (a-Si) nano-pillars were fabricated on quartz substrates using electron-beam lithography. The pillar height was 500 nm, the pillar diameter was either 100 or 500 nm, and the distance was either twice or four times the pillar diameter. Rat cortical neurons were obtained from Wister rat cortex (embryonic 18 days), and cultivated on the nano-pillar substrate, without coatings, for 7 days in a neurobasal medium with L-glutamine, glutamate, gentamycin, and 2% B27 supplement, at 37 °C in 5% CO₂. After cultivation, the cells were fixed in two steps; the first was fixation with

paraformaldehyde (PFA) and glutaraldehyde (GA), and the second was fixation with osmium tetroxide (OsO₄). Then the cells were dehydrated using ethanol and freeze-dried in t-butanol.

RESULTS AND DISCUSSION

Figure 2 shows SEM images of tips of neurites, called growth cones and filopodia, cultivated on the nano-pillar substrates. Filopodia, which are thought to sense and to determine the growth direction, were successfully observed as they developed from growth cones attached to the nano-pillars (Fig. 2a,b). The widths of filopodia on different patterned substrates (Fig. 2c) indicated that the filopodia were wider with larger pillar diameters, and thinner on thin pillars. However their width was not greatly affected by the pillar distance.

These results suggested that the filopodia detected the pillars as an environment and that they changed their widths to enable them attach and to grow.

CONCLUSION

Although we must undertake a more detailed examination, this study demonstrated the possibility of controlling neuronal growing conditions using nano-pillar substrates. This will contribute to the development of artificial synapses, and also new nano-bio interfaces.

Biodegradable and Bioadhesive Hemostatics Comprising Polymer Complex Gel and Chitosan

Tomoko Ito, Masazumi Eriguchi and Yoshiyuki Koyama*

*Japan Anti-tuberculosis Association, Shin-Yamanote Hospital, Japan, ykoyama@shinyamanote.jp

INTRODUCTION

Local hemostasis is sometimes difficult especially in patients taking anticoagulant. When the patient taking anticoagulant underwent tooth extraction, dental surgery operation, or gastrointestinal endoscopy, they used to be indicated to quit taking the drug for several days prior to the surgery. However, serious adverse side effects such as formation of thrombosis were sometimes observed. They are, thus, now instructed not to stop taking the drug. Patient of this type should have periodic blood coagulation test, but blood sampling often caused prolonged and continuous bleeding. For such difficult-to-control bleeding, safe and efficient hemostatic device is desired.

We focused on a hydrogen bonding gel consisting of Poly(acrylic acid) (PAA) and poly(vinylpyrrolidone) (PVP), which are both highly safe synthetic polymers approved as pharmaceutical excipients. When PAA and PVP are directly mixed in water, soft hydrogel is immediately formed, but soon precipitated as a insoluble solid. Resulting rigid gel is not swelled, nor dissolved in water. Recently, we succeeded in preparation of a water-swellaable PAA/PVP spongy sheet by regulating the movement of polymer molecules. It formed a soft hydrogel on wet tissue, and strongly stick to it. Then, we applied it to patients taking anticoagulant medicines to control the bleeding after tooth extraction. Soon after putting on the bleeding site, the PAA/PVP sponge swelled to a hydrogel, tightly adhered to the tissue, and arrested the haemorrhage, effectively. However, it was sometimes difficult to achieve satisfactory hemostatsis in the patients with high PT-INR.

In this study, chitosan (CS), a blood-coagulating polysaccharide, was employed to improve the hemostatic effect of the gel. Here, we introduced CS into PAA/PVP spongy sheet, and application of the CS containing hemostatic device to patients with high PT-INR was attempted.

EXPERIMENTAL METHODS

Preparation of PAA/PVP/CS spongy sheet: PAA solution was dried up to a clear film. PVP aqueous solution containing CS was then poured upon the PAA film. It was then freeze dried, and spongy sheet was obtained.

Hemostatic effect on mice: Mice were injected with 50 IU of fragmin, a low molecular weight heparin. They were anesthetized by pentobarbital, and the skin over the femur was incised to expose the femoral vein. Soon after cutting the vein, PAA/PVP/CS sponge was put on the bleeding site, and hemostatic behavior was observed.

Clinical study: Clinical study was carried out on the patients taking the anticoagulant medicine after tooth

extraction. PAA/PVP/CS spongy sheet was placed on the bleeding socket, soon after the extraction, and hemostatic effect and recovery condition was observed.

RESULTS AND DISCUSSION

Mixing of the aqueous solutions of PAA and PVP results in formation of water-insoluble, and -inswellable precipitate. On the other hand, pouring PVP solution onto a dried PAA film, followed by lyophilization afforded a water-swellaable white spongy sheet. CS-containing sponge was similarly prepared by adding CS to the PVP solution, previously. PAA/PVP/CS spongy sheet immediately swelled on a wet tissue, and firmly stuck to it. Their adhesion strength was more than 50 g/cm².

Hemostatic effect of the spongy sheet was examined on the mouse treated with 50 IU of fragmin. The femoral vein was exposed and cut. The water-swellaable PAA/PVP or PAA/PVP/CS spongy sheet was placed on the bleeding site. When the thin PAA/PVP sheet without CS was put on the heavily bleeding site, spongy sheet sometimes got a hole in minutes being dissolved by the blood. Thick, or piled sheet was required for complete hemostasis. On the other hand, the treatment by the CS-containing PAA/PVP sheet effectively stopped the bleeding, and single thin spongy sheet could achieved immediate hemostasis.

Clinical study of the PAA/PVP/CS spongy sheet to control the bleeding after tooth extraction was performed on the patient taking anticoagulant medicine such as bayaspirin or warfarin. After tooth extraction, the PAA/PVP/CS spongy sheet was placed into the bleeding socket. The sponge absorbed the blood, and swelled to a hydrogel. It adhered to a bleeding site, and arrested the hemorrhage effectively, even in the anticoagulated patients.

CONCLUSION

Water-swellaable PAA/PVP/CS sponge could be obtained under certain particular conditions. It showed high hemostatic efficiency in mice treated with a large amount of heparin. Excellent efficacy of the sponge as a hemostatic device was also confirmed in the clinical studies, and no adverse side effect was as yet observed. Further clinical study is now ongoing.

The Effect of Water Saturation on the Compressive Properties of Calcium Sulphate Dihydrate

I Koh^{*1}, A López², B Helgason¹ and S Ferguson¹

¹Institute for Biomechanics, ETH-Zürich, Switzerland

²Division of Applied Material Science, Uppsala University, Sweden, ikoh@ethz.ch

INTRODUCTION

In the past years, ceramic cements started to gain popularity as biomaterials for musculoskeletal reconstruction due to their biological advantages. Characterisation of the biological and mechanical properties of newly developed ceramic cements is essential, and needs to be performed prior to clinical application. The mechanical properties of ceramic cements are often tested using an international testing standard developed for ductile acrylic cements and performed mostly in a dry condition. Given that ceramic cements are known to be brittle and degradable, the testing standard designed for ductile materials may not be suitable for ceramic cements. Therefore, the aim of the current study was to evaluate the suitability of the testing standard on dry and wet ceramic cements. The study was performed using calcium sulphate dihydrate (CSD).

EXPERIMENTAL METHODS

160 CSD cylinders (aspect ratio=2) were prepared by mixing β -CSH powder and water (L/P-ratio=0.67). Cylindrical Teflon molds were filled with slurries and vibrated on a vibration table for 5 minutes to remove entrapped air. The resulting CSD cylinders were removed from the mold and dried at room temperature for 21 days. The cylinders were randomly divided into four groups having different saturation levels (dry, wet) and end conditions (capped, non-capped). The cylinders in the wet groups were immersed in PBS for 24 hours prior to the test. Aluminium caps were glued to the end surfaces of the cylinders in the capped groups. Unconfined compression tests to failure were performed on all prepared cylinders. Specimen deformation was measured using two different methods (platen-to-platen, extensometer). Two effective moduli were derived, E_p and E_e (platen-derived and extensometer-derived, respectively). The moduli were compared between the groups to determine the effect of saturation level, end conditions and measurement methods. The testing standard developed for acrylic cement prescribes non-capped specimens and platen-derived displacement.

RESULTS AND DISCUSSION

The end condition in the wet group did not influence E_e . However, E_p of the wet capped group was higher than E_p of the wet non-capped group. This can be explained by the chemical and physical changes of CSD with water saturation. The formation of CSD is a reversible reaction. This means, reintroduction of water to CSD induces crystal dissociation, reducing the occurrence or weakening the crystal interlocks. As a result, the

mechanical strength of CSD decreases [1]. In addition, water molecules allocated within the CSD may act as a lubricant, reducing the frictional resistance, hence shear strength, at the crystal interlocks [1]. As a combined effect of reduced occurrence of crystal interlocks and frictional resistance, local shear deformation and damage at the platen-sample boundary (end effect) occur in wet non-capped specimens. Due to these local deformations and damage, the platen records a larger deformation than the extensometer, hence a lower E_p compared to E_e in non-capped samples.

On the other hand, the end condition in the dry group did not affect the moduli, when the same displacement measurement was used. This indicates that the end effect arises only in the presence of water.

The results indicate that the commonly adopted testing standard developed for ductile acrylic cement may not be suitable when wet ceramic cements are tested to determine effective modulus. It is suggested to use endcaps and/or an extensometer to measure displacements. These techniques remove and avoid the end effect respectively.

	Dry		Wet	
	Cap	NoCap	Cap	NoCap
E_p (GPa)	4.6±0.5	4.6±0.7	1.7±0.5	0.9±0.3
E_e (GPa)	6.3±1.5	5.7±1.3	1.9±0.3	1.7±0.5

Table 1 shows the summary of effective E-moduli derived using two different deformation measurement methods. Four groups having different saturation level and end-conditions were compared (Mean±SD).

CONCLUSION

It was found that water saturation substantially alters the mechanical properties of CSD. It is proposed that crystal dissociation and reduction in interstitial frictional resistance reduce the strength of the material. The reduction in the strength causes local shear deformation and damage at the platen-sample boundary (end effect). It is suggested to use endcaps and/or an extensometer to determine the effective elastic modulus of wet ceramic cements.

Flexural Properties of Calcium Sulphate Dihydrate and Dicalcium Phosphate Dihydrate: Potential Role of Degradation with Water Saturation

I Koh*, B Helgason and S Ferguson

¹Institute for Biomechanics, ETH-Zürich, Switzerland, ikoh@ethz.ch

INTRODUCTION

Vertebroplasty is a common surgical procedure used to augment weakened vertebrae caused by osteoporosis or metastasis. In the recent years, studies were conducted to extend the usage of vertebroplasty for the treatment of young patients with complex vertebrae fractures [1]. The application of vertebroplasty in complex fractures is promising, when the biological advantages of ceramic cements are considered (osteoconductive, osteogenic). However, our own simulations indicate that the cement augmenting a complex fractured vertebra experiences tensile/flexural stresses under physiological, multi-axial loads, due to interfragmentary movement. Newly developed ceramic cements are commonly tested only under compression in dry conditions. To obtain complete tensile/flexural properties of ceramic cements, two common ceramic cements, calcium sulphate dihydrate (CSD) and dicalcium phosphate dihydrate (DCPD), were tested in 3-point bending in both dry and wet conditions. The results were used to identify the changes in the flexural properties of CSD and DCPD due to water saturation.

EXPERIMENTAL METHODS

67 CSD and 80 DCPD beams (90x8x6mm) were prepared for 3-point bending tests. CSD beams were prepared by mixing β -CSH and water (L/P ratio=0.67), while DCPD beams were prepared by mixing equimolar fractions of β -TCP and MCPM, and water (L/P ratio=0.5). Custom designed aluminium molds were filled with slurries of CSD and DCPD. The molds were placed on a vibrating table for 5 and 1 minute, respectively, to remove entrapped air. The beams were removed from the molds and air dried at room temperature for 21 days. 24 hours prior to the testing, 34 CSD and 40 DCPD beams were immersed in separate baths of PBS. This resulted in four different testing groups of: dry and wet CSD and dry and wet DCPD. 3-point bending tests were performed on an Instron at a crosshead speed of 1mm/min until failure. A custom made 3-point bending apparatus (designed according to ASTM standard [2]) was used to accommodate imprecise beam geometry. Effective flexural strength (strength) and modulus (modulus) as well as deflection at failure (deflection) were calculated.

RESULTS AND DISCUSSION

CSD had higher strengths than DCPD in both dry and wet groups (Table 1). Both CSD and DCPD showed lower strength in the wet groups. The observed strength reduction due to water saturation was higher in DCPD (74%) than CSD (58%). The reduction of compressive strength in water-saturated ceramic cements is commonly explained as a result of degradation.

However, given that the reduction in the strength of DCPD (with lower degradation rate) was higher than CSD (with higher degradation rate), the dissociation of crystals cannot fully explain the results observed in this study. Therefore, the existence of a different mechanism (other than crystal dissociation) that lowers the strength of DCPD or a factor that facilitates the degradation of DCPD is cautiously proposed.

The deflection of dry CSD at failure was equivalent to the deflection of wet CSD. However, wet DCPD showed a 56% lower deflection, compared to dry DCPD. This reflects the differences in the percentage reduction in strength and modulus. While the reduction of the CSD strength (58%) was matched by the reduction of the modulus (57%), the reduction of the DCPD strength (74%) was greater than the reduction of the modulus (46%) (Table 1). The larger reduction in the strength further supports the proposed differential degradation of DCPD.

Given that the degradation kinetics of DCPD is not fully understood, it is difficult to provide an accurate reasoning behind the results of the current study. Therefore, to better understand the dynamic mechanical properties of degradable ceramic cement, a series of carefully designed studies are required to determine the role of possible factors on the degradation of such cements.

	CSD		DCPD	
	Dry	Wet	Dry	Wet
Strength (MPa)	3.0	1.2	1.9	0.5
Modulus (GPa)	9.0	3.9	9.4	5.1
Deflection (mm)	0.14	0.14	0.09	0.04

Table 1 shows the summary of flexural test results (mean).

CONCLUSION

In conclusion, the influence of water saturation on is significantly different in CSD and DCPD cements. Further experiments examining the degradation kinetics of ceramic cements are required.

Osteoconductivity of Super Hydrophilic Valve Metals and Titanium Alloys

Kensuke Kuroda^{1*} and Masazumi Okido²

^{1*} EcoTopia Science Institute, Nagoya University, Japan, kkuroda@numse.nagoya-u.ac.jp

² EcoTopia Science Institute, Nagoya University, Japan

INTRODUCTION

Valve metals, such as titanium, niobium, tantalum, and zirconium, and also their alloys are widely attracted as bone-substitutional materials in dental and orthopaedic fields because they have high resistance to corrosion. It is important to modify the surface chemical characteristics to improve the osteoconductivity because of their poor bone-forming properties, for example, using hydroxyapatite¹ or oxide coatings².

Hydrophilicity of biomaterials surface is considered to be one of the most important properties to influence on the osteoconductivity. In this study, super hydrophilic surface was tried to attain on valve metals and their alloys using hydrothermal treatment, and their osteoconductivity was then evaluated in *in vivo* testing.

EXPERIMENTAL METHODS

Valve metals and their alloys (Ti, Nb, Ta, Zr, Ti6Al4V, Ti6Al7Nb, Ti29Nb13Ta4.6Zr) were polished with 0.05 mm Al₂O₃ powder and mirror finishing (Ra / μm < 0.15). Hydrothermal treatment of each sample was carried out in distilled water to obtain the hydrophilic surface at 180 °C for 3 h, and the hydrophilic samples were kept in the phosphate buffered saline solution (PBS) with 5 times concentration: 5PBS(-) in room temperature in order to maintain and improve the hydrophilicity. Surface characterizations of the samples were evaluated using SEM and XRD, XPS, water contact angle (WCA) measurement (2 mL), and the surface roughness. The surface roughness of the samples was measured using a laser microscope, and expressed with the average roughness, Ra (analysis area 150 × 112 μm). In *in vivo* testing, the rod samples ($\phi 2 \times 5$ mm) were implanted in male rat's tibiae for 14 days and the bone-implant contact ratio, BIC, was used to evaluate the osteoconductivity in the cortical and cancellous bone parts, respectively.

RESULTS AND DISCUSSION

The hydrothermal treated samples had thin oxide film, their surface roughness was equivalent to as-polished substrates. As-polished samples had WCA= ca. 70 deg. and hydrothermal treatment gave hydrophilic surface around WCA=15 deg. XPS analysis of the sample surface before and after hydrothermal treatment revealed that the amount of adsorbed -OH did not change and C-H reduced drastically. This is because the hydrothermal treatment at high temperature and high pressure removed adsorbed hydrocarbon on the surface. Therefore, this processing brought a clean surface and the hydrophilicity was improved. Furthermore, immersing hydrothermal treated substrates in 5PBS(-) gave super hydrophilic surface with WCA < 10 deg.

Various ions in 5PBS(-) were adsorbed on the clean surface, and they provided hydrophilicity.

Substrates immersed in 5PBS(-) after hydrothermal treatment were subjected to *in vivo* testing (Fig. 1). The surface treated samples had very high BIC value and which were higher than anodized TiO₂ films¹. We have already reported that the hydrophilic surface adsorbed much cell-adhesive protein in the body selectively, such as fibronectin and Type I collagen³. It is thought that this promoted the production of hard tissue on the implants.

CONCLUSION

Surfaces of Ti, Nb, Ta, Zr and Ti alloys became hydrophilic by applying hydrothermal treatment after polished without anodizing. Furthermore, immersing hydrothermal treated substrates in 5PBS(-) gave super hydrophilic surface with WCA < 10 deg. and shown high osteoconductivity.

INTRODUCTION

Foot diabetic ulcers are characterized by an impaired wound healing. In some cases, the absence of wound closure leads to infection and amputation. Current treatments combine an antibiotherapy with the application of wound dressings¹. With the aim of improving the effect of antibiotics, research orientation is towards medicated dressings. Collagen-based biomaterials are broadly used to treat chronic wounds as collagen is biocompatible, biodegradable and favors wound healing. Nevertheless, drug content is rapidly released from current collagen materials because of their opened porosity. In this study, highly dense collagen matrices have been evaluated as novel medicated wound dressings for the treatment of foot diabetic ulcers.

EXPERIMENTAL METHODS

Collagen matrices were synthesized by gelation of collagen solutions concentrated at 5, 10, 20 or 40 mg/mL. Collagen matrices were called CM5, CM10, CM20 and CM40, respectively. Mechanical properties of matrices were assessed by rheological measurements. Their structure was analyzed by scanning (SEM) and transmission electronic microscopy (TEM). Dense collagen matrices were implanted in subcutaneous pockets in rat abdomen in order to study their biocompatibility. For this purpose, macrophages and neutrophils were detected on histological sections. Swelling abilities, resistance to collagenase digestion and water retention were evaluated over one week. Last, dense collagen matrices were loaded with ampicillin. Biological activity of ampicillin, released from collagen matrices, was evaluated on *Pseudomonas Auriginosa*. In parallel, cytotoxicity of matrices was studied on primary fibroblasts using Alamar blue test.

RESULTS AND DISCUSSION

Fig 1: (A) Structure of CM40 (SEM). (B) Inhibition of bacterial growth by ampicillin-loaded CM40 after 4 days.

The stiffness of collagen matrices increased with the collagen concentration. Improved mechanical properties were associated with the high fibrillar density and the fibril thickness observed in CM40. In addition, fibrils bundles were observed (Fig 1A). After subcutaneous

implantation in rats, collagen matrices exhibited different behaviours. Macroscopic views revealed a good stability of CM20 and CM40. In contrast, CM5 and CM10 were partially degraded after 30 days. The absence of macrophages and neutrophils on histological sections revealed the absence of severe host response regardless of collagen concentration.

Fig 2: Swelling properties of dense collagen matrices.

CM40 exhibited the best swelling abilities as they could absorb 20 times their dry weight in water. Compared to CM5, swollen CM40 retained water for a longer period than the other matrices. Last, dense collagen matrices (CM40) had the highest resistance against accelerated digestion by collagenase (Fig 3). When loaded with 10 mg of ampicillin, CM40 released efficient doses of antibiotics which allowed the inhibition of *P. aeruginosa* over 4 days (Fig 1B). In parallel, no cytotoxicity was observed on human fibroblasts.

Fig 3: Degradation of collagen matrices by collagenase.

CONCLUSION

Our study shows that dense collagen matrices could be used as medicated wound dressing for the treatment of diabetic foot ulcers. They can absorb exudates as they have high swelling properties. In addition, they can prevent infection by the delivery of antibiotics; they are biocompatible, biodegradable and are stable.

INTRODUCTION

The demand for medical implants expanded during the past decades owing to increased life-expectancy and changing lifestyles. With it, an urgent need for a new generation of biomaterials has upsurge, in particular to assist several orthopaedic and cardiovascular disorders, two infirmities annually affecting millions of patients^{1,2}. Zinc seems to be a promising biomaterial with a corrosion rate apparently adequate for tissue healing³. In human physiology this micronutrient is emerging as ubiquitous element able to modulate several important processes, among them the regulation of skeletal development and cardiac remodelling⁴.

As the failure of medical implants is often associated to chronic inflammation and infections, zinc ability to modulate inflammatory responses in the human body together with an antibacterial coating, like zinc oxide, can potentially improve the success of implants. To produce a zinc oxide coating in a zinc substrate, an electrodeposition procedure was used and the resulting films characterized.

EXPERIMENTAL METHODS

The electrodeposition was performed in a conventional three-electrode electrochemical cell, using Pt as counter electrode, SCE as reference electrode, Zn (99%) as working electrode (2.5 cm²), and 50 mM Zn(NO₃)₂ and 50 mM H₃BO₃ at pH 6 as electrolyte. The process was carried at room temperature in a Voltalab PGZ 100 potentiostat (Radiometer). A square-wave potential (-0.6V and -1.9V with the same pulse duration of 1 s and a total of 20 cycles) was applied. The microstructure and chemical composition of the deposited film was analyzed by scanning electron microscopy (SEM, Hitachi S2400) and energy dispersive X-ray spectroscopy (EDS, Bruker), respectively. Static contact angles of water were measured through the sessile drop method. Drops generated with a micrometric syringe were deposited on the surface, inside a chamber saturated with water. The images were obtained with a microscope (Wild M3Z) coupled to a video camera (JAI CV-A50). The analyses were performed 30s after the droplet deposition using the ADSA-P software (Axisymmetric Drop Shape Analysis-Profile).

RESULTS AND DISCUSSION

The electrodeposition of the film with the square-wave potential, when the potential was switched from -1.9V to -0.6 V, the cathodic current density abruptly increased because of the reduction of nitrate. After having reached the maximum of 5 mA cm⁻², the cathodic current density decayed as a result of a declining slope of the nitrate concentration profile

(Fig.1A). The resulting electrodeposited structures, composed of small laminas intersected in one another as shown in Fig. 1B, have an average width of 200 nm.

Fig.1. A) Applied potential (grey) and observed current density (black) during electrodeposition, B) SEM images of the resulting ZnO film.

The putative identification of zinc oxide was performed by EDS, where an increase in oxygen content was visible (Fig. 2). Further analyses are underway to confirm the presence of zinc oxide.

Fig.2. EDS mapping of ZnO film deposited on zinc, A) SEM image of ZnO crystal, B) EDS map of oxygen and C) EDS map of zinc.

Wettability, as an important property for cells adherence was evaluated. The resulting nanostructures did not change the water contact angle of pure zinc (92±4°).

CONCLUSION

The electrodeposition of nanostructured zinc oxide was successfully achieved in zinc. Further assays have to be performed to assess the immunoinflammatory modulation and antibacterial activity of the produced biomaterial.

The approach used in this work has good potential to improve bioresorbable materials for medical implants.

⁴IMR, Tohoku University, Japan, akahori@meijo-u.ac.jp

INTRODUCTION

Beta-type Ti-29Nb-13Ta-4.6Zr (TNTZ) was recently developed as a representative biomedical Ti alloy. As-solutionized TNTZ has a low elastic modulus of less than 60 GPa close to that of cortical bone along with very low cytotoxicity and good bone biocompatibility. Solution treatment and aging (STA) is a typical heat treatment for improving the mechanical properties of beta-type Ti alloys. However, STA also drastically increases the elastic modulus. Therefore, this study investigated the effects of fine particle bombarding, which is one of shot peening processes, on the mechanical properties of TNTZ subjected to more severe thermomechanical treatment in order to maintain a relatively low elastic modulus. The bone contact characteristics of TNTZ samples subjected to surface modification and cancellous bone were also compared.

EXPERIMENTAL METHODS

This study used cold-swaged TNTZ (working ratio: around 94%), which was designated as TNTZ_{SW}. TNTZ_{SW} was solutionized at 1063 K for 3.6 ks in a vacuum followed by water quenching (WQ); it was designated as TNTZ_{ST}. Some samples of TNTZ_{SW} were aged at 573 to 723 K in under aging conditions. Surface modification by a fine particle bombarding (FPB) machine was applied to some samples of TNTZ_{SW}, TNTZ_{ST} and aged TNTZ_{SW}; these specimens were designated as TNTZ_{SW}/FPB, TNTZ_{ST}/FPB and aged TNTZ_{SW}/FPB, respectively. Optical microscopy (OM), scanning electron microscopy (SEM), and X-ray diffraction (XRD) spectroscopy were carried out on each specimen to evaluate the microstructure. The Vickers hardness elastic modulus and the tensile and fatigue properties were investigated for each specimen to examine the mechanical properties. For the bone contact characteristics, some cylinder-type samples of TNTZ_{SW}/FPB and TNTZ_{SW} with mirror and as-machined surfaces were implanted into the femurs of Japanese white rabbits. All samples were extracted 12 weeks after implantation. The bone contacts were evaluated by image analysis.

RESULTS AND DISCUSSION

Figure 1 shows Vickers hardness profiles from very edge of samples of TNTZ_{SW} and TNTZ_{SW}/FPB to around 300 μm in depth on TNTZ_{SW}/FPB and TNTZ_{ST}/FPB. The Vickers hardness of the very edges for TNTZ_{SW}/FPB and TNTZ_{ST}/FPB showed the highest value, which is Hv 270 and Hv 235, respectively), and it tends to decrease

Fig. 1 Vickers hardness of ST/FPB and SW/FPB.

drastically as a function of distance from the surface to a depth of around 20 μm .

The fatigue strength of TNTZ_{SW}/FPB increased, especially in the high cycle fatigue life region. The fatigue limit of TNTZ_{SW}/FPB was around 400 MPa and around 100 MPa higher than that of TNTZ_{SW}. The Vickers hardness near the surface of the TNTZ_{SW}/m-SP specimen was around 200 Hv higher than that at the center of specimen, as noted above. As a result, the effect of residual compressive stress by FPB was marked in the high cycle fatigue life region.

In animal tests, TNTZ_{SW}/FPB had the highest bone contact ratio among the three kinds of sample, although the bone formation ratios of the three were almost the same.

CONCLUSIONS

- (1) The Vickers hardness of cold-swaged TNTZ subjected to fine particle bombarding was significantly increased within 20 μm from the very edge of the specimen surface.
- (2) The fatigue strength of TNTZ_{SW} subjected to fine particle bombarding increased in the high cycle fatigue life region only. The fatigue limit was around 400 MPa.
- (3) The bone contact ratio of TNTZ subjected to fine particle bombarding was better than that of TNTZ with the mirror surface.

Stoichiometric Control for Hydroxyapatite Thin Film Prepared by Pulsed Laser Deposition Technique

Hiroaki Nishikawa*, Ryota Yoshikawa

Fac. Bio.-Oriented Sci. and Technol., Kinki University, Japan, nishik32@waka.kindai.ac.jp

INTRODUCTION

Hydroxyapatite (HA), $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$, is a typical bioceramics with excellent bone conduction ability. We have demonstrated that pulsed laser deposition (PLD) technique can be used to coat materials with very high quality HA thin films that have high adhesion strengths¹. One of the greatest advantages of PLD technique is that the target has a similar chemical composition to the thin film. However, the chemical composition of HA thin films we previously grew slightly deviated from the stoichiometry. Energy-dispersive x-ray (EDX) analysis revealed that our HA thin films had a Ca/P ratio of approximately 2.0. Therefore, in the present study, we investigate the optimal PLD conditions for growing high quality HA thin films with a Ca/P ratio close to 1.67 (10/6) of the stoichiometric ratio. The chemical composition of films grown by PLD technique depends on the energy density² (fluence) and the spot size³ of the laser beam that irradiates the target surface. The spot size can be controlled by varying the distance between the focal lens and the target. Because the total energy of the laser beam can be varied independently of the spot size, the fluence and the spot size can be changed independently of each other.

In this study, we have investigated the effect of each fluence and spot size for the stoichiometric control for the HA thin films independently.

EXPERIMENTAL METHODS

The HA thin films were prepared by PLD technique with KrF excimer laser (wavelength = 248 nm, pulse width = 14 ns) on Ti plates. The target used was commercially available HA pellet (PENTAX CELLYARD). The substrate was room temperature. During the thin film growth, O_2 gas through water bath was introduced with the partial pressure of 1.0×10^{-1} Pa. The thickness of the HA thin film was 250 ± 25 nm measured by a stylus surface profiler (ULVAC Dektak 150).

In order to change the fluence and the spot size independently, we employed following procedure. Since the fluence is energy density of laser pulse on the target, it can be calculated that the laser energy irradiating the target is divided by the spot size. So, when the fluence is changed independent of spot size, only the laser energy is changed. On the other hand, when the spot size is changed independent of fluence, the focal lens of the laser is moved as shown in Fig. 1. With the controlled spot size, the laser energy irradiating the target is changed to keep the constant fluence. The chemical composition of the prepared HA thin film was measured by an EDX.

Fig. 1. Control of the spot size independent of the fluence.

Table I Measured Ca/P ratio of HA thin film with the various fluences and spot sizes.

Fluence [J/cm ²]	Spot size [mm ²]		
	0.77	1.6	3.8
2.0	2.1±0.2	2.0±0.1	1.9±0.2
2.7	2.0±0.1	1.9±0.1	1.7±0.1

RESULTS AND DISCUSSION

Four samples were prepared for each set of experimental conditions. Table I gives the average Ca/P ratio measured by EDX. The results show that increasing the spot size reduces the Ca/P ratio. Because the Ca/P ratio varies in a similar manner for both values of the fluence, the spot size was deemed to have a greater influence on the Ca/P ratio of HA thin films than fluence. Ohnishi *et al.* reported a change in the chemical composition²), but they simultaneously varied the spot size and the fluence. Thus, the present study is the first report of the independent effect of spot size on the chemical composition.

CONCLUSION

In order to prepare high quality HA thin film, we have noted to control the stoichiometry of the HA by the independent change of fluence and spot size. From the EDX measurement, it is found that the spot size can drastically control the Ca/P ratio as an important stoichiometry of the HA.

The Influence of PBS and Lactic acid on vacuum-sintered bodies of a novel apatite for artificial bone and tooth

Kenichi Tamura¹ and Tomohiro Uchino¹

¹College of Engineering, Nihon University, Japan, tamura@mech.ce.nihon-u.ac.jp

INTRODUCTION

Titanium medical apatite (TMA[®]: $[\text{Ca}_{10}(\text{PO}_4)_6]\text{TiO}_3 \cdot n\text{H}_2\text{O}$) is a novel apatite for biomaterials. TMA bodies sintered at 1000–1500°C were converted to mixtures composed of three crystalline materials, namely α -TCP (tricalcium phosphate), β -TCP, and Perovskite- CaTiO_3 . After sintering temperature at 1300°C, the TMA vacuum-sintered bodies were white and the density was approximately 2.3g/cm³ (corresponding to that of a compact bone or a tooth). Further, it was possible to cut the TMA bodies into various forms with a cutting machine. On the other hand, the implants made from TMA vacuum sintered at 1300°C were inserted into a rabbit jaw bones. After one month, the TMA implants were well tolerated by the surrounding tissue, and no adverse tissue reactions were seen in any of the sections. The outer surface of TMA implants were covered by new bone formation because of the high biocompatibility of the TMA vacuum-sintered bodies [1-4]. An international patent on “Sintered body of titanium compound,” i.e., “TMA sintered body,” have in the United States, Canada, Australia, Japan, South Korea and China.

In this study, we have investigated the pH on TMA vacuum-sintered bodies using PBS and Lactic acid solutions by the in vitro.

EXPERIMENTAL METHODS

Materials are TMA vacuum-sintered bodies at 1300°C, $\times 10^{-3}\text{Pa}$ and HAp atmosphere-sintered bodies at 900°C using a resistance heating furnace. Test specimens are the disk (11mm in diameter \times 1.5mm in length). TMA bodies for the artificial bone are soaked PBS (-) solutions within 28 days. On the other hand, TMA bodies for the tooth are soaked Lactic acid solutions of pH2, pH3 and pH4 within 128 hours. The pH adjusts dilute the undiluted Lactic acid solution with pure water. So, pH2=500mM, pH3=6.40mM and pH4=0.21mM. Solution amount into the centrifuge tube has 30 ml per a specimen. Temperature of the centrifuge tube is kept 37°C using drying chamber. Tests carried out 3 times.

RESULTS AND DISCUSSION

Figure 1 show Relationships between pH and soaking time of TMA and HAp specimens into PBS solutions (pH7.4). The pH of TMA vacuum-sintered bodies and HAp atmosphere-sintered bodies were stable at pH7.4 solutions until 28 days. From this result, we think that TMA vacuum-sintered bodies were use as artificial bone materials to regenerate bone parts and produce bone reinforcement structures.

Figure 2 show Relationships between pH and soaking time of TMA specimens into Lactic acid solutions. The pH increase approximate 1.1 in the pH 2 solution, approximate 1.7 in the pH 3 solution and approximate

2.6 in the pH 4 solution. The change value is large as large pH because the molecular formula of Lactic acid: $\text{C}_3\text{H}_6\text{O}_3$. Lactic acid has both weak acidity of COOH and alkalinity of OH^- . So, the pH4 of diluted solution moved for alkalinity side. Test specimens are little melted the pH2 and pH3, but didn't melted the pH4.

Sol-gel assisted preparation of collagen hydrolysate scaffold: A Novel biomaterial for the treatment of chronic wounds

Satiesh kumar Ramadass[#], Sathiamurthi Perumal and Balaraman Madhan^{*}

¹CSIR- Central Leather Research Institute, Chennai-20, Tamil Nadu, India

[#] ramsatiesh@gmail.com

INTRODUCTION

Collagen based biomaterials remains as a treatment of choice for chronic wound therapy. Multi-step extraction procedure of collagen at cold condition indirectly increases cost of the collagen based biomaterial. In addition, low therapeutic loading of collagen due to its limited solubility, less porosity and ease collagenase degradation emphasize the need of developing a better therapeutic alternative and cost effective collagen based biomaterial. Collagen hydrolysate, an enzymatic hydrolyzed product of collagen contains peptides having beneficial properties such as stimulatory collagen synthesis, haemostatic property, tissue adhesiveness, maintaining moisture balance and antimicrobial property emphasize the need of developing collagen hydrolysate based wound dressing. The preparation of collagen hydrolysate would be simple, cost effective and it does not require multi-step extraction procedure. Therefore, the approach of using collagen hydrolysate as a main constituent in the scaffolding was proposed and composite material design adopted for sponge fabrication.

EXPERIMENTAL METHODS

Collagen Hydrolysate Composite Scaffold (CHCS) was fabricated through sol-gel transition methodology using tetraethoxysilane as silica precursor. The scaffold was characterized for morphology, porosity, water uptake capacity, enzymatic stability, biocompatibility and antimicrobial activity. *In vivo* study was experimented in rats using full thickness skin excision wound healing model.

RESULTS AND DISCUSSION

Rheology observation confirmed the increases in viscosity and sol-gel transition of CHCS composite solution. SEM morphology of CHCS scaffold revealed that the scaffold is porous with pore size ranging from 380 to 760 μm with an average pore size of 596 μm . CHCS showed controlled collagenase degradation and better water uptake capacity compared to the collagen scaffold. *In vitro* culturing with 3T3 Fibroblast cells showed that the CHCS could significantly promote the proliferation of cells compared to the collagen scaffold. Interestingly, CHCS exhibited inherent antimicrobial activity against tested wound pathogens. *In vivo* study demonstrated significant acceleration of wound healing treated with CHCS compared to the collagen sponge dressing.

CONCLUSION

The conclusions have to be based on the facts in CHCS scaffold exhibited better property compared to collagen scaffold in terms of porous morphology, biostability, water uptake capacity and biocompatibility. The antimicrobial activity of collagen hydrolysate is a great value addition for CHCS in treating infectious chronic wound. Against these findings, the CHCS sponge has a potential as a candidate for the treatment of chronic wound

Stress and Deformation in a Sutured Tendon Repair; an *in silico* Model

S D Rawson¹, L Margetts², J K F Wong³ and S H Cartmell¹

¹School of Materials, University of Manchester, UK, shelley.rawson@postgrad.manchester.ac.uk

²School of Earth, Atmospheric and Environmental Sciences, University of Manchester, UK

³Plastic Surgery Research, University of Manchester, UK

INTRODUCTION

Many suture repairs have been described to re-approximate severed tendons, yet no one repair is regarded as the gold standard. At present, 25% of hand tendon repairs do not obtain satisfactory mobility following healing, and over 7% of repairs re-rupture (1). Concluding the ideal suture repair would benefit over 800,000 people in the UK who suffer tendon injury per annum (2). Finite element (FE) modelling enables detailed stress analysis of implantable devices and materials for tissue regeneration. However, the *in silico* model is limited by the description of biological tissues. Past 2D (3) and 3D (4) isotropic descriptions of tendon are unsuitable for modelling complex suture repair geometry. As such, the aim of this work was to mathematically describe tendon tissue, informed by *ex vivo* tensile testing, to model and compare stress patterns arising due to various suture techniques.

EXPERIMENTAL METHODS

Porcine flexor digitorum profundus (FDP) tendons (n=12) were sliced 5mm wide and 2mm thick and loaded transverse to the long tendon axis in an instron 5569 load frame using Bose tissue grips placed 2.5mm apart. Strain was applied at 1%/s until failure. Stress and strain were calculated, followed by the transverse modulus and matrix modulus.

Fibril modulus (200-3000MPa; 5,6) was obtained from literature and the matrix modulus was calculated using the rule of mixtures for a continuous fibre composite. An idealised finite element model of tendon microstructure was developed (Fig. 1) and material properties were varied within the model, approaching those obtained experimentally. Homogenisation was performed to deduce the engineering constants which represent the microstructure model. This was then input into an FE model of a Kessler suture repair and suture loading was simulated. Results were validated against *ex vivo* tensile tests of sutured tendons (n=10).

Fig. 1 FE tendon microstructure model, detailing model properties and dimensions.

RESULTS AND DISCUSSION

Tensile testing of the porcine FDP tendon yielded a transverse young's modulus ranging from 0.1035 ±0.0454MPa to 0.2551 ±0.0818MPa and a matrix modulus ranging from 0.0416MPa to 0.1021MPa.

As matrix modulus tends towards the experimentally determined values, FE results agree closer with laboratory data (Fig. 2.a). A higher matrix modulus results in a circular high stress region at the suture anchor point (See orange region in Fig. 2.b). As matrix modulus is reduced, and the material description approaches the highly orthotropic behaviour of tendon tissue, we see an elliptical high stress region (Fig 2.c). The elliptical high stress area agrees with areas of acellularity observed in a murine *in vivo* study (7) suggesting the acellular zone results from high stress.

Fig. 2 (a) FE results with varying matrix properties compared with lab results. (b) Stress map when matrix modulus is 100MPa and 0.5mm gap between tendon ends is simulated. (c) Stress map when matrix modulus is 1MPa and 0.5mm gap between tendon ends is simulated.

CONCLUSION

We have developed an FE model of sutured tendon repair suited to identifying regions of augmented stress within the tendon that would adversely affect tissue health. High stress regions resulting in acellularity, and areas of stress shielding which affects tissue remodelling can be identified.

INTRODUCTION

Peptide-based hydrogels are 3D fibrillar network, where fibres are formed by the self-assembly of short purposely designed peptides. One of the key challenges is the control of the mechanical properties and stability of these materials in order to expand their potential range of applications. In our group we have developed a platform for the design of such hydrogels through the exploitation of the self-assembly of so-called β -sheet forming peptide. In this project we will explore the possibility of using chemically cross-linked peptides to control of the mechanical properties and stability of these hydrogels (Fig 1).¹ Two cross-linking strategies based on the use of cysteine-containing peptides will be explored: disulphide bridging and Maleimide cross-linking.

EXPERIMENTAL METHODS

Solid Phase Peptide Synthesis: peptides, typically 8 amino acids long and based on the alternation of hydrophobic and hydrophilic residues, will be synthesized on a CEM LibertyTM automated microwave peptide synthesizer using standard solid phase synthesis protocols.

Peptide Cross-linking: The cross-linked peptides will be synthesised by treating the cys-containing peptide solutions with NaI and H₂O₂ (disulphide bridging) or dibromomaleimide/N-substituted dibromomaleimide pre-dissolved in the minimal volume of DMF (Maleimide cross-linking). The precipitated cross-linked products will be collected by filtration.

Hydrogels preparation and characterisation: Hydrogels will be prepared by dissolving the peptides (cross-linked and non-cross-linked) in water as described

previously^{2,3}. The hydrogels will be characterised using a range of techniques including rheology and microscopy.

RESULTS AND DISCUSSION

The gelation properties of the cross-linked peptides investigated as a function of peptide concentration allows us to understand the effect that cross-linking. In particular the effect of the position of the cross-link along the peptide chain, has on self-assembly and gelation properties of these peptides.

Characterisation of the effect of introducing cross-linked peptides in the hydrogel made from our usual peptides (FEFKFEFK)³ shows that the ratio between cross-linked and non-cross-linked peptides is important for the self-assembly process.

CONCLUSION

This project will allow us the possibility of using a simple peptide cross-linking approach to manipulate and control the properties of the peptide hydrogels expanding their potential uses, in particular in the biomedical field

Calcium phosphate spheres incorporated into PMMA cement for enhanced antibacterial properties

Tao Qin, Alejandro López, Caroline Öhman, Håkan Engqvist, Cecilia Persson, Wei Xia

Department of Engineering Sciences, Uppsala University, Sweden
Tao.qin@angstrom.uu.se

INTRODUCTION

Infection at the site of an implant is a rare but potentially devastating complication, which could lead to painful disability, prolonged hospital stay and increased medical expenses. Antibiotic-loaded bone cement has been found to play a crucial role in the prevention and treatment of infection during and after arthroplasty^{1,2}. However, the present drug release from PMMA cements is not optimal. An increase in the release rate, after the initial burst release, would be beneficial. In this study calcium phosphate spheres were incorporated into PMMA cement in order to increase the rate of drug release. Mechanical properties, radiopacity and injectability were also investigated.

EXPERIMENTAL METHODS

Strontium doped calcium phosphate spheres (SCPS) were prepared in accordance with a previous study⁴. PMMA cements were prepared containing 2.5% of vancomycin, with and without 10% SCPS (wt% of powder). The release of vancomycin was carried out in PBS solution (pH 4 and pH 7.4) and samples were extracted at different time points (0.5 hour to 7 days). The antibiotic concentrations were measured at a wavelength of 280 nm, using UV-Vis spectrophotometer (Shimadzu UV1800, Kyoto, Japan). The mechanical properties were tested using AGS-H materials tester (Shimadzu, Kyoto, Japan). A displacement rate of 20mm/min was used. Injectability was investigated with an injection device which was placed in the materials tester and compressed at a displacement rate of 3 mm/min. Radiographs of the cements were taken of three specimens, 1mm in height and 5mm in diameter, per group at 80kv using MicroCT (Skyscan 1172, Bruker, Kontich, Belgium). The radiopacity was calculated using a standard curve (amount of light vs mm Al) created from an aluminum scale (0.5-4mm).

RESULTS AND DISCUSSION

Figure 1 shows that all groups gave an initial burst release during the first few hours, which was followed by a sustained release over the entire period investigated. When SCPS and vancomycin were mixed with PMMA, the modified cement showed a higher release rate of vancomycin. Incorporation of SCPS into cement may create more room for vancomycin to be easily released. In acidic environment, the release rate was higher since it facilitates the dissolution of SCPS. The incorporation of SCPS did not change the mechanical strength of the cement. The setting time was slightly increased for the PMMA/SCPS cement, but still in an acceptable range. The relative radiopacity of PMMA/SCPS was significantly higher than that of unmodified PMMA.

Figure 1 Cumulative releases of vancomycin in PBS

Figure 2 Morphology of SCPS (A) and Cross-section images of PMMA cement before (B) and after (C) drug release (pH 4).

CONCLUSION

After incorporation of SCPS, antibiotic-loaded PMMA cements showed enhanced antibiotic release while maintaining their mechanical properties, which suggests that this material could be advantageous in comparison to regular PMMA cement for the prevention and treatment of infections.

MP-SPR New characterization method for interactions and ultrathin films

Annika Jokinen, Niko Granqvist, Willem M. Albers and Janusz Sadowski

BioNavis Ltd., Finland
annika.jokinen@bionavis.com

Please download and read the instruction sheet to ensure all necessary formatting and abstract criteria are adhered to.

INTRODUCTION

Surface Plasmon Resonance (SPR) has been used already for a few decades for label-free detection and characterization of biochemical kinetics and affinities of many different types of analytes. The physical phenomenon is not limited to biochemistry, but is applicable to other nanoscale characterization of thin films¹.

EXPERIMENTAL METHODS

Aside of the traditional interactions, Multi Parametric Surface Plasmon Resonance (MP-SPR) can be utilized to determine unique refractive index (*RI*) and thickness (*d*) of ultrathin (*d* 0.5-100 nm) and slightly thicker films (*d* 300 nm- few μ m) without prior assumptions of the *RI* of the material. These are important properties not only for thin film coating industries and applications, but also for gaining important knowledge in biomaterials. Two methods utilizing MP-SPR to thickness and *RI* calculations have been introduced, either measuring in two different media (2M) with high *RI* difference, such as air and water¹⁻³, or at two or more different wavelengths (2W) of light^{2,3} in order to characterize properties of the thin films.

RESULTS AND DISCUSSION

MP-SPR is suitable for film deposition *in situ* or *ex situ*, which makes it compatible with several deposition methods and thereby makes it applicable to a wide range of polymers also. Polyelectrolyte multilayer deposition *in situ* was monitored in real-time with MP-SPR. Thickness of each deposited layers was determined utilizing two wavelength method (Fig.1).

Similarly layer thickness and *RI* was determined also for *ex situ* spin coated cellulose layer. MP-SPR was used not only to determine thickness and *RI* of the deposited layer but also for real time monitoring of other molecules interaction to the cellulose model surface^{4,5}.

Recently, MP-SPR was used also to monitor polymer layer structural changes in real time, such as polymer

swelling due to pH or electric potential change⁶. At pH = 9 poly (acrylic acid) (PAA) brushes were extended but the brushes collapsed at acidic pH (Fig.2).

Fig1. Polyelectrolyte multilayer thickness and *RI* was determined with MP-SPR utilizing multiple wavelength method. Full angle range SPR curves before and after layer deposition.

CONCLUSION

With the ability to characterize both kinetics and nanoscale layer properties, MP-SPR proves to be a versatile tool for nanomaterial, biomaterial and biochemical interactions research, which makes MP-SPR invaluable for multidisciplinary research, where both physical and interaction properties of the materials need to be characterized.

A Dimensionless Number for Electrospinning

William W. Sampson

School of Materials, University of Manchester, Manchester, UK
sampson@manchester.ac.uk

INTRODUCTION

Electrospinning of biocompatible polymers to yield heterogeneous fibre networks for application as scaffolds for tissue engineering is widely researched. Essentially the process of electrospinning is one of splitting a jet of dissolved polymer and extending the resultant filaments to produce very fine fibres in a disordered network on a collector. The process variables affecting fibre morphology and hence network structure include, but are not limited to: solution concentration, flow rate, voltage, surface charge, syringe needle diameter¹.

Typically, for electrospun scaffolds, we seek to optimise the pore dimensions and the specific surface of the resultant network. Theory describing the special case of *random* fibre networks, *i.e.* those where the location and orientation of any fibre is independent of all others, is well established and has been widely applied in many contexts².

Importantly, the dependence of pore size and specific surface on fibre dimensions and network densities are known and the primary variables of interest are the cross-sectional dimensions of fibres and the expected total fibre length per unit volume in the network³. As such, a useful descriptor of the efficiency of an electrospinning process would be a single number that quantifies the total fibre length generated by that process, relative to the volume of polymer solution delivered. Here we introduce a dimensionless number that provides this quantification.

THEORY

Consider a volume of polymer solution, V (cm³) with concentration, c (g cm⁻³) delivered via a syringe. If the diameter of the jet after the Taylor cone is d_j (μm), then total length of the solution delivered from the syringe is

$$L = \frac{4V}{\pi d_j^2}, \quad (1)$$

and the mass per unit length, or *linear density*, of the jet, on a dry basis, is

$$\delta = \frac{cV}{L} = \frac{\pi d_j^2 c}{4}. \quad (2)$$

Similarly, if the constituent fibres in the resulting network, have mean diameter, \bar{d}_f (μm), and the dry polymer has density, ρ_p (g cm⁻³), then their linear density is

$$\delta^* = \frac{\pi \bar{d}_f^2 \rho_p}{4}. \quad (3)$$

The ratio of the total fibre length in the mat, L^* , to that delivered from the jet provides our dimensionless number to characterize the electrospinning process; it is

easy to show that this is given by the ratio of the linear densities, *i.e.*:

$$\eta = \frac{L^*}{L} = \frac{\delta}{\delta^*} = \frac{\bar{d}_j^2 c}{d_f^2 \rho_p} \quad (4)$$

The dimensionless number, η provides a new variable against which measurable parameters of electrospinning processes can be compared. We know, for example, that the applied voltage and the distance from the syringe to the collector influence the dimensions of electrospun fibres and hence the properties of the network. If these result in different η , then we know that they have had a different net effect on the structure. The approach is illustrated by example in Figure 1 for the data of Wang *et al.*⁴; the gradients of the plots represent the number, η , with the steeper gradients representing the more efficient electrospinning process.

Figure 1. Data of Wang *et al.*⁴ for changes in solvent, collector distance and concentration for electrospun polystyrene.

CONCLUSION

A simple theoretical treatment has been presented to obtain a dimensionless number quantifying the efficiency of electrospinning processes. Preliminary comparison with experimental data from the literature suggests that this number may aid interpretation of the relative influence of the many variables affecting electrospinning, thus focussing experimental effort. Comparison of the theory with larger experimental data sets is ongoing.

INTRODUCTION

Chitosan (Chi) coating on titanium (Ti) implant surfaces have been proposed over the last decades to improve antimicrobial properties against peri-implantitis [1,2]. However, the attachment and stability of Chi coatings under drastic environments like the oral cavity have proven to be highly influenced by different factors such as pH value variations [3]. In this work, attention was mostly devoted to elaborating and evaluating a novel bioactive coating process to maintain greater Chi surface immobilization to withstand variations in the oral environment.

EXPERIMENTAL METHODS

Functionalization of Ti Surface. Ti foil samples were cleaned oxidized in fresh piranha solution and silanated by immersion in triethoxysilylpropyl succinic acid anhydride (TESPSA) in extra-dry toluene (v/v, 10/90) for 24 h. A biopolymer solution containing 4 wt.% Chi), 3% (v/v) acetic acid, and 97% (v/v) deionized water was grafted on the surface by dip coating. The Chi coated samples were then dried at 80  C for 24 h.

Titanium-coated Surface Chemical Properties. To evidence the Chi presence and resistance of coating on the substrate, infra-red (ATR-FTIR) and X-ray photoelectron (XPS) spectra were recorded at different pH levels (3 and 5) in saliva.

Adhesive Properties of Coating. The adhesion strength of the TESPSA/Chi coating on the Ti surface was observed by peel test. Standard adhesive tape was put on the pattern and pulled off at an angle of 180  . Results were compared with surfaces coated by simple dip deposition.

In vitro Analysis. Human gingival fibroblast-like (HGF-1) cells were seeded (1×10^4 cells/scaffold) onto Ti surfaces for 24 and 72 h. Actin microfilaments and cell nuclei were stained by immunostaining at room temperature. Image series were obtained with FV10i a confocal laser scanning biological inverted microscope.

RESULTS AND DISCUSSION

By XPS analysis, successful grafting of TESPSA on the Ti surface was indicated by the decrease in the Ti components and the arrival of Si components. Moreover, the presence of Chi is confirmed since the recorded spectrum presents at around 285.5, 399.3 and 532.5eV which are characteristic of the C1s, N1s and O1s Chi photoelectron peaks. After immersion in pH5 and pH3 solutions, the peak at 399.3eV which was assigned to N1s was still present for both immersions. The chitosan coating was also highlighted by ATR-

FTIR. The peaks at 1070, at 1011 and at 887 cm^{-1} are attributed to the saccharide structure of Chi [4]. Both of the added FTIR-ATR spectra showed equivalent signatures, meaning that Chi chains were still present on the sample surface even after acidic immersion. The peel-test revealed that at the samples coated by simple dip deposition, a large part of the coating has been removed, thus revealing the naked Ti substrate. By contrast, the TESPSA/Chi grafting is entirely stuck to the Ti surface. HGF-1 cell growth on uncoated and coated Ti implant surfaces respected their normal morphology following the 3 days of incubation (Fig. 1). The morphology of cells in contact with the TESPSA/Chi coated substrate was similar to that in contact with the uncoated titanium.

Fig.1. Confocal images of HGF-1 morphology: (a, c) and (b, d) cells cultured on uncoated and TESPSA/Chi Ti surfaces for 24 and 72 h, respectively. Scale bar = 50  m.

CONCLUSION

We have performed a biocompatible TESPSA/chitosan coated implant surfaces with chemical resistibility due to stable peptide bindings in a hostile environment such as in the oral cavity.

Ex vivo osteo-chondral organ culture

Andrea Schwab, Jenny W Reboredo, Heike Walles

Tissue Engineering & Regenerative Medicine, University Hospital Wuerzburg, Germany

andrea.schwab@uni-wuerzburg.de

INTRODUCTION

Cartilage is an avascular and highly organized tissue that limits the regeneration capacity of (large) defects.

Intensive research has been performed in the development of functional cartilage implants that mimic the zonal tissue structure that is comprised of the following layers (Figure 1): superficial zone, middle zone, deep zone and calcified layer.

Up to now, successful tissue engineering (TE) strategies and clinical techniques in cartilage repair remain a major challenge as they only lead to insufficient tissue repair without maintaining the cartilage functionality and hierarchy.

Beside the cartilage tissue itself the sub-chondral bone and the synovial fluid may have an important role in cartilage regeneration. Pre-clinical testing of cartilage implants as well as new treatments in an osteo-chondral environment is needed to validate new healing approaches.

Therefore we want to establish a 3D osteo-chondral test system that incorporates TE scaffolds within an ex vivo environment. This more physiological in vitro cartilage defect model will allow predictive long term results on cartilage regeneration and repair therapies.

EXPERIMENTAL METHODS

Standardized and reproducible osteo-chondral explants (plugs) were isolated from porcine femoral condyles.

The explanted plugs were trimmed to a defined height, embedded in agarose and cultured in a 12-well plate under static conditions up to 4 weeks.

Cell vitality within the plugs was analyzed weekly over a period of 4 weeks via 3-(4,5-Dimethylthiazol-2-yl)-2,5-Diphenyltetrazoliumbromid (MTT). During static culture the supernatant of selected plugs was collected to measure LDH content. The plugs themselves were characterized immunohistologically with cartilage (collagen I, II, X, aggrecan (aggr), RUNX2, SOX9) and bone (bone sialo protein (BSP), osteopontin (OP), osteocalcin (OC)) specific antibodies as well as by histological stainings, such as Safranin-O and Alcian Blue. Biochemical analysis of the Glycosaminoglycan (GAG), DNA- and collagen content was performed of the cartilage layer at several time points during static culture.

Critical point drying of static cultured plugs was performed at several time points to analyze the characteristic structure of the plug by raster electron microscopy (REM).

RESULTS AND DISCUSSION

After cutting the plugs into half, the host cells of the explant reduced the MTT reagent to the blue formazan product for at least 4 weeks of static culture.

The histological stainings (Figure 1) clearly show the zonal architecture of articular cartilage. Within the different layers of the cartilage the chondrocyte density varies. Following, the GAG content of the superficial zone is diminished compared to the quantity in the deep zone.

Figure 1: Safranin-O (left) and Alcian Blue (right) staining of a decalcified osteo-chondral plug at day 0; Scale bar 100µm

The normalized GAG content in cartilage part of the plug remained stable over more than 1 week. Histological analysis has shown positive expression of the bone markers BSP, OP, OC. Beside the SOX9 immune histological staining all other cartilage markers (collagen I, II and X, aggr, RUNX2) could be observed. During culture time the structural changes within the bone part of the plug were monitored.

CONCLUSION

Cutting edge bioreactor systems will improve the in vitro culture conditions and allow long term plug culture under more physiological cues up to 6 weeks. For this reason we need to give consideration to mechanotransduction.

Regarding the limited diffusion of the MTT reagent into the core of the plugs the diffusion of nutrients and removal of waste products will be characterized in more detail by µCT and MRI. Data obtained from REM, µCT, MRI and experimental results of plug culture will be used as input for the developing of a mathematical model. The in silico model will allow the simulation of biochemical and biophysical processes within the plug and contribute a better understanding of the different processes in the defect healing as well as in nutrition supply to keep the explant culture vital.

The establishment of the predictive 3D in vitro assay for (sub-) chondral implants requires the validation of the outcomes from our test system against in vivo models.

INTRODUCTION

Calcium phosphate (CaP) bioceramics are widely used as pre-shaped bone graft for bone fracture treatment. However their brittleness, low reliability and toughness, limit their application¹. The main strategy to improve these limitations is to produce bone grafts with a core CaP phase, reinforced with a thin layer of a tough synthetic polymer, which was reported to have low degradation and reduce cell adhesion². Natural polymers, like alginate, are suitable for tissue engineering, thanks to their ease of gelation, excellent biodegradable and cell interaction properties³. Our approach was to develop directly a new structured biocomposite bone graft, composed of TCP/Alginate, by using a modified layer by layer low temperature 3D powder printing process (3DP)⁴.

EXPERIMENTAL METHODS

Four different powder mixtures were investigated, consisting of TCP (T) and different amounts of alginate (Alg), 2.5wt%, 5wt% and 7.5wt% (T2.5Alg, T5Alg, T7.5Alg). Sample manufacturing was performed with a 3DP system (Z510, Z-Corporation) using the powder mixtures and a phosphoric acid as binder. After printing, the samples were treated with binder solution. Different dense samples were prepared. Phase composition was evaluated by X-ray diffraction. Arquimedes porosity (ϕ), X-Ray microcomputed tomography (μ -CT) and SEM were used for sample characterization. Mechanical properties were evaluated under uniaxial compression (UC), three point flexure (3PF) and diametral compression (DC) tests, in dry conditions and in PBS buffer solution at 37°C, for 1, 7 and 14 days (wet14). Stress states were represented in Mohr's plane, and materials intrinsic strength determined (Fig 1). Weibull distribution parameters were estimated using the maximum likelihood method, and material toughness was evaluated by the strain energy density, U_0 , determination.

Figure 1: Schematic Mohr's plane, representing TAlg intrinsic strength curve and respective intrinsic strengths, σ_0 and τ_0 .

RESULTS AND DISCUSSION

3D structured TAlg samples were successfully printed. μ -CT (Fig 2), enabled us to access the microstructure differences of T and TAlg samples. Porosity decrease for T2.5Alg sample and increase with the content of Alg, being a function of Alg gelling efficiency. Intrinsic

strengths (Fig 3a) and toughness (~ 50 -70%) greatly improve for the T2.5Alg sample in dry tests. For immersed tests the intrinsic strengths are lower, but the verified improvement remains and keeps uniform over the 14 days of evaluation. Weibull analysis revealed that the sample reliability slightly lowered with Alg introduction (Fig 3b). Achieved mechanical properties for T2.5Alg are in the upper limit of the reported mechanical properties of the human trabecular bone.

Figure 2: μ -CT reconstruction showing microstructure organization of a) T ($\phi=49\%$) b) T2.5Alg ($\phi=32\%$) c) T7.5Alg ($\phi=37\%$)

Figure 3: a) Intrinsic strengths as function of powder mixture and testing condition. b) Weibull modulus as a function of powder mixture, testing technique and condition.

CONCLUSION

As far as we know this is the first time report about the successful direct fabrication of structured 3D biocomposites of T and Alg, by 3DP. Alginate inclusion within the ceramic matrix, enhances the mechanical limitations addressed to the standard used ceramic bone grafts, and also preliminary biological tests evidence improvements in biological properties. These results suggest that 3DP powder printing of TCP/alginate biocomposites is a promising strategy for bone tissue regeneration.

Surface modification of Ti-6Al-4V alloy controlling OCP nucleation by electron cyclotron resonance plasma oxidation

Hiroshi Masumoto¹, Mayumi Oikawa², Yusuke Orii², Takahisa Anada², Osamu Suzuki² and Keiichi Sasaki²

Frontier Research Institute for Interdisciplinary Sciences (FRIS), Tohoku University, Japan¹

Graduate School of Dentistry, Tohoku University, Japan²

hiromasu@fris.tohoku.ac.jp

INTRODUCTION

Ti-6Al-4V alloy is used by dentistry and orthopedics as an implant material, since it is excellent in biocompatibility or mechanical property. It is known that the biocompatibility of Ti will change with the condition of the surface oxide (titania: TiO₂) film of implant Ti alloy. However, since the thermal expansion difference of Ti and TiO₂ is large, it is difficult to deposit the good TiO₂ film on Ti alloy at low temperature for a short time. Electron cyclotron resonance (ECR) plasma is high-active plasma, and high-quality crystalline films can be obtained at low temperature for short time. ECR plasma oxidation is effective surface modification of metal Ti for biocompatibilities, which became clearly in previous study^[1]. Our previous studies indicated that implantation of octacalcium phosphate [Ca₈H₂(PO₄)₆ · 5H₂O, OCP] was efficiently enhanced bone regeneration compared to HAp^[2]. In the present study, TiO₂ films were deposited on Ti-6Al-4V alloy by ECR plasma oxidation, and the effect of oxidation conditions on structure and precipitation behavior of OCP were investigated.

EXPERIMENTAL METHODS

ECR plasma apparatus was used for oxidation of Ti-6Al-4V alloy surface (10 x 10 x 1.0 mm³). A magnetic field (8.75x10⁻² T) was applied to the plasma chamber to satisfy the ECR condition. The microwave power was 900 W. The oxygen gas pressure during ECR oxidation was set to 0.003 -1.5 Pa and the oxidation time was set to 1.8ks. An infrared lamp was used for controlling the substrate temperature in the range from room temperature (RT) to 600 °C.

OCP was precipitated in phosphate-buffered solution on TiO₂ film deposited Ti substrate^[2]. The calcification ability was estimated by weighing the substrate before and after

the immersion. The structure and morphology of the films were characterized by X-ray diffraction analysis (XRD) and optical and scanning electron microscopy (SEM).

RESULTS AND DISCUSSION

Fig. 1 shows XRD patterns of the substrates that were oxidized by ECR plasma at various temperatures. Crystalline rutile-type TiO₂ films were obtained above 400 °C. The amount of rutile TiO₂ increased with increasing oxidation temperature. The ECR plasma was significantly effective to prepare crystallized TiO₂ films at low temperatures.

Fig. 2 shows macroscopic images of calcium phosphate deposits formed on the Ti-6Al-4V alloy substrate after ECR plasma oxidation at 400°C. Mixtures of OCP and dicalcium phosphate dihydrate (DCPD) peaks were observed after calcification. Whole surface was covered by Many flocculent precipitates of calcium phosphate. The amount of OCP and DCPD after calcification increased with increasing total pressure (P_T) from 3.3x10⁻³ - 1.5x10⁻² Pa, and showed the maximum at P_T = 1.5x10⁻² Pa.

Fig. 3 shows the effect of the oxidation temperature and time on calcium phosphate deposition onto the substrate surfaces. The amount of calcium phosphate deposition was maximized at 400°C.

It was suggested that ECR plasma oxidation method is effective surface modification for the Ti-6Al-4V alloy , because of their calcification ability.

Introduction

The human being peripheral nerve has strong regeneration potentiality. The disrupted peripheral nerve could successfully regenerate if a proper environment were provided. There are certain limits for autografts, To overcome those disadvantages, artificial nerve scaffold has been developed [1]. Since the surface to volume ratio in electrospinning nanofibers is high, using them in neural tissue engineering [2]. In this research, 3D PLGA/Gelatin nanofibrous scaffolds were prepared by electrospinning method. We selected 2,2,2-trifluoroethanol as solvent to dissolve both synthetic and natural polymer with organic and aqueous basis, respectively.

Materials and methods

The experimental polymer composite solutions were prepared by dissolving PLGA and gelatin with the weight ratio 8:2 and concentration of 15% w/v in TFE. The mixture was stirred for 12 h room temperature to obtained homogeneous composite solution for electrospinning. The resulting biological and structural effects were evaluated using a range of methods including SEM images, porosity, cell culture, MTT assay.

Results and discussions

Fig. 1 shows the SEM images of electrospun nanofibrous PLGA/gelatin scaffolds. It illustrated nanofibers possessed smooth without bead defects with the average fiber diameters of 924nm and 777nm with injection rate 0.1 and 0.2 $\frac{ml}{hr}$, respectively. nanofibers diameter decreased with the addition of gelatin, because of increased the charge density of the solution which improved the stretching force and self repulsion of the jet, in addition decrease porosity of scaffolds. Increasing flow rate causes decreasing fiber diameter, so it can increase strength. The porosity of scaffolds was approximately 90%, indicating that they were beneficial for the adherence and proliferation of the cells. The cell proliferation (L929) of nanofibers with the injection rate of 0.2 $\frac{ml}{hr}$ after 2 and 7 days of cell culture are shown in Fig. 2. After 2 day, the cell adhered well randomly on the surface of all electrospun scaffolds. After 7 day, more cells were clustered around the nanofibers Initial cell adhesion could be affected by the surface hydrophilicity of scaffold. Figure 3 illustrate Cytotoxicity and biocompatibility of samples 2 and 7 days after cell culture. It shows increasing the number of cells in control samples (polystyrene plates) and test

samples. There was no significant difference between number of cells and rate of growth in samples.

Fig. 1. Morphology of PLGA/gelatin scaffolds with injection rates 0.1 $\frac{ml}{hr}$ (A) and 0.2 $\frac{ml}{hr}$ (B)

Fig. 2. Morphology of fibroblast on PLGA/Gelatin nanofibers after 3 (A) and 7 (B) days.

Fig. 3. Result of MTT assay

Conclusion

In this study, randomly PLGA/G scaffolds were fabricated through electrospinning. PLGA improve the mechanical properties. Gelatin causes hydrophilic structure and can improve the water absorption but decrease mechanical properties. The addition of gelatin enhanced the adhesion and proliferation of the cell. Scaffolds have about 90% porosity and Fiber diameter changes with changes in flow rate. In addition, morphology showed smooth and bead free surface feature of nanofibers.

INTRODUCTION

Chemotherapy is among radiotherapy and surgical resection, one of the most often applied ways of cancer treatment. The efficacy of chemotherapy is, however, limited by severe toxic side effects of anticancer drugs on healthy tissues [1]. This limitation could be overcome by employing local drug delivery systems (DDS) for anticancer agents [2]. Nowadays, intrinsically conducting polymers (CP) have been considered as promising materials for drug reservoirs in DDS because of their ion-exchangeable properties [3]. CPs are able to immobilise anionic drugs during oxidation and release them in the process of reduction. Triterpenoids are one of the most promising groups of anticancer compounds. These compounds are secreted by living tissues of numerous higher plants, granting them exceptionally good availability [4]. Oleanolic acid (HOL) has been found to be active in various stages of tumor development, including inhibition of tumor promotion, invasion and metastasis; its anticancer effects have been reported in several cancer cell lines, such as HeLa [5], L1210, K562 and HL-60 [6].

EXPERIMENTAL METHODS

Oleanolic acid (HOL) was isolated from waste-product obtained during production of mistletoe extract. Cyclic voltammetry (CV) was utilised for the fabrication and in situ analysis of PEDOT/OL⁻ composite layers *via* two different procedures: in-situ during the process of polymerisation (1-step procedure) and post-polymerisation modification (3-step procedure). The release of OL⁻ from the composite was followed by time-resolved UV-Vis spectroscopy. The biological activity of HOL solutions was determined using HeLa cancer cell lines.

RESULTS AND DISCUSSION

In the immobilization step, the positive potential was applied to entrap OL⁻ into the structure of PEDOT matrix.

Fig.1. Release of OL⁻ from PEDOT/OL⁻ synthesised *via* 1- and 3-step procedures in passive and active modes.

The release of the immobilised OL⁻ was performed under spontaneous (passive) and electro-assisted (active) modes in PBS. The passive mode showed short term drug release followed by a plateau. When PEDOT/OL⁻ matrix was electrically stimulated, longer term sustained release was observed with higher OL⁻ concentration. PEDOT/OL⁻ matrix synthesized *via* 3-step procedure proved to be more effective drug carrier than matrix obtained *via* 1-step procedure.

Fig.2. Cytotoxic activity against HeLa cells for OL⁻ immobilised and released from PEDOT/OL⁻ matrices.

It was crucial to determine whether immobilised and released OL⁻ maintains its anticancer properties. All OL⁻ solutions for which OL⁻ concentration was higher than 0.25 mM demonstrated anti-cancer activity. The highest anti-cancer activity showed OL⁻ solution obtained after active release from matrix synthesized *via* 3-step procedure.

CONCLUSION

PEDOT/OL⁻ composite was demonstrated to be a promising and robust material for drug delivery. The processes of immobilisation and release did not affect the anticancer properties of OL⁻.

INTRODUCTION

Hydrophobized polymers have gained popularity as vehicles for drug delivery. Among the widely studied vehicles are polymeric micelles formed from self-assembled amphiphilic polymers having core-shell architecture with diameters ranging from 20 to 200 nm. While the hydrophilic shell ensures aqueous dissolution of the polymeric micelle, the hydrophobic core may accommodate non polar drugs through non covalent bonding (encapsulation). Since such encapsulation of a hydrophobic molecule in aqueous media is only a result of thermodynamic equilibrium, the question which arises is how much the polymeric micelle integrity will be disturbed in time *in vivo*, after dispersion in blood.

To probe the drug encapsulation stability, a lipophilic donor – acceptor FRET (Fluorescence Resonance Energy Transfer) dye pair was loaded into polymeric micelle cores. When the micelle core is intact, distance between FRET pair dyes is short enough for energy transfer, resulting in FRET evolution. However, when the micelle core undergoes conformational changes or is disrupted, the distance between donor and acceptor dye becomes larger, and as a result FRET evolution is suppressed.

It was the aim to probe the stability of FRET loaded hyaluronan (HA) polymeric micelles in aqueous (pH 7.4 and 5.5) and saline media as well as in whole human blood.

EXPERIMENTAL METHODS

Caproyl (HAC6, Mw 5-42 kDa, DS = 60%) and Oleyl hyaluronan (HAC18:1, Mw 5-42 kDa and DS = 10%) were loaded with FRET pair dyes (DiIC18 and DiOC18) by solvent evaporation method.

Fluorescence emission spectra were collected after polymeric micelle dissolution in aqueous and saline solvents, human plasma and blood using Quanta Master 400 fluorescence spectrometer at excitation wavelength 484 nm and emission wavelength range from 490 to 600 nm. FRET ratio was calculated as $I_{DiI}/(I_{DiI}+I_{DiO})$.

RESULTS AND DISCUSSION

Since polymeric micelles are mostly prepared with the intention of intravenous applications, the micelle stability was tested at pH 7.4 (pH of blood), pH 5.5 (pH in some tumoral tissues) and in physiological solution (0.9% NaCl). Independently on hyaluronan Mw or length of hydrophobic acyl chain (C6 and C18:1), the FRET ratio of all samples remained constant during 24 hrs incubation of polymeric micelles in any of the media. The value of FRET ratio was close to 1.0, which suggested that the micelle cores remained intact and FRET dyes were not released from the core (i.e. their distance remained constant).

However, FRET ratio dropped to 0.8 (HAC18:1) and 0.7 (HAC6), when polymeric micelles were dispersed in serum. The micelle instability was attributed to the interaction of HA with plasma proteins. Among these proteins, albumin was found to be the prime factor disturbing the original integrity of micelle core and causing FRET dyes separation. As it is summarized in Table 1, showing half-life of HA micelles calculated from FRET ratio decrease, this interference was more evident (i) with decreasing concentration of polymeric micelles and (ii) for HA with shorter length of acyl chain. Similar tendency was then observed when polymeric micelles were incubated with human blood (Figure 1). The higher the polymeric micelle concentration, the smaller amount of interfered or disrupted micelles. Concentrations around 3.0 mg/mL of hyaluronan polymeric micelles in blood are reachable *in vivo*.

Table 1. Half-life ($\tau_{1/2}$) of polymeric micelles in the presence of albumin in 0.9% NaCl at 37°C.

Polymeric micelle	Mw (kDa)	$\tau_{1/2}$ (hod) c=0.5mg/mL	$\tau_{1/2}$ (hod) c=1.5mg/mL
HAC6	5	1.2	5.2
	15	0.8	2.5
	38	0.8	7.2
HAC18:1	5	2.8	>>24
	15	3.0	>>24
	38	Not soluble	

Figure 1. The amount of intact HAC18:1 polymeric micelles (15 kDa) after dispersion in full human blood.

CONCLUSION

The thermodynamic stability of hyaluronan polymeric micelles is mainly influenced by serum proteins, especially albumin. The stability is concentration dependent. Increased polymeric micelle concentration resulted in increased stability. For this reason, initial concentration of hyaluronan polymeric micelles *in vivo* in blood should be at least around 3.0 mg/mL so that drug bursting or adsorption to albumin is prevented right after intravenous injection.

Extracellular matrix proteins regulate Adipose Derived Mesenchymal Stem Cells and Amniotic Fluid Stem Cells attachment and proliferation: utility for tissue and organ regeneration

Anna Bajek^{1*}, Joanna Olkowska¹, Natalia Gurtowska¹, Tomasz Drewa^{1,2}

INTRODUCTION

Cells in tissues and organs are located in microenvironments which consist of Extracellular matrix (ECM) and neighboring cells. ECM affects different characteristics of cells including cell architecture, mechanics, polarity and function¹. Moreover, cell-matrix interactions are crucial for the successful repair and regeneration of damaged tissue and organ. The aim of this study was to check how different extracellular matrix (ECM) proteins affect proliferation and adhesion potential of human Adipose Derived Mesenchymal Stem Cells (hADSCs) and human Amniotic Fluid Stem Cells (hAFSCs).

EXPERIMENTAL METHODS

Human ADSCs and AFSCs were cultured on dishes coated with 4 types of ECM including collagen IV, fibronectin, laminin and poly-D-lysine for 7 days, and simultaneously cultured on a noncoated dish as a control. Proliferation potential was assessed by MTT assay while adhesion capacity by macroscopic observation.

RESULTS AND DISCUSSION

All of tested ECM proteins do not decrease the proliferation potential of hADSCs. However,

different trend was observed regarding hAFSCs. Laminin and poly-D-lysine caused the decrease in proliferation compared to the control. In both populations, the largest increase of proliferation was observed on collagen IV and fibronectin-coated dishes, which promote the spindle morphology of cultured cells as well. Additionally, we observed good adhesive properties of hADSCs and hAFSCs in 30 minutes after seeding on ECM-coated dishes.

CONCLUSION

These results suggest that the signal transduction of the cell-matrix interaction for the proliferation and adhesion of hADSCs and hAFSCs was activated when cultured on collagen IV and fibronectin-coated dishes. It indicates on ECM as an important component of the cellular niche in the tissue, supplying critical biochemical and physical signals to initiate or sustain cellular functions. It is also possible that ECM is required for the reconstitution of the niche of stem cells *in vitro*.

INTRODUCTION

Hyaluronan (HA) is a lineal polysaccharide found in extracellular matrices of connective tissue and possesses a large number of biological functions. The use of HA in drug delivery is impeded by its high hydrophilicity and short self-life. In this study, we will present the design and synthesis of a novel derivative (SOH) based on Hyaluronic acid (HA) conjugated with oleic acid¹. The development of the reaction was transferred from laboratory scale to pilot plant with highly purity and chemical reproducibility. The aim of this work is to demonstrate the applicability of a new derivative of HA towards formulation in cosmetics or pharmaceutical fields.

EXPERIMENTAL METHODS

Amphiphilic derivatives were obtained by reaction of the hydroxyl groups of HA with mixed aliphatic aromatic anhydrides¹⁻². Mixed anhydrides obtained by the reaction of substituted-benzoyl chlorides (sBC) and oleic acid, were used as versatile reagents for the esterification of HA. The characterization of the derivatives was performed by SEC-MALLS, NMR, IR and Rheology. The effect of the degree of substitution on the critical micellar concentration (cmc) was determined by fluorescence spectroscopy. Cell viability assay was studied by interaction of the derivative with dermal fibroblasts.

RESULTS AND DISCUSSION

This novel protocol allows the modification of low (LMW-HA), medium (MMW-HA) and high molecular weight (HMW-HA) in a broad range of degrees of substitution (DS). As an example, it produces chemical modification from 2 up to 50% in (6,000-26,000 g/mol), up to 15% (MMW-HA) and 5% in (HMW-HA). The reproducibility of the reaction was tested in laboratory and semi-production scales. The covalent bond of the fatty acid and HA was demonstrated by DOSY (Figure 1). The structural characterization demonstrates that in aqueous solvents, the hydrophobic oleyl moieties of the SOH assembled themselves in hydrophobic cores, while these cores were surrounded by hydrophilic HA backbones (Figure 2). The encapsulation of different model drugs was tested. It was observed that (DS) may slightly change the value of critical micellar concentration from 1 to 0,5 $\mu\text{g}\cdot\text{mL}^{-1}$, which is around 1500 times lower than the concentrations needed to form micelles with low-molecular-weight surfactants such as SDS³.

The *in-vitro* results indicate that the tested compounds are non-cytotoxic (to a concentration of 1 mg/ml). Cell viability was not changed compared with unaffected control part up to 72 hours (Figure 3). We observe that after the chemical modification, the derivatives were more stable to enzymatic degradation

in compared to native HA and without losing biocompatibility. The hydrophilicity of the polysaccharide was decreased due to the covalent bonding of the fatty acid but the derivatives were still water soluble, which is a necessary condition for encapsulation.

Figure 1. DOSY of sodium oleyl Hyaluronate

Figure 2. Formation of nano-aggregates of SOH loaded with α -Tocopherol

Figure 3. Cell viability of SOH derivative

CONCLUSION

The use of mixed anhydrides proved to be a good alternative for the chemical modification of Hyaluronic acid up to 50 %. The main advantages of the proposed reaction pathway are the mild conditions that allowed negligible degradation of the biopolymer after reaction. The chemical modification has not affected the biocompatibility of the polysaccharide.

Imaging of Biofilm Removal on Titanium and Glass by Dental Instruments

E. Pecheva^{1*}, N. Vyas^{1,2}, R.L. Sammons¹ and A.D. Walmsley¹

^{1*}School of Dentistry, University of Birmingham, UK, e.v.pecheva@bham.ac.uk

²Physical Sciences of Imaging for Biomedical Sciences (PSIBS), University of Birmingham, UK

INTRODUCTION

Bacterial biofilms, also known as plaque, form on teeth dental and implants, and may lead to dental caries, periodontal disease with tooth loss, serious infections or implant failure. Biofilms also mineralise, forming calculus that has to be removed mechanically.

Ultrasonic dental scalers are used in dentistry for plaque and calculus removal due to their efficiency and greater comfort for the patient than hand instruments. Another advantage is the generation of cavitation within the water flow over the dental tip, which increases the cleaning efficiency¹. Since ultrasonic scalers are not 100% efficient, in order to improve their ability to remove biofilm it is essential to study dental plaque growth, removal and structure, and non-destructive imaging techniques are integral to this work. This model can then be used to assess removal by the ultrasonic scaler. Each imaging technique has its own advantages and limitations. Therefore for detailed investigations, a selection of two or more complementary and non-destructive techniques is required to provide complete information on the components of the surface.

Our research aims to investigate the biofilm removal by a piezoelectric dental scaler.

EXPERIMENTAL METHODS

An in vitro biofilm model system using a non-pathogenic Gram-negative species of *Serratia* (NCIMB40259) was developed in a bioreactor² on titanium and glass surfaces. *Serratia* is capable of forming biofilm on various surfaces, as well as mineralising it to calcium deficient hydroxyapatite that chemically resembles calculus². A Satelec ultrasonic dental scaler (P5XS Newtron, France) with water irrigation of the tip was used to disrupt the biofilm for 30 seconds. The tips were applied with their front side parallel to the biofilm and tip end facing down. The removal was visualised by SEM, white light interferometry, optical microscopy, AFM and micro-CT, and quantified using image analysis.

Fig.1 Design of the tips chosen for the study: front of the tips. The free end of the tip is placed parallel to the biofilm during the disruption. The threaded end of the tip is attached to a handpiece.

RESULTS AND DISCUSSION

Tips with different shapes (fig.1) were operated at fixed power setting giving a tip displacement of 15µm. Two

Fig.2 Images of the disrupted biofilm on glass, obtained by Nikon camera (left) and optical microscope (right). Tip 1 was used at 40 µm distance from the sample.

Fig.3 Disrupted biofilm on titanium imaged by SEM (left) and white light interferometry (right).

positions along the tip length were chosen to contact the biofilm – the tip end (A) and the tip curved side (B) where previous work has demonstrated higher cavitation in comparison to the tip end (unpublished data). An area of disruption on both glass and titanium occurred when the tip distance to the biofilm was set at 40 µm to avoid direct mechanical contact of the tip to the material surface (figs. 2 and 3). The most efficient removal was with the thinner tips 1 and 10P. The effect of the position along the tip (A or B) on the biofilm removal still has to be elucidated. It was more difficult to clean the titanium surface due to its higher surface roughness ($R_a = 415$ nm in comparison to the glass – 6 nm). SEM revealed bacteria still present in the cleaned area while there were no bacteria on the glass.

CONCLUSION

We have shown how to image biofilm removal. Both tip shape and material surface roughness were effective in biofilm removal when using an ultrasonic scaler.

Poly (ϵ -lysine) dendrons as modulators of quorum sensing in *Pseudomonas aeruginosa*

Rahaf Issa, Steve Meikle, Stuart James, and Ian R. Cooper

School of Pharmacy and Biomolecular Sciences, University of Brighton, UK

r.issal@uni.brighton.ac.uk

INTRODUCTION

Quorum sensing (QS), an intercellular signalling system in *Pseudomonas aeruginosa*, regulates the expression of multiple extracellular virulence determinants via three main pathways (*las*, *rhl* and *PQS*). Given the rapidly expanding problem of antibiotic resistance, interrupting these pathways using synthetic molecules is being explored as a novel alternative to conventional antibiotics. We have previously shown the potential of hyperbranched poly (ϵ -lysine) dendrons, and their ability to enhance the efficacy of ciprofloxacin and reduce toxin production¹. In this study, we evaluate the effects of generation 3 poly (ϵ -lysine) dendrons, RG3K, on the production of QS-regulated virulence factors.

EXPERIMENTAL METHODS

Dendron Synthesis: RG3K, a hyperbranched macromolecule composed of 3 branching generations of lysine (K) and an arginine (R) root, was synthesised using solid-phase peptide synthesis. Dendrons were assembled from Fmoc-protected amino acids using a 4x molar excess of reagents, and characterised by analytical HPLC (Waters) and microTOF MS (Bruker).

Application: *P. aeruginosa* (PAO1) was exposed to increasing concentrations of RG3K (1 to 1000 μ M) after 0, 3 and 8h of growth. Cellular viability was determined at 18h. To ascertain the effects of RG3K on QS, a range of virulence factors was examined. LasA protease activity was determined by measuring the ability of PAO1 supernatants (20 μ L) to lyse boiled cells of *Staphylococcus aureus* NCTC 6571 (180 μ L) within 1h of exposure. The extent of PAO1 attachment and degree of biofilm biomass production was examined 2, 4, 6, 8, and 24h after treatment with RG3K in 96-well plates. Biofilms were stained with 0.1% (w/v) crystal violet, and quantified at OD₅₉₅. To further elucidate the effects of RG3K on biofilm structure, PAO1 was grown in the presence of RG3K (400 μ M) on borosilicate coverslips for 20h, stained with 0.01% (w/v) acridine orange, and the structure was analysed using CLSM. Data ($n = 4$ per assay) was analysed using ANOVA or t-test, where $P < 0.05$ was considered significant.

RESULTS AND DISCUSSION

Addition of RG3K after 3 and 8h of growth exhibited no significant inhibitory effects at $\leq 400\mu$ M, and the cell density at 18h was closely related to medium-only PAO1 ($P > 0.6$). Thus, any effects in subsequent assays at these concentrations are exhibited via a mechanism other than direct killing. RG3K did however cause a five-fold reduction in viability when added simultaneously with PAO1 at 1000 μ M ($P < 0.002$). LasA, a staphylolytic protease, is induced after ~6h of growth. At 400 μ M, RG3K reduced LasA activity when added after 0 and 3h ($P < 0.001$, respectively), but not

8h ($P > 0.68$), of growth (Table 1), suggesting that RG3K inhibits LasA production, but cannot reduce LasA levels post-production.

Table 1. LasA activity in response to RG3K, 400 μ M.

Conditions	LasA activity (at 18h)*
Medium-only	0.230 \pm 0.004
RG3K at 0h	0.004 \pm 0.003
RG3K at 3h	0.014 \pm 0.002
RG3K at 8h	0.262 \pm 0.010

*Expressed as reduction in OD₅₉₅ per hour ($n = 4 \pm$ SD).

The biofilm crystal violet assay, which stains extracellular matrix polymers, showed that exposure to RG3K caused a significant reduction in biofilm biomass in nutrient-rich and minimal media ($P < 0.005$). At concentrations between 100 and 400 μ M, RG3K caused a 10 to 40% biomass reduction in 2 to 8h-old biofilms, respectively. As QS is a cell-density dependent process², RG3K appeared to be more effective at preventing biofilm biomass production after 24h ($P < 0.001$), causing a dose-dependent activity. Thus, RG3K exerts its full effects with QS activation.

CLSM analysis revealed a reduction in microcolony formation (indicated using dashed lines) following exposure to RG3K (400 μ M), causing biofilms to appear notably thinner and more disperse (Figure 1).

Figure 1. Biofilm structure in response to RG3K.

CONCLUSION

RG3K has the potential to intercept QS-regulated virulence factor production in *P. aeruginosa*, offering a promising novel and alternative strategy for eradicating antibiotic resistant bacterial infections.

Comparative Osteogenesis of Calcium Silicate Cement and Calcium Phosphate Cement

Shinn-Jyh Ding^{1*} and Shu-Ching Huang²

¹Institute of Oral Science, Chung Shan Medical University, Taichung 402, Taiwan, sjding@csmu.edu.tw

²School of Dentistry, Chung Shan Medical University, Taichung City 402, Taiwan

INTRODUCTION

Many artificial materials have been proposed as bone graft substitutes in replace of autografts, which are the gold standards. Calcium phosphate similar to the mineral components of bone tissue has been used to provide support, fill voids, and enhance the biological repair of skeletal defects. However, with the increasing popularity of minimally invasive techniques, the development of injectable systems that mould to the shape of the bone cavity and polymerise when injected in situ has attracted a great deal of attention. Thus, a variety of injectable cement systems have been widely developed. The self-setting calcium phosphate cement (CPC) has many favourable properties that support their clinical use in the repair of bone defects¹. Beside, calcium silicate cement (CSC) is shown to enhance the proliferation and differentiation of osteoblasts, suggesting that CSC could have potential as a material for orthopedic and dental surgical implants². This study aims to investigate comparatively the osteogenesis of the two calcium-based cements for clinical applications.

EXPERIMENTAL METHODS

Calcium silicate powder was prepared by the sol-gel method, as described elsewhere³. For the preparation of the cement the powders were hand-mixed at a liquid to powder ratio of 0.4 mL/g with distilled water. To prepare BoneSource® classic CPC (Stryker), the liquid phase was 0.25 M sodium phosphate and a liquid to powder ratio of 0.25 mL/g was used. The specimens were stored in an incubator at 100% relative humidity and 37 °C for 1 day to set. Prior to cell culture, the hardened cement discs were sterilized by soaking in a 75% ethanol solution and exposure to ultraviolet light for 2 h. The osteogenic properties of all the cement specimens were evaluated by incubation with human mesenchymal stem cells (hMSCs). To observe cell morphology on the specimen surface, specimens were washed three times with PBS and fixed in 2% glutaraldehyde after 3 h of seeding and then were dehydrated using a graded ethanol series. The dried specimens were viewed using a scanning electron microscopy. The reagent Alamar Blue was used for real-time and repeated monitoring of cell proliferation. The alkaline phosphatase (ALP) activity of hMSCs on the cement specimens was measured. The mineralized matrix synthesis was analysed using an Alizarin red S staining method. One-way ANOVA statistical analysis was used to evaluate the significance of the differences between the mean values. The results were considered statistically significant at a p value of less than 0.05.

RESULTS AND DISCUSSION

Scanning electron micrographs show that stem cells attached to the CSC surfaces are spread out, but the shape of cells attached to the CPC surfaces is round. This demonstrates that CSC could facilitate the cell attachment higher than CPC. Regarding cell proliferation, the results indicate that more cells significantly ($p < 0.05$) grow on CSC surface than on CPC surface at all culture times. Similarly, the ALP levels on CSC are significantly ($p < 0.05$) greater than those on CPC at most of culture times, indicating that the effect is material-dependent. It is generally accepted that an increase in the specific activity of ALP in bone cells reflects a shift to a more differentiated state. ALP enzyme activity is also associated with bone formation, and it is produced in high levels during the bone formation phase. Alizarin Red S staining is a common histochemical technique used to detect calcium deposits in mineralized tissues and cultures. The noticeable differences are observed after cell culture on the CSC and CPC surfaces. Clearly calcified tissue formation is seen in the cultures grown in the presence of the CSC on day 21 compared to CPC. The Si component of CSC plays important roles in the early stages of bone formation and the calcification process. According to the literature⁴, that silicate-substituted calcium phosphate supported attachment and proliferation of MSCs and induced osteogenesis to a greater extent than hydroxyapatite (HA).

CONCLUSION

Overall, these findings indicate that the CSC could enhance mesenchymal stem cell differentiation, making it suitable for bone repair applications. It also confirms that CSC may be more effective than CPC in such a way as to provide an osteoinductive microenvironment without addition of exogenous growth factor or pre-treatment with osteogenic medium.

⁴ Materials Biology Interactions/EMPA, St Gallen, Switzerland

INTRODUCTION

Biodegradable polymeric systems are potential candidates to replace metallic devices for fixation of small size bone fractures. Polylactide (PLA) presents remarkable physical properties in line with the requirement of high strength bone fixation materials. However, PLA implants will need nanofiller loading to form a composite material with improved properties. In this respect, a strategy consists in the formation of PLA-based nanocomposites including carbon nanotubes (CNTs) as nanofiller.^{1,2} One important pre-requisite to using CNTs as fillers, is to be able to improve the adhesion to and to disperse them into the polymer matrix. Purposely, the non-covalent functionalization will maintain the conjugated structure and therefore, the intrinsic properties of the CNTs within the nanocomposite.³

EXPERIMENTAL METHODS

PLLA and CNTs were provided by PURAC BIOCHEM and Arkema respectively; pyrene-end-functionalized PLLA (py-end-PLLA) was synthesized by Ring Opening Polymerization (ROP) of L-lactide.

Dispersion of the nanocomposites was examined by TEM. The mechanical properties were determined by tensile tests and the analysis of fracture surfaces was carried out by SEM. Biocompatibility was evaluated regarding cytotoxic effects cell adhesion and spreading of bone marrow derived mesenchymal stem cells (HBMC) on the composite surface and by assessing the multipotential to differentiate towards pre-osteoblastic phenotype taking the expression of osteogenic genes as an index.

RESULTS AND DISCUSSION

The ability of py-end-PLLA to interact with the surface of CNT through π - π interactions contributes to improve dispersion. In consequence, stillness and interphase adhesion of nanocomposites was enhanced. The tensile modulus and the elongation at break of nanocomposites containing py-end-PLLA increase regarding to PLLA (Fig.1). The morphology of the fracture surfaces observed by SEM show in PLLA/py-end-PLLA/CNT nanocomposites CNTs embedded in PLLA matrix, while in PLLA/CNTs nanocomposite the CNTs are agglomerated (Fig.2). Therefore, the incorporation of py-end-PLLA helps dispersion and increases the adhesion of interfaces leading to an improvement in

mechanical properties. Altogether, a good in vitro bioacceptance of the nanocomposites was shown with HBMC. The presence of CNT at the analyzed concentration range, indicate no adverse effects on cell adhesion or cell population size (Fig. 3).

Fig 1. Tensile curves of PLLA/py-end-PLLA/CNT nanocomposites with a) 0, b) 0.1, c) 0.5 and d) 1.0 wt. % CNT.

Fig 2. SEM images of a) PLLA/CNT, b) PLLA/py-end-PLLA/CNT nanocomposites.

Fig 3. Cell adhesion, proliferation and spreading on PLLA/py-end-PLLA/CNTs nanocomposites.

CONCLUSION

In conclusion, the present study provides solid attestation that py-end-PLLA act as a good compatibilizer between PLLA and CNTs; and simultaneously those PLLA/py-end-PLLA/CNT nanocomposites exhibit excellent biocompatibility properties. Consequently, these new nanocomposite materials, from a bioacceptance point of view, can be interesting candidates for bone reconstruction applications.

Microgels Immobilizing Eudragit Nanoparticles for Indomethacin Release

Mihaela Nicoleta Holban*, Anca Niculina Cadinoiu, Elena Folescu and Vasile Burlui

*Acad. Ion Haulica" Research Institute; "Apollonia" University of Iasi, Romania, Faculty of Medical Dentistry
*holban_mihaela.nicoleta@yahoo.com

INTRODUCTION

The aim of this work was to develop complex systems of drug delivery, consisting of nanoparticles-containing microparticles. A major advantage is thought to be the retarded drug release and the higher protection of active principle from the environmental factors. Thus, new polymer systems were prepared by inclusion of cationic Eudragit RS100 or E100 nanoparticles into anionic polysaccharide microgels.

EXPERIMENTAL METHODS

Preparation of polymer nanoparticles. Eudragit RS100 or Eudragit E100 nanoparticles were prepared by nanoprecipitation, using a slightly modified version of a method described elsewhere¹. Indomethacin loaded nanoparticles were prepared by solving 0.05 g drug into organic phase prior to its addition to the aqueous phase. Fluorescent marked nanosuspensions were prepared by dissolving 1mg Nile Red at room temperature into the organic phase.

Preparation of pectin/HA microparticles. One part an aqueous solution containing low methyl pectin (LMP), hyaluronic acid sodium salt (HA) (LMP/HA=6/1 w/w) and polymer nanosuspension was emulsified into 4 parts silicone oil containing 2% (w/v) stearate sucroester for 30 min, at 1000 rpm. Then, 150 ml of calcium chloride (0.1 M) were added under stirring and then left for 30 min for particle curing. The formed microparticles were removed from the aqueous phase by paper filtration and washed twice with distilled water. Microparticles were stored at +4°C into HCl solution (pH 2).

Particles characterization. Size, size distribution and zeta potential of polymer nanosuspensions and nanoparticles-containing microparticles were measured. Nanoparticles morphology was observed by transmission electron microscopy (TEM). Microparticles morphology was visualized by optical microscopy and Nile Red-marked nano- and microparticles were observed by fluorescence microscopy. The entrapment efficiency (%) and *in vitro* release of Indomethacin were determined by UV-vis analysis.

RESULTS AND DISCUSSION

All nanoformulations were obtained as opalescent bluish liquids. The use of cationic polymers is reasoned by the aim of establishing electrostatic interactions between polymer nanoparticles and microgels composed of pectin and HA, the latter being a anionic natural polymer.

Microgels size was situated in the 40-110 µm range, a slight increase being registered when using Eudragit RS100. Zeta potential records were in accordance with

polymer charge; the presence of indomethacin into polymeric nanoformulations was shown by the decrease of zeta potential.

Nanoparticles are immobilized into microgels, as shown by fluorescence microscopy (Fig.1).

Figure 1. Superimposed photos of microgels containing Eudragit E nanosuspension (A) or Eudragit RS nanosuspension (B) in transmission and fluorescence mode (x 100)

Indomethacin was entrapped into nanoparticles in a rather satisfying percentage (~53%), considering the fact that a large portion was lost during microgels preparation.

Figure 2. Release kinetics of indomethacin

The release of indomethacin from microgels in phosphate buffer pH 6.8 shows a delay compared with the release from nanoparticles.

CONCLUSION

New complex drug delivery systems have been prepared using Eudragit RS100/Eudragit E100 nanoparticles immobilized into pectin and hyaluronic acid based microgels. The systems showed ability to retard and control the release of indomethacin in simulated media.

INTRODUCTION

Biomimetic material development presents an important interest in biomedical and tissue engineering field and many engineered biomaterials are developed. The immobilization of bioactive molecules aimed specifically at improving rapid biointegration and promoting selective adhesion which has attracted considerable attention^{1, 2}. Cell adhesion is mediated by many biomolecules and one of the most important is a multifunctional glycoprotein: fibronectin (FN), used by many cells as adhesive substrate. FN contains a specific cell attachment site RGD exhibiting a strong affinity to integrin $\alpha_5\beta_1$ cell receptors³. Thus, FN is an interesting candidate for functional surface modification. The present study aims to produce a chimeric protein containing the cell adhesion domains III9-10 (rFN.9-10) of fibronectin and to immobilize this bioengineered protein on biomaterial surface in order to investigate its influence on cell attachment. A Colored Multi Affinity Tag (CMAT) (Fig. 1) containing a tracking marker (cytochrome b5) and two purification tags (HIS and SBP) was designed for expression and purification monitoring of rFN.9-10.

EXPERIMENTAL METHODS

Recombinant protein production and purification

DNA sequence encoding FNIII9-10 was amplified from pFN103 plasmid by standard PCR. The amplified sequence was cloned in phasis with CMAT (Fig. 1) into pET15b and sequenced. rFN.9-10 was generated in *Escherichia coli* BL21pLysS and purified by double affinity chromatography on Ni-NTA and streptactin columns then dialyzed.

Figure 1: rFN.9-10 cloning in phasis with CMAT

Protein Analysis

rFN.9-10 was analyzed by SDS-PAGE and identified by mass spectrometry (MS/MS).

Protein adsorption and cell adhesion assay

rFN.9-10 and full length FN were used for an overnight coating at 4°C. Cells were seeded (in the presence or absence of 1% BSA / serum) and allowed to adhere at 37°C and then quantified using an automated cell counter (Beckman coulter).

Experiments were run in triplicate. The variance and the significance (p value <0.05) were determined using ANOVA method.

RESULTS AND DISCUSSION

Protein analysis

SDS-PAGE analysis of the eluted fractions (Fig. 2) affirmed the expected molecular size (40 KDa) of the fused rFN.9-10 and revealed high purity purification.

The MS analysis of rFN.9-10 using Mascot software matrix generated peptides matching with a human FN and a murin cytochrome b5 precursors.

Figure 2: Expression and purification analysis of rFN.9-10. 1: molecular weight marker. 2 and 3: insoluble and soluble fractions respectively. 4 and 5: Ni NTA and Streptactin purified fractions respectively.

Protein adsorption and cell adhesion assay

Blocking with BSA in serum free condition reduces non-specific cell adhesion and material demonstrates the same cell attachment as the control. Surfaces coated with rFN.9-10 support cell attachment (Fig. 3a). Obviously, tethering efficiency of rFN.9-10 displays a comparable level to plasma FN (pFN) while no significant difference is observed relative to the control (Fig. 3b).

Figure 3: Cell adhesion (a) Effect of BSA and serum on cell adhesion. (b) Cell adhesion on surface coated with rFN.9-10 (R) and pFN. Reported values are the mean \pm sd (n=3)

In this work, we evaluated rFN.9-10 binding site as an adhesive ligand and we compared material adhesive property to a control. Thus, results demonstrated similar adhesive properties as the plasma FN.

CONCLUSION

This study provides active chimeric fragment implicated in cell adhesion process. The present experiment suggests that rFN.9-10 offers advantage for its novel oriented immobilization strategy on biomaterial. More results will be provided in the communication.

INTRODUCTION

The ionic beta-sheet peptides that can self-assemble to form hydrogels is of interest for the development of materials that can be used in applications such as cell culture. Towards this end understanding the influence of the different residues in these peptides is important. It is already known that altering the length and the overall hydrophobicity of these types of peptide alters the self-assembly¹. However this has concentrated on replacing all of the hydrophobic residues in a peptide with an alternative amino acid. Here we have looked at variable amounts of differing amino acids for the hydrophobic content. The two peptide sequence extremes used in these studies are FEFKFKFK and AEAEAKAK with intermediates with different amounts of alanine and phenylalanine have been studied.

EXPERIMENTAL METHODS

Peptides were purchased from Biomatik and dissolved in ddH₂O at increasing concentrations to determine the critical concentration for hydrogel formation. Additionally, the pH of the solutions was varied to determine how this effected the hydrogel formation.

Rheology on a TA instruments Discovery Hybrid Rheometer using a plate/plate geometry.

The secondary structure of the peptides was determined using FTIR spectroscopy of peptides at a number of concentrations was used to confirm hydrogel formation

RESULTS AND DISCUSSION

The results from this study show that increasing numbers of alanine residues in the peptides increases the critical gelation concentration (CGC) for hydrogel formation. Additionally, the presence of more alanine residues results in a shift in the secondary structure of the peptides at low concentration, below the CGC,

towards an alpha-helical structure in comparison to a beta-sheet structure above the CGC.

These results support the concept that the amount of beta-sheet secondary structure is important for the formation of a hydrogel. Altering the hydrophobicity of the hydrophobic component of these peptides has a direct impact on the hydrogel formation. Also incorporation of amino acids that favour an alpha-helical secondary structure over a beta-sheet secondary structure also impacts on the CGC.

These results show that it may be possible to control hydrogel formation in these types of peptides by altering either the hydrophobicity or the secondary structure propensity of the peptides. This is an important factor in developing these peptide hydrogels towards applications.

CONCLUSION

Replacing the phenylalanine in FEK octapeptides with alanine, a less hydrophobic amino acid, results in an increase in the CGC and also a propensity to form alpha-helical structures

INTRODUCTION

Total disc replacement is a surgical technique designed to reduce back pain and restore movement in the spine. Many artificial disc prostheses are manufactured using cobalt-chrome alloy popularized by the successful cobalt-chrome alloy artificial hip prostheses. The nanometre sized wear debris generated from such metal prostheses can however lead to adverse tissue reactions^(1,2). We have previously reported that clinically relevant CoCr nanoparticles can have significant biological effects upon cells isolated from the dura mater, a tissue in close proximity to spinal implants⁽³⁾. The aim of the current study was to investigate the biological effects of clinically relevant CoCr nanoparticles on the dura mater in an organ culture model.

EXPERIMENTAL METHODS

Dura-mater tissue organ-cultures were exposed to physiologically relevant doses of CoCr nanoparticles [5 and 50 $\mu\text{m}^3 \cdot \text{cell}^{-1}$] generated using a pin-on-plate tribometer. The resulting biological and structural effects were evaluated using a range of methods including tissue viability (MTT assay) pro-inflammatory cytokine production (ELISA) histology (H&E), immunohistochemistry, and TEM imaging of the CoCr-particle treated tissue compare to control tissue.

RESULTS AND DISCUSSION

There was no loss of tissue viability when the dura-mater was treated with either of the two doses of CoCr nanoparticles over 7 days. However, histological analysis and TEM imaging identified loosening of the epithelial layer of the dura-mater at both doses of nanoparticles (Fig.1).

Figure 1. TEM images of the dura mater tissue after 7 days of incubation with (A) no particles, (B) 5 and (C) 50 $\mu\text{m}^3 \cdot \text{cell}^{-1}$ cobalt chrome nanoparticles. Single black lines arrows indicate the dural epithelial cells. Black circles indicated disruption of the collagen layer.

These structural alterations were associated with increased cell and tissue expression of MMP-1, -3, -9, -13 and TIMP-1 in response to both doses of CoCr nanoparticles but the expression varied between epithelial and fibroblast cells as well as the extracellular matrix as shown in Table (1)

Type of MMP	5 μm^3			50 μm^3		
	Epithelial cells	Fibroblasts cells	Extracellular matrix	Epithelial cells	Fibroblasts cells	Extracellular matrix
MMP-1	++	+	---	+	+	---
MMP-3	++	+	+	+	+/-	---
MMP-9	+++	++	++	+++	++	+++
MMP-13	+	+/-	+/-	++	++	++
TIMP-1	+++	+/-	---	+	+/-	---

Table 1. Expression pattern of different matrix metalloproteinases in dural epithelial and fibroblast cells as well as in the extracellular matrix. (Intensity of signal was assessed as: ---: no signal, +: light signal, ++: strong signal, +++: very strong signal)

Significantly increased levels of IL-8, TNF- α , IL-6, IL-33 and tenascin C were released after exposure of the dura mater to CoCr particles. Specifically, IL-8 levels for particle stimulated tissues were persistently higher than for the control tissue for the duration of the treatment (7 days) (Fig. 2).

Figure 2. IL-8 release from the dura mater after exposure to CoCr nanoparticles for 7 days. Data is expressed as the mean (n=3) \pm 95% confidence limits. (*: $p < 0.05$)

CONCLUSION

The exposure of the dura-mater to CoCr-nanoparticle caused histologically detectable structural distortion after 7 days of treatment. This was possibly due to a local inflammatory response as well as the action of matrix metalloproteinases. The results generated from this study contributed to a greater understanding of the potential risks associated with the use of MOM total disc prostheses.

New Materials with Antibacterial Action of Functionalized Au Nanoparticles and Ga^{3+} Ions

Mario Kurtjak, Marija Vukomanović and Danilo Suvorov

Advanced Materials Department/Jožef Stefan Institute, Slovenia
mario.kurtjak@ijs.si

We designed a new kind of material with dual antimicrobial action: the release of Ga^{3+} ions and the contact-based action of Au nanoparticles, functionalized with amino acid. The material is a composite of Ga(III)-containing hydroxyapatite and Au nanoparticles with different amino acids on their surface.

INTRODUCTION

In our previous work¹ we prepared nanocomposite of Au nanoparticles functionalized with arginine and hydroxyapatite that possesses contact-based antibacterial activity. Here, we report on the further improvement of this material. We retained hydroxyapatite as the bioactive component and functionalized Au NPs as the selective antibacterial agent by mimicking the antibacterial peptides. However, we added another antibacterial component, the Ga(III) ions, which are known to prevent biofilm formation² and act mainly by substituting Fe(III) ions and thus hinder crucial redox reactions and enzymes for bacterial growth³. Moreover, some Ga(III) compounds are already in clinical use⁴. Hence, the nanocomposite should remain non-toxic to humans since all its components are non-toxic.

EXPERIMENTAL METHODS

Sonochemical method was used for the preparation of all the materials.

RESULTS AND DISCUSSION

For the development of Ga(III)-containing hydroxyapatite with functionalized Au nanoparticles, three different amino acids were used: glycine (Figure 1 (a), (b)), arginine (Figure 1 (c), (d)) and histidine (Figure 1 (e), (f)). This not only created different functionalization of the nanostructures, but also affected the size of the resulting Au nanoparticles. Their size increases in the order: Au/His, Au/Arg, Au/Gly. The presence of Ga in the material is confirmed by the EDS analysis (Figure 1 (g)). According to the literature, these ions are most probably present in the interstitions of hydroxyapatite structure⁵. The materials were tested for aging in medium with physiological acidity as well as in media with weak and strong acidic environments, which confirmed the release of Ga-ions. Antibacterial activity of materials is tested in *E. coli* (MG1655 strain). Observed action against bacteria is a consequence of coupling of antibacterial activity of functionalized Au nanoparticles and antibacterial activity of released Ga^{3+} ions.

Figure 1: TEM images of Au/Gly@HAP(Ga) (a, b), Au/Arg@HAP(Ga) (c, d), Au/His@HAP(Ga) (e, f) and EDS analysis of Au/Arg@HAP(Ga) (g).

CONCLUSION

We developed nanocomposites with combined antimicrobial effect, which present an innovative way for prevention and cure of bacterial infections. Their different size and functionalization might provide different selectivity. Thus, they seem a promising human-friendly alternative for antibiotics and Ag-based antibacterial materials in treatments of infections by antibiotic resistant bacterial strains.

Biomimetic mineralization of early caries lesions with a self-assembling peptide

Sabrina Stevanovic¹, Lucy Kind¹, Iwona Dziadowiec², Bert Müller², Uwe Piesles¹

¹Institute of Chemistry and Bioanalytics, University of Applied Sciences and Arts Northwestern Switzerland (FHNW), Switzerland, sabrina.stevanovic@fhnw.ch

²BMC- Biomaterials Science Center, University Basel, Switzerland

INTRODUCTION

Enamel caries is the number one disease world-wide, presenting as progressive subsurface demineralization and ultimately resulting in mechanical failure and cavitation. Currently early dental caries is mainly treated by mechanical techniques, e.g. dental fillings or tooth extraction, or by applying protective barriers to the tooth surface, like fluoride containing varnishes¹. Therefore biomimetic mineralization is a very promising field to combine biocompatible materials with a non-invasive application. The present study is focused on a remineralization method to regenerate sub-surface carious lesions / early carious lesions in tooth enamel by means of a short self-assembling peptide, P11-4. This approach, based on the supramolecular fibrillar 3D network, is hypothesized to trigger the nucleation of hydroxyapatite (HA) nanocrystals along the fibrous network and consequently resulting in biomimetic mineralization^{2,3}.

EXPERIMENTAL METHODS

Artificial lesions in human teeth (Figure 1) were generated by incubation in acidic demineralization buffer (pH 4.4). P11-4 was directly applied on the lesion and then incubated in remineralization buffer (pH 7.4). For the detection of the monomeric and self-assembled P11-4 a specific primary antibody and Congo red was used. To detect the peptide P11-4 in treated lesions after a long term study (14 d) a matrix-assisted desorption/ionization-time of flight (MALDI-TOF) spectroscopy method was developed. The nucleation and growth of hydroxyapatite crystallites initiated by the self-assembled network of P11-4 was analysed by μ -computer tomography (μ -CT) measurements.

Fig. 1: Computer tomography (μ -CT) image of a natural human tooth crown with artificially generated carious lesions (arrows).

RESULTS AND DISCUSSION

A standardized procedure to demineralize natural human teeth in order to obtain sub-surface lesions (white spots - WS) has been successfully established. With the specific primary antibody and Congo red

staining we were able to selectively detect monomeric and self-assembled peptide P11-4. Remineralisation of the artificial lesion was observed with μ -CT. Increased density was clearly visible after two weeks (Figure 2). Moreover after incubating the tooth in remineralisation buffer for two weeks, P11-4 was still present in the lesions detected by MALDI-TOF.

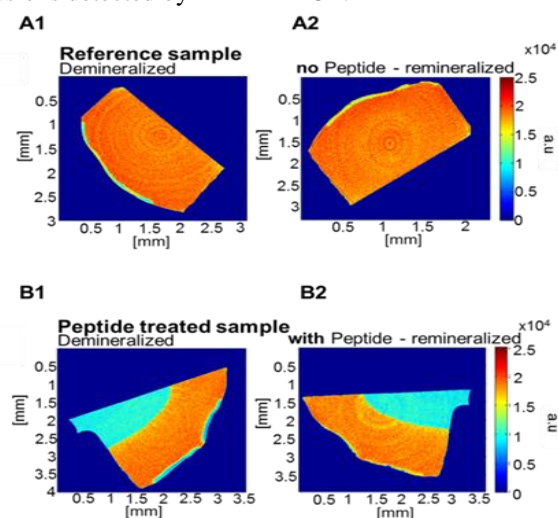

Fig. 2: μ -CT images of a transversal profile through a sub-surface lesion in a human tooth enamel. (A1 and B1) Tooth imaged after demineralization. (A2) Tooth treated without peptide (Reference sample). (B2) Tooth treated with peptide (P11-4), 14 days in remineralization buffer (Peptide treated sample).

CONCLUSION

The aim of the study was to analyse the remineralization process of artificial induced white spot lesions after treatment with the self-assembling peptide P11-4. MALDI and μ -CT were suitable methods to observe the presence of peptide P11-4 in the tooth and the biomimetic mineralization of the artificial induced white spot lesions.

Furthermore studies on restorative remineralization therapy by 3D-self-assembled peptide supramolecular networks, either in natural teeth or in artificial tooth model are in process.

maria.godoy.gallardo@upc.edu

INTRODUCTION

Implant failure can be associated to infections which develop into peri-implantitis. In order to reduce biofilm formation, several strategies focusing on the use of antimicrobial peptides (AMP) have been studied^{1,2}. To covalently immobilize these molecules onto metallic substrates several techniques have been developed, including silanization³ and polymer brush prepared by surface-initiated atom transfer radical polymerization (ATRP).⁴

The aim of the present study was to compare the efficiency of these two methods to immobilize the hLf1-11 antibacterial peptide onto titanium, and evaluate their effect in the antibacterial activity *in vitro*.

Figure 1. Synthetic route for silanization, copolymer brushes and peptide conjugation.

The aim of the present study was to compare the efficiency of these two methods to immobilize the hLf1-11 antibacterial peptide onto titanium, and evaluate the antibacterial activity *in vitro*.

EXPERIMENTAL METHODS

Smooth titanium (Ti) samples were coated under three different conditions: silanization with APTES, and polymer brush based (ATRP) coatings with two different initiators. These surfaces were conjugated with the hLf1-11 peptide. Surfaces were characterized by contact angle measurements, white-light interferometry, ellipsometry, and X-ray photoelectron spectroscopy (XPS). Moreover, the mechanical stability of the coatings under ultrasonication was studied. Cellular viability and proliferation were studied by LDH assay with human fibroblasts. The *in vitro* antibacterial properties of the modified surfaces were tested with two oral strains (*Streptococcus sanguinis* and *Lactobacillus salivarius*) by means of bacterial adhesion assay at 2 h and evolution of biofilm formation after 24 h.

RESULTS AND DISCUSSION

Compared to silanization, ATRP treatments formed polymer brushes on the titanium surface with an increased density of anchoring points for peptide

attachment, as estimated by GPC and ellipsometry. XPS analyses confirmed that the two strategies allowed a successful covalent attachment of the Lhf1-11 onto Ti. Surface roughness was not affected by these treatments. Cell viability and proliferation in the LDH assays were not affected by the presence of peptides. All surfaces biofunctionalized with the hLf1-11 peptide presented a significant antibacterial effect. The immobilization of the hLf1-11 peptide via polymer brush techniques showed a statistically significant higher reduction of bacterial adhesion than the use of silanization. However, both methods had a similar effect in the inhibition of biofilm formation. After 2h of sonication bacterial adhesion and biofilm formation slightly increased for all treatments, indicating some extent of mechanical instability for the coatings.

Figure 2. Effect of the surface modifications on bacterial adhesion.

Figure 3. Effect of the surface modifications on biofilm formation for 24h.

CONCLUSION

A decrease in bacterial adhesion and biofilm formation was achieved once the peptide was immobilized onto titanium surfaces. A higher decrease in bacterial attachment was noticed when samples were modified by ATRP methods compared to silanization. This effect is likely due to the capacity to immobilize more peptide on the surfaces by using polymer brushes and hydrophilic nature of polymer brushes.

A Preliminary Examination of Composition-Property Relationships for Methotrexate-Loaded Germanium-Based Glass Ionomer Cements

Lauren Kiri^{1*}, Daniel Boyd^{1,2}

^{1*}School of Biomedical Engineering, Dalhousie University, Canada, lekiri@dal.ca

²Department of Applied Oral Science, School of Biomedical Engineering, Dalhousie University, Canada

INTRODUCTION

The addition of antineoplastic drugs to bone cement may prevent local cancer progression and failure of stabilization devices used to treat pathologic fractures. Germanium-based glass ionomer cements (Ge-GICs) have been recently identified as potential injectable bone cements, as they are (1) chemically adhesive to bone, (2) inherently radiopaque, (3) non-exothermic, (4) clinically practical in terms of handling and mechanical properties, and (5) aluminum-free and therefore circumvent the biocompatibility issues that have been identified with using conventional GICs for orthopaedic applications.¹ However, the effect of adding antineoplastic drugs to such GIC matrices is unknown. Consequently, the aim of this work was to investigate the ability of such materials to act as a drug vehicle for the anticancer agent, methotrexate (MTX).

EXPERIMENTAL METHODS

Glass powder (Mol. Fraction: 0.36ZnO/0.04SrO/0.215SiO₂/0.215GeO₂/0.025ZrO₂/0.025Na₂O/0.12CaO; particle size: $\leq 45\mu\text{m}$) was synthesized¹ and characterized using XRD and DSC. Cements were mixed at a constant powder/liquid ratio of 1.5/1.0 and poly(acrylic) acid (PAA) concentration of 50%. MTX was mixed into the cement at 0, 1, 5 and 10% w/w. Working time (t_w ; $n=3$), setting time (t_s ; $n=3$) and 1-day compressive strength (CS; $n=5$, incubated in PBS at 37°C) were measured for each drug loading condition, as per conventional methods.² For each drug loading condition, cement cylinders ($d=4\text{ mm} \times h=6\text{ mm}$) were synthesized ($n=5$) and incubated in PBS in a shaking mixer (2Hz) at 37°C. PBS was replaced after 1 h and each day for 10 days. MTX concentration was quantified using UV/VIS spectroscopy ($\lambda=303\text{nm}$). The release data was fitted to zero-order, first-order, Higuchi, Korsmeyer-Peppas, Weibull and Hopfenberg models, and statistically analysed to show model adequacies (Prism 6).

RESULTS AND DISCUSSION

The average t_w , t_s and 1-day CS are reported in Table 1. Curiously, the addition of MTX significantly decreased t_w ; however, there was no significant difference in t_w found among the different MTX loadings (1-way ANOVA). Furthermore, and also surprisingly, MTX addition did not significantly impact t_s or CS (1-way ANOVA).

Table 1: Handling and mechanical properties of MTX-loaded Ge-GIC.

Loading	t_w (sec)	t_s (sec)	1-day CS (MPa)
0	229	653	32
1	205	610	38
5	208	740	35
10	193	660	40

Figure 1 shows the MTX release profiles for each loading scenario. All profiles demonstrate the same general trend: a burst release followed by a slow sustained release over the 10 day period. Determination coefficients (R^2) for the resulting model linearizations are summarized in Table 2.

Figure 1: MTX release profiles (M) with respect to LD50 ($1 \times 10^{-5}\text{ M}$).

Table 2: R^2 values for modelled release profiles.

Model	R^2		
	1%	5%	10%
Zero-Order	0.5554	0.6314	0.5102
First-Order	0.8929	0.7303	0.6364
Higuchi	0.6119	0.7636	0.6667
Korsmeyer-Peppas	0.9066	0.9795	0.9912
Weibull	0.9194	0.9555	0.9741
Hopfenberg	0.7344	0.6868	0.6003

From Table 2, it is seen that the release profiles are best described by the Korsmeyer-Peppas and Weibull models. The resulting Korsmeyer-Peppas release exponents fell below 0.45 for all loading scenarios, which suggests Fickian diffusion is the primary mechanism of release. As shown in Figure 1, increased drug loading significantly increased the amount of drug released from the cement. However, increased drug loading did not significantly influence the percentage of MTX released; 1.3, 1.1 and 1.5% of the total MTX load was released at 240 hours for 1, 5 and 10% loading, respectively. At 24 h, the MTX concentration exceeded the LD50 for all loading scenarios. This was maintained for the 5% and 10% loading, while the 1% loading bordered the threshold for the elution period.

CONCLUSION

Ge-GICs are a potential vehicle for MTX. MTX loading imparts minimal effects to GIC handling properties with no effect to strength. The MTX-loaded Ge-GICs demonstrated sustained drug release at concentrations that imply cytotoxicity.

INTRODUCTION

Conventional cancer treatment techniques like chemotherapy, radiation therapy and surgical operations are not sufficiently efficient and they even are harmful for healthy tissues. Recent studies suggest that small interfering RNA (siRNA) based gene silencing can be used as a highly effective targeted therapy¹. However, siRNA delivery into tumors and target tissues have proved to be difficult². This study aimed to develop an siRNA delivery system to cancer cells using positively charged nanospheres constructed of polyethyleneimine (PEI) and starch (S).

EXPERIMENTAL METHODS

PEI-starch nanospheres were prepared at different ratios by water-in-oil microemulsion method. PEI molecules were crosslinked using genipin. The PEI-starch nanospheres were characterized by measuring the zeta potential and the particle size, studying the topography with SEM, and measuring release rate of their content by spectrofluorometer. We also evaluated siRNA and nanoparticle uptake and target downmodulation by confocal laser scanning microscopy (CLSM) and western blot analysis, respectively.

RESULTS AND DISCUSSION

The mean diameter of PEI-starch incorporating siRNA was 84.6 nm. Zeta potential of PEI-starch nanospheres increased when the PEI /starch ratios were increased and was the highest (8.7 mV) at PEI:Starch, 9:1 (w/w) (Table 1).

Table 1: Surface potential of PEI: starch nanospheres and viability of MCF 7 cells treated with PEI – starch nanospheres constructed with PEI: starch (w/w) ratios of 1:9, 1:3, 1:1, 3:1 and 9:1.

PEI:starch (w:w)	Zeta potential (mV)	Cell viability (%)
1:9	-31	90.7
1:3	-26	86.6
1:1	-19	85.6
3:1	0	81.9
9:1	9	78.0

The nanospheres released 50 % of their siRNA content in the first 3 days and all of the content in a week. CLSM micrographs show the nanospheres and siRNA were taken up by MCF 7 breast cancer cells (Figure 1).

Figure 1: Confocal microscopy of MCF 7 cells treated with Alexa-555 labelled siRNA loaded PEI-starch nanospheres (A) fluorescence image of MCF 7 cells (green) treated with Alexa-555 labelled siRNA loaded PEI-starch nanospheres (red) (x 40), (B) Z-stack.

Western blot analysis demonstrated that EF2-Kinase siRNA loaded nanospheres significantly inhibited EF2K protein expression (90-100%) (Figure 2).

Figure 2: Western blot analysis of MCF 7 cells treated for 72 h (100 nM EF2K siRNA and 100 000 cells per well). (A) with EF2K siRNA loaded nanospheres (NP), (B) with various batches of EF2K siRNA loaded nanospheres (NP) (NP1, NP2, NP3).

CONCLUSION

In this study construction of a novel PEI-starch based siRNA carrier to initiate apoptosis in breast cancer cells was aimed. The PEI-starch nanospheres effectively penetrated into MCF 7 cells. Thus, we showed that the PEI-starch nanospheres are suitable in size, charge, release kinetics and as such they exhibit a potential to serve as an efficient vector for siRNA delivery to cancer cells.

³Institute of Biophysics AS CR, Czech Republic

INTRODUCTION

Various carrier systems, including polymeric micelles (PMs), are being developed for drug delivery or cell labelling purposes. Since hyaluronan and its derivatives represent biodegradable and biocompatible polymeric material, PMs based on acylated hyaluronan¹ have great potential for clinical use and applications.

The aim of this work was to probe the ability of acylated hyaluronan based PM to transport active compounds to the intracellular space and test if this transport is influenced by level of expression of the main receptor for hyaluronan, CD44.

EXPERIMENTAL METHODS

Nile red (NR) and 7-aminoactinomycin D (7-AAD) were loaded into hyaluronan PMs by solvent evaporation method. Human cancer cell lines MCF-7 and MDA-MB231 and primary human dermal fibroblasts (NHDF) were cultivated in DMEM supplemented with 10% FBS. Measurement of CD44 expression and quantification of intracellular transport of PM was performed on MACSQuant® flow cytometer (Miltenyi Biotec). Widefield fluorescence images were obtained using Ti-Eclipse inverted microscope (Nikon). Confocal images were obtained on confocal microscope TSC SP-5 X (Leica).

RESULTS AND DISCUSSION

For basic quantification and also to decipher if the PM uptake is influenced by CD44 presence on cell surface the three cell types with different CD44 expression were measured by flow cytometry after incubation with NR loaded PMs. Accumulation of fluorescent NR in cells didn't correlate with CD44 expression (Fig.1).

Fig.1: Accumulation of NR loaded in PMs during 3hrs incubation with cells. Graph shows the means from 4 independent experiments, error bars = SEM. Insert shows relative expression of CD44.

To confirm whether the NR is transported within the PM or is released from PM outside the cell and then transported alone the PMs were labelled with blue

pyrene. After incubation with MCF-7 cell the colocalization of NR and pyrene fluorescence was observed both on widefield and confocal microscopes (Fig.2). This suggests that PM is transported intact into cells and then the loaded compound is released.

Fig.2: Colocalization of NR loaded in PM and pyrene labelled acylated hyaluronan in MCF-7 cells. Dotted circle indicates the position of nucleus. Scale bars = 10 μm

For further prove of role of PM as active transporter inside the cells NR in PMs was substituted for 7-AAD, compound normally impermeable for living cell plasma membrane. Viable cells (verified by calcein-AM staining) treated with 7-AAD in DMSO didn't show any red fluorescence while cells treated by 7-AAD loaded PMs has high red fluorescent signal from 7-AAD bound to DNA (Fig.3)

Fig.3: MCF-7 cell treated with 7-AAD in DMSO and 7-AAD loaded into PM. Green calcein marks viable cells. Scale bar = 100 μm

CONCLUSION

Results show that PMs based on acylated HA are able to transport active compound inside cell independently on the CD44 presence on cell surface. This transport is based on internalization of whole PM and not the release of active compound in the vicinity of plasma membrane. Thus PMs based on acylated hyaluronan are suitable for drug and other active compound delivery into cells.

***In vivo* Investigations of the Early Stages of Bone Healing with Microdialysis**

Yvonne Foerster¹, Claudia Rentsch¹, Stefan Kalkhof², Martin von Bergen², Stefan Rammelt¹

¹University Centre of Orthopaedics and Trauma Surgery and Centre for Translational Bone, Joint and Soft Tissue Research, University Hospital Carl Gustav Carus Dresden, Germany

²Helmholtz Centre for Environmental Research, Department Proteomics, Leipzig, Germany
Yvonne.Foerster@uniklinikum-dresden.de

INTRODUCTION

The treatment of critical-size bone defects represents a significant clinical problem. The bone healing itself is a complex process influenced by growth factors, cytokines, and other mediators, but the regulation of this process is not yet sufficiently understood. Because the early stages of bone healing are crucial for consolidation, it is important to characterise the active molecules and cellular mechanisms in the fracture hematoma directly after the injury. Therefore the authors developed microdialysis in bone defects as a method to identify mediators and growth factors in the early stages of the bone healing process.

EXPERIMENTAL METHODS

A 5 mm defect was created in the femur of male adult Wistar rats and stabilized with an internal fixator. The microdialysis catheter (cutoff 100 kDa, CMA microdialysis, Solna, Sweden) was placed within the defect, fixed to the skin and the dialysate was collected continuously under anaesthesia for 24 hours. The dialysates were analysed by ELISA (enzyme-linked immunosorbent assay) and Proteome Profiler™ array. The proteins attached at the membrane of the catheter were determined by HPLC/MS (high-performance liquid chromatography/mass spectroscopy). Rats with soft-tissue defects were used as controls.

RESULTS AND DISCUSSION

Determination of protein concentration showed that it was possible to collect protein continuously from the bone defect with the chosen experimental setting. The total protein concentration varied between 0.15 mg/ml and 0.44 mg/ml. We were able to determine interleukin-6 (IL-6) and transforming growth factor-β1 (TGF-β1) concentration over 24 hours. IL-6 was secreted within

the first 3 h and the highest concentration was measured between 12 and 15 h after the injury. The anti-inflammatory cytokine IL-10 could be detected in all samples with a slight increase toward the end of the detection period. By Proteome Profiler™ array and HPLC/MS analysis further chemokines that are potentially relevant to bone healing like chemokine (C-X-C motif) ligand 1 (CXCL1), CXCL4 and CXCL7 could be detected in the dialysate. Detailed studies of CXCL4 and CXCL7 by ELISA showed a rapid decrease of the concentration of these proteins immediately after injury suggesting the release of these proteins by activated platelets. The analysis of samples by HPLC/MS resulted in more than 1000 collected proteins that could be assigned to biological processes like immune system response, response to stimuli, cell adhesion and others. In addition, we were also able to assign the identified proteins to more than 100 different pathways which seem to be activated in the early stage of bone healing.

CONCLUSION

It can be concluded from these experiments that microdialysis appears to be a valuable method to characterise the humoral events during the early stages of bone healing. Further investigations are needed to show the influence of implant modifications on the composition of the fracture hematoma.

Characterization of Oxygen Plasma-treated Dental All-Ceramic Zirconia

Hsiang Kao, Chung-Kai Wei and Shinn-Jyh Ding*

Institute of Oral Science, Chung Shan Medical University, Taichung 402, Taiwan, kao52226@ms21.hinet.net

INTRODUCTION

Zirconia (ZrO_2) is applied as a base in clinical fixed prosthetic dentistry and femoral head of hip prostheses because of the merits of zirconia ceramics such as high strength, toughness, abrasion resistance, and chemical stability *in vivo*¹. However, this material has a limited applications range because it is a bioinert material that does not interact with bone tissue and thus does not easily integrate directly in the bone. To pursue the high bioactivity is still a concerned theme although commercial ZrO_2 systems are available today. Oxygen plasma treatment is relatively inexpensive and time efficient, as it is simple to transform the hydrophobic hydrocarbon surface of materials to the hydrophilic hydroxyl surfaces². This study was to create a hydrophilic layer on the commercially available ZrO_2 surface for improving the biocompatibility using oxygen plasma. Evaluation of this potential method included phase composition and contact angle analysis, particularly the protein adsorption and cell attachment and proliferation on oxygen plasma-treated ZrO_2 surfaces.

EXPERIMENTAL METHODS

The oxygen plasma treatment of Cercon ZrO_2 plates was carried out by using plasmochemical generator. Before treatment, the samples were mechanically polished to a roughness to #1200 grit level. The plasma was generated using a source power of 200 W.

High resolution X-ray diffractometry (XRD) was used to investigate the phase composition. Micro-Raman measurements were taken with a DXR instrument equipped with a laser at 780 nm. The static water contact angles were determined by the sessile drop method at room temperature. Bovine serum albumin (BSA) adsorption studies were done to investigate the effect of treated specimens on protein coverage.

Human mesenchymal stem cells (hMSCs) were used to assay the osteogenic properties of the plasma-treated samples. The cells were grown in Dulbecco's modified Eagle's medium supplemented with 10% fetal bovine serum and 1% penicillin/streptomycin solution. Cells seeded on the ZrO_2 samples without plasma treatment were used as a control. Actin cytoskeleton was analysed by fluorescence microscopy. Cell viability was examined using the MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) assay. To evaluate early cell differentiation, the alkaline phosphatase (ALP)

activity of hMSCs on the various specimens was measured. One-way analysis of variance (ANOVA) was used to evaluate the significance of differences between means. In all cases, the results with a p-value of less than 0.05 were considered statistically significant.

RESULTS AND DISCUSSION

XRD and micro-Raman consistently indicated that the used oxygen plasma did not induce any significant phase evolution. The sample was composed of tetragonal zirconia phase with a tract of monoclinic zirconia. As expected, the water contact angle measured on the pristine substrate was significantly ($p < 0.05$) reduced from 65° to 18° after 1 min of plasma irradiation. The oxygen plasma can improve effectively the hydrophilicity of the ZrO_2 surfaces, possibly due to both the introduction of polar hydroxyl groups into the sample surfaces and elimination of hydrocarbon molecules. At 1 h of adsorption, greater amount of BSA protein was bound to the plasma-treated surface compared to the pristine ZrO_2 .

Early cell-cement interactions affect subsequent differentiation and mineralization. The fluorescence staining showed that at hour 3, hMSCs cultured on plasma-treated surfaces displayed highly tensioned actin stress fibres, whilst compared to the control, in agreement with the results of the contact angle and protein adsorption. Initial cell adhesion and spreading to the material surface is strongly dependent on the absorbed proteins³. The MTT assay was used to quantify cell number on the different samples. Cell attached to the plasma-treated surfaces at a rapid rate more than 100% binding at day 3 compared to the control. This demonstrated that during the culture periods, the number of viable cells on plasma-treated surface was significantly higher ($p < 0.05$) than on the pristine YZP. Regarding cell differentiation, the ALP level presented a higher value for the plasma group than the control after 10 days of incubation.

CONCLUSION

In summary, the present plasma method provides an effective method for improving the hydrophilicity and biocompatibility of dental all-ceramic ZrO_2 .

Email: G.F.B.Hulshof@utwente.nl

INTRODUCTION

Surface topography can have large effects on cellular parameters such as proliferation, orientation, morphology, gene expression and differentiation. Insight into the underlying mechanisms is valuable for the design for future biomaterials.

The TopoChip was developed for high throughput screening of thousands of topographies(1). An in-silico library of over 150 million unique topographies is generated using multi-parametric algorithms. From this library 2178 features are randomly selected and applied in duplo inside 300x300 μm^2 'TopoUnits' on a 2x2 cm^2 polymer surface, the 'TopoChip'.

Here we identified micro-topographies which are able to up-regulate tissue non-specific Alkaline Phosphatase (ALP). Moreover correlations of ALP expression changes with cell morphological parameters were explored.

EXPERIMENTAL METHODS

TopoChips are fabricated by hot embossing of a polymer using a silicon mould holding the inverse pattern that is fabricated by photolithography.

Human mesenchymal stromal cells (hMSC's) have been cultured on 8 poly(lactic acid) (PLA) TopoChips with a 200 nm titanium coating (n=16 for each unique surface topography).

ALP, filamentous actin and chromatin of hMSC's were fluorescently labelled for high content imaging. Images were analysed by Cellprolifer and custom Matlab® scripts.

RESULTS AND DISCUSSION

Analysis of the Topochip screen yielded a number of candidate hits that significantly up-regulated or down-regulated ALP compared to the mean of the data set. From these candidate hits several were verified by up-scaling the topographies from the 0.09 mm^2 TopoUnit size to 2.54 cm^2 discs and quantifying ALP expression by microscopy and flow cytometry (Fig 1). Positive Hits (PH1&PH2) almost doubled the amount of ALP positive cells in a similar range to the dexamethasone positive control.

Analysis of the actin cytoskeleton of the cells in the TopoChip screen showed a correlation between morphological parameters and ALP expression. This

suggests that changes in cytoskeletal properties induced by micro-topographies might be able to affect ALP expression, probably through a mechano-transduction pathway.

Fig1: ALP expression measured by Flow cytometry. Percentages of ALP positive cells cultured for 5 days on Tissue culture poly styrene(TCPS), non-patterned Ti coated PLA (NP) and positive (PH) and negative hit-topographies(NH) on Ti coated PLA.

CONCLUSION

Using the TopoChip we were able to identify several topographies which significantly up-regulated ALP expression of hMSC's. Cytoskeletal morphology showed a strong correlation with the changes in ALP expression.

INTRODUCTION

Nowadays, titanium and its alloys are the most used metals for bone substitution in orthopaedics and dentistry due to their favourable mechanical properties and biocompatibility. Immediately after surgery, proteins coming from the blood circulation adsorb on the exterior of the inserted material, forming a pre-conditioning film which influences the “race” among cells and bacteria for colonizing that surface¹. Thus, the study of protein adsorption, cell differentiation, osteogenesis and bacterial adhesion, is fundamental to predict *a priori* the *in vivo* implant performances.

EXPERIMENTAL METHODS

Hydrothermal treatment (HT) is a well-known synthesis method for growing nanocrystalline TiO₂-anatase coatings on titanium substrates. Such coatings enhance the surface properties of Ti-based bone implants in favour of a higher biocompatibility after implantation. Moreover, photo-induced phenomena (e.g. super-hydrophilicity) can arise by UV irradiation of the anatase nanocrystals².

Coatings with different crystals morphology, wettability and surface charge were used in these studies in both non-irradiated and UV pre-irradiated state, in comparison with the non-treated titanium (Ti NT).

First of all, the study of the protein adsorption was accomplished by using the whole plasma; the quantification and identification of the species were performed on the gel maps obtained by 2D-PAGE, one of the most used proteomics techniques. Furthermore, ALP (alkaline phosphatase) production and Ca²⁺ uptake from the medium were used in order to evaluate *in vitro* the cell activity and the osteogenesis process of primary human mesenchymal cells. Fluorescence and scanning electron (SEM) microscopy were applied, as well, to observe cell morphology and spreading. Finally, the observation of the *E. coli* adhesion and the eventual biofilm formation on the TiO₂-coatings (with/without UV pre-irradiation) were estimated by fluorescence microscopy and CFU (colony forming units) counting.

RESULTS AND DISCUSSION

The different characteristics of the surfaces, together with the photo-induced effects, were taken into account for comparing the biocompatibility of the surfaces, under several points of view. The results suggested that the surface charge and the wetting grade of the coatings were the most influencing parameters for the plasma protein adsorption, while the UV photo-induced hydrophilicity generally decreased the amount of adsorbed proteins. In particular, the most favourable result was the significant reduction in the adsorption of inflammation-promoting proteins after UV pre-irradiation of the substrates. Photo-induced hydrophilicity was the fundamental parameter which enhanced the osteogenic ability of the HT coatings, leading to the cell differentiation and resulting in the formation of a well-developed mineral phase, even in the shape of bone-like nodules (Figure 1). Finally, the HT samples reduced the bacteria adhesion in comparison to the bare substrates and glass references.

CONCLUSION

Accordingly, the results suggested that the hydrothermally synthesized anatase coatings with an adequate morphology and surface properties can have a better osseointegration of the implant and that a large potential to be used in self-disinfection of medical devices may be expected, as a result of surface photo-activation before surgery.

Fabrication of Tissue Engineering Scaffolds from Poly(ester-anhydride) by Projection Stereolithography

Harri Korhonen¹, Pekka Lehtinen², Jouni Partanen², Jukka Seppälä¹

¹Laboratory of Polymer Technology, Aalto University, Finland

²Department of Mechanical Engineering, Aalto University, Finland, harri.korhonen@aalto.fi

INTRODUCTION

Additive manufacturing methods have been increasingly used in the preparation of 3D structures from bioresorbable polymers. We have previously fabricated tissue engineering scaffolds by stereolithography from photocurable poly(ϵ -caprolactone) macromers¹. The aim of the current study was to investigate if SLA can be used also for the fabrication of photocurable poly(ϵ -caprolactone) based poly(ester-anhydrides). The poly(ester-anhydrides) have been shown to exhibit a very fast surface erosion type degradation kinetics due to incorporation of labile anhydride linkages along the poly(ϵ -caprolactone) backbone. The poly(ester-anhydrides) have been used for zero-order drug release^{2,3} and for porogenization of scaffolds consisting of fast degrading poly(ester-anhydride) and a slower degrading polymer⁴.

EXPERIMENTAL METHODS

Photocurable poly(ester-anhydrides) were prepared in three steps. OH-terminated oligomers were synthesized by ring-opening polymerization of ϵ -caprolactone. Oligomers were further functionalized with succinic anhydride to carboxylic acid functionality. In the final step, COOH-terminated oligomers were methacrylated by reaction with methacrylic anhydride to obtain photocurable oligomers.

3D structures were fabricated by a self-made projection stereolithography (PSLA) system. The setup of PSLA is shown in Figure 1. The system was based on commercial video projector (Acer H6510BD, 1920*1080 pixels), collimating lens, and a narrow bandpass filter. In fabrications campherquinone (1 wt-%) and ethyl 4-dimethylaminobenzoate (1 wt-%) were used for photoinitiation, and Orasol Orange c (0.1 wt-%) as neutral absorber to control penetration depth of light into resin.

Figure 1. Illustration of projection stereolithography.

RESULTS AND DISCUSSION

Fabrication was carried out by using light intensity of 7000 $\mu\text{W}/\text{cm}^2$, layer thickness of 30 μm , and curing time

of 7s for each layer. Well-controlled 3D structures were obtained with the used fabrication parameters. The dimensions of the samples were 5*5*5 mm.

Figure 2. Fabricated samples before purification

The designed scaffold model had a gyroid-like pore architecture and porosity of 70 %. The prepared scaffolds closely followed the structure of the designed model.

Figure 3. a) Designed model, b) fabricated sample

Poly(ester-anhydrides) are expected to find use in fast eroding tissue engineering scaffolds. In addition, they can be used as porogens for scaffolds prepared from slower eroding polymer. Since PCL-based poly(ester-anhydride) degrades by surface erosion, designed 3D structures obviously provide new possibilities for controlled release applications.

CONCLUSION

The results showed that poly(ϵ -caprolactone) based poly(ester-anhydride) is suitable material to be used in the fabrication by SLA.

²Department of Chemistry/Faculty of Math and Physical Science, University College London, UK

F.Foroutan.11@ucl.ac.uk

INTRODUCTION

Recently, interested in soft and hard tissue engineering to improve tissue regeneration has fuelled the need for novel biomaterials having specific bioactivity and controllable degradation rates^{1,2}. Bioresorbable materials can be resorbed in the body and replaced by bone and tissue cells. It is well accepted that phosphate-based glasses exhibit a great potential to act as a bioresorbable material for biomedical applications, since they show a controllable degradation rate with releasing bioactive and biocompatible ions^{3,4}. In addition, low synthesis temperature of the sol-gel method leads to the opportunity to incorporate drug molecules into the glass network for drug delivery applications, which can be homogeneously dispersed throughout the sol-gel derived glass during the synthesis procedure⁵.

Here we report the sol-gel preparation of a quaternary P_2O_5 -CaO- Na_2O - Fe_2O_3 (PCNF) glass system. The structure of the sample has been characterized using XRD, DTA, FTIR and elemental proportion measured by EDX analysis.

EXPERIMENTAL METHODS

The reaction was started by diluting n-butyl phosphate in MeO-EtOH (at the molar ratio of 1:3). Following that Ca-methoxyethoxide was added dropwise into the mixture (the whole reaction being carried out in a dried vessel). Then $Fe[OCH(CH_3)_2]$ solution was added to the mixture while it was magnetically stirring. After 1 h stirring NaOMe was poured into the vessel and in the last stage the vessel was cooled down in an ice-bath before n-DMF added to the mixture. The mixture turned to gel after about 10 min and aged at room temperature for 3 days. The sol-gel preparation is outlined by the flowchart in Fig. 1

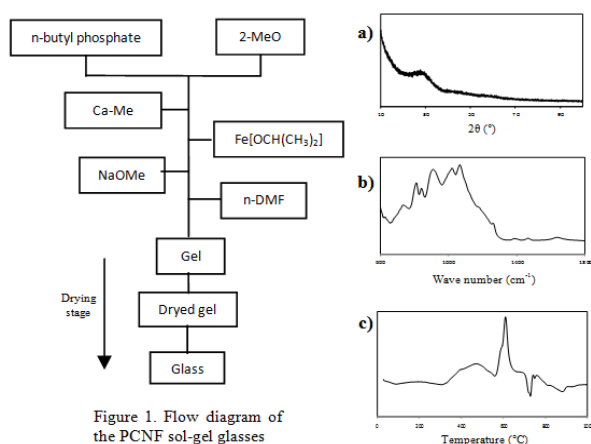

Figure 1. Flow diagram of the PCNF sol-gel glasses

Figure 2. a) XRD, b) FT-IR, and c) DTA analysis trace of the stabilized PCNF sol-gel glass

In the drying stage the gel was kept at 60 and 120 °C for 3 and 2 days respectively before keeping at 150 °C for 1 h to remove any remained solvent and bulk, glassy-like sample was obtained.

RESULTS AND DISCUSSION

The XRD pattern was free from any detectable crystalline phase and a broad peak at 2θ values of around 20-35° confirmed the amorphous structure of the sample (Fig. 2a). The EDX result showed a reduction of around 5 mol% P_2O_5 with a concomitant increase in the percentage content of the other oxides to compensate. This loss was expected due to the relative volatility of phosphorus precursor. From the FTIR spectrum (Fig. 2b) of the glass sample three main regions can be distinguished⁶: the range between 1400-1150 cm^{-1} is characteristic of the vibration of non-bridging PO_2 groups, the region between 1150 and 900 cm^{-1} for terminal P-O- and PO_3 , and vibration of bridging P-O-P groups for the range between 900 and 700 cm^{-1} . And from the DTA graph (Fig. 2c) glass transition temperature (T_g) value of 435 °C was obtained. Also clear peaks were observed for the crystallization (T_c) and melting temperature (T_m), which are 609 and 728 °C respectively.

CONCLUSION

In this study for the first time a quaternary glass in the system P_2O_5 -CaO- Na_2O - Fe_2O_3 has been successfully synthesized via sol-gel method. The amorphous pattern and glassy nature were confirmed by XRD and EDX results revealed loss of phosphorus during the sol-gel process in relatively low. FTIR data show that while Fe_2O_3 slightly disrupts the glass network, however, its improved cross-linking of the phosphate units that can decrease the solubility of the glass for biomedical application. Future work will be undertaken on degradation study of these quaternary sol-gel glasses and production of nano/micro size glass beads for their potential drug delivery and imaging contrast agent applications.

Development of novel nanofunctionalised glass ionomer cements containing chlorhexidine-hexametaphosphate nanoparticles: mechanical properties and method of incorporation

Candice A Bellis^{1*}, James A Holder^{1,2}, Dominic J O'Sullivan¹, Michele E Barbour¹

¹Oral Nanoscience, School of Oral and Dental Sciences, UK ²Kemdent, UK; *candice.bellis@bristol.ac.uk

INTRODUCTION

Glass ionomer cements (GICs) are biomaterials used extensively in dentistry. Their applications include restorations, orthodontic adhesives, cavity liners and in atraumatic restorative treatment. GICs have many favourable properties, but a limitation to their use is their low strength, and it is important that any development in GIC science does not adversely affect strength. The main reason dental restoratives are replaced is due to bacteria-mediated decay adjacent to the biomaterial. A dental biomaterial with a sustained antimicrobial effect could have significant clinical impact. Chlorhexidine (CHX) is a cationic antiseptic which has broad spectrum antibacterial activity and is widely used in oral care products. CHX-releasing nanoparticles have recently been reported.^{1,2} The aim of this study was to incorporate CHX nanoparticles into a GIC using two different methods and to investigate how this affected mechanical properties.

EXPERIMENTAL METHODS

Nanoparticle synthesis-100 mL each of 10 mM CHX digluconate and sodium hexametaphosphate (HMP; both Sigma-Aldrich, Gillingham, UK) were combined under ambient laboratory conditions with vigorous stirring. 30 mL 1M KCl was added after 1 min and stored for 24 h without stirring. The supernatant was discarded and the remaining sediment centrifuged for 30 min at 5000 rpm. The supernatant was again discarded leaving a viscous white sediment paste.

Preparation of nanoparticles for GICs-Nanoparticles were added to GICs as either the viscous white paste described above, or as dry particles. To create the dry particles, the paste was dried under ambient laboratory conditions in a fume hood and then milled in a ball mill for 4 h on a rotating platform. Nanoparticles were then substituted at 1, 2, 5 or 10 % for the glass component with adjustment of acid concentration to correct for water in sediment specimens.

GIC specimens using nanoparticle paste-Powder and liquid were mixed in a 4:1 ratio according to the manufacturers' instructions. The nanoparticle sediment was added to the GIC liquid first and then this combined liquid was mixed with the powder.

Specimen preparation-For diametral tensile strength (DTS) testing, GIC specimens were created in cylindrical PTFE moulds of 4 mm (height) by 6 mm (diameter). For compressive strength (CS) testing a steel mould of 6 mm (height) by 4 mm (diameter) was used. After 5 min, specimens were removed from the moulds and stored in 100% humidity for 7 days.

Strength testing-DTS and CS were measured using an Instron universal testing machine.³ Data were analysed using Kruskal-Wallis tests. DTS n values: sediment

(n=15-20), ball milled (n=14-18). CS n values: sediment (n=16-21), ball milled (n=17-22).

RESULTS AND DISCUSSION

Figure 1. DTS of GIC specimens. Error bars are standard deviations. Letters indicate homogeneous groups (lower case: sediment; upper case: ball-milled).

Figure 2. CS of GIC specimens. Error bars are standard deviations. Letters indicate homogeneous groups (lower case: sediment; upper case: ball-milled).

DTS decreased numerically as a function of % nanoparticle substitution; the effect was only statistically significant for the sediment-incorporated specimens. CS was statistically significantly reduced for 5 and 10 % substitutions using both methods but numerically lower for sediment specimens.

CONCLUSION

Experimental GICs containing CHX-HMP nanoparticles at a range of dopings were created. Reduction in both DTS and CS was observed for higher substitutions; the detrimental effect on strength was less pronounced for specimens made using dry, ball-milled nanoparticles than for wet, sedimented nanoparticles.

Evaluation of the effect of polymer content on drug release and mechanical strength of a Geopolymer ER Formulation for opioid drugs

Bing Cai, Håkan Engqvist, Susanne Bredenberg

Division for Applied Materials Science, Department of Engineering Sciences, Uppsala University, Sweden.
bing.cai@angstrom.uu.se

INTRODUCTION

Geopolymer is a porous ceramic material composed of a three-dimensional polysialate framework and has been suggested as a possible matrix material for ER formulation of opioid drugs¹. The diffusion process through the meso-pores is the main rate-limiting step for the drug release from the geopolymer-based delivery systems. However, in that study, the geopolymer formulation released drug faster in lower pH solutions, which in-vivo could cause dose dumping and serious side effects. Since the gastrointestinal absorption of most drugs usually takes place in small intestine, it is more safe and effective to have the major drug release at neutral pH in a controlled manner. In addition a high mechanical strength is of importance for a safe ER formulation².

This study aims to evaluate the impact of addition of one enteric coating polymer to the geopolymer formulation on drug release performance and tamper-resistance to physical milling. The geopolymer-based formulation was compared with ER formulation manufactured according to the reference regarding the drug release profiles and compressive strength³. Zolpidem tartrate was used as model drug.

EXPERIMENTAL METHODS

The geopolymer pellets were synthesized and moulded into cylindrical pellets (1.5 x 1.5mm diameter x height) and cured as the previous study². Eu x is noted for the geopolymer formulation with x g of the enteric coating polymer, Eudragit®, into 4g of metakaolin. The reference ER formulation was moulded into the same cylindrical shape with the composition published by Shailes³.

The drug releases from geopolymer and reference formulation were evaluated in triplicate by a standardized dissolution method in a USP 2 apparatus (Sotax AG, Switzerland) at two typical gastric conditions: pH 1 and pH 6.8. Aliquots (1 ml) were withdrawn and analyzed using a UV/VIS spectrophotometer (Shimadzu 1800, Japan). The compression strength was tested using Autograph AGS-H universal testing machine (Shimadzu corp., Japan) according to a standard testing method⁴.

RESULTS AND DISCUSSION

The drug release rate decreased with increasing amount of enteric coating polymer at pH 1 (Fig. 1). In contrast, the drug release rate increased with the polymer content at pH 6.8, probably due to the higher the dissolution of the polymer at neutral pH resulting in a higher surface area. The drug release profile for Eu 0.75 showed a lower drug release rate at pH1 and a higher rate at pH 6.8, which could improve the gastrointestinal absorption.

The drug release profiles of Eu 0.75 were compared with the comparison formulation. The release profiles

of geopolymer formulation at both pH conditions fitted well into the Higuchi model ($R_2 > 0.99$). It indicates that Eu 0.75 could maintain controlled release during the measured period and reduce the possibility of dose dumping. In contrast, the comparison formulation released the drug readily at both pH 1 and 6.8 and thus could not sustain the drug release for an elongated period.

Fig. 1 The drug release from comparison ER formulation and geopolymer matrices with different amount of enteric coating polymer.

The compressive strength of Eu 0 was 83 MPa (SD: 7.5); of Eu 0.5 was 59 MPa (SD: 13.1) and of Eu 0.75 was 21 MPa (SD: 5.0). Even though the polymer content influenced the mechanical strength of geopolymer formulation, Eu 0.75 had the double mechanical strength of the comparison formulation (11 MPa, SD: 1.3). The higher compressive strength of geopolymer formulation could thwart the tampering formulation by physical manipulation.

CONCLUSION

The study showed that the enteric coating polymer reduced the drug release rate at pH 1 but increased release rate at pH condition similar to the small intestine. Although, the polymer content influenced the compressive strength of the geopolymer formulation, the strength was still higher than the reference ER formulation. The results indicate the enteric coating polymer has potential as an excipient in geopolymer formulation to improve the drug release performances.

Poly(butylene succinate) nanocomposites containing strontium hydroxyapatite nanorods for tissue engineering applications

M. Nerantzaki¹, Z. Terzopoulou¹, E. Roumeli¹, D. Papageorgiou¹, D. Bikiaris¹, J. Will², J. Hum², A. Hoppe², J.A. Roether², A.R. Boccaccini²

¹ Aristotle University of Thessaloniki, GR-541 24 Thessaloniki, Macedonia, Greece.

² Institute of Biomaterials, Department of Materials Science and Engineering, University of Erlangen-Nuremberg, Cauerstrasse 6, 91058 Erlangen, Germany, marinera002@gmail.com

INTRODUCTION

Poly(butylene succinate) (PBSu), a novel biodegradable aliphatic polyester with excellent processability is a promising substance for bone and cartilage repair. However, it typically suffers from insufficient bioactivity after implantation into the human body and low mechanical properties, which reduce its application possibilities¹. So, in order to overcome this problem, strontium hydroxyapatite nanorods $\text{Sr}_5(\text{PO}_4)_3\text{OH}$ (SrHNRs), were synthesized and introduced into the polyester via *in situ* polymerization. Concerning strontium it affects positively new bone growth inhibiting resorption and enhancing bone formation².

EXPERIMENTAL METHODS

In this work SrHNRs were synthesized by a chemical solution method. Afterwards, PBSu nanocomposites containing 0.5, 1 and 2.5wt% nanofillers were prepared by *in situ* polymerization technique for the first time and we examine the ability to be used as potential tissue engineering scaffolds. The prepared composites scaffolds were characterized using SEM, FTIR and XRD. Mechanical testing (Instron 3344) and contact angle measurements were also carried out. Additionally, the enzymatic degradation in aqueous solution containing mixture of *R. Oryzae* and *P. Cepacia* lipases, at 37°C and pH=7.2 and the *in vitro* biomineralization in simulated body fluid (SBF) were studied. Osteosarcoma cell line (MG-63) was applied in order to assess the biocompatibility of the composites.

RESULTS AND DISCUSSION

PBSu has a tensile strength at break of 27.4MPa and Young's Modulus 408. Its nanocomposite containing 0.5wt% SrHNRs, presented improved tensile strength and elasticity values of 30.7MPa and 415 respectively. However increasing the nanorods concentration the mechanical properties deteriorated. This small decrease could be attributed to the absence of any interaction between $\text{Sr}_5(\text{PO}_4)_3\text{OH}$ nanorods and the polyestheric matrix, as was verified from FTIR spectroscopy and thus the adhesion between the different materials is too low. From enzymatic hydrolysis, it was found that all nanocomposites have higher hydrolysis rates than neat PBSu and as the amount of nanofiller increases the hydrolysis rate becomes higher. The presence of hydroxyl groups in $\text{Sr}_5(\text{PO}_4)_3\text{OH}$ makes the nanocomposites more hydrophilic than neat PBSu and hence, absorb more water and subsequently degrade more rapidly. XRD study after biomineralization in SBF indicated the appearance of a crystalline phase of hydroxyapatite (Fig. 1).

Fig. 1. SEM views of a) PBSu b) PBSu/ $\text{Sr}_5(\text{PO}_4)_3\text{OH}$ 0.5% after soaking in SBF for 28 days display that scattered and clustered particles are formed on the samples.

Fig. 2. Metabolic activity of MG-63 cells cultivated for 48h on plane composite samples.

SrHNRs can also induce osteoblast compatibility. Nanocomposites have rougher and more hydrophilic surfaces compared to pristine PBS, thereby causing more osteoblasts to adhere and proliferate on them¹.

CONCLUSION

PBSu nanocomposites containing $\text{Sr}_5(\text{PO}_4)_3\text{OH}$ nanorods at different concentrations were prepared and studied as potential materials for tissue engineering applications. The mechanical properties of PBSu improved only for the sample with 0.5% SrHNRs. The nanoadditives can accelerate the enzymatic hydrolysis of PBSu increase materials hydrophilicity. SrHNRs can transform the bioinert PBSu surface into a bioactive one, promoting hydroxyapatite formation in SBF solution, too. Cell biology studies showed that PBS/SrHNRs are biocompatible materials and metabolic activity was best at the cells on the PBSu/SrHNRs 0.5 wt% sample.

New N-(2-carboxybenzyl)chitosan hybrid biocomposites for scaffolds applications

M. Nerantzaki¹, Z. Terzopoulou¹, M. Mavidou¹, D.N. Bikiaris¹, M.D. Anastasopoulou², M.A. Karakassides², A.R. Boccaccini³

¹ Aristotle University of Thessaloniki, Chemistry Department, GR-541 24 Thessaloniki, Macedonia, Greece.

INTRODUCTION

Chitosan is a biocompatible substrate for cell propagation but is soluble only in acidic aqueous environment, characteristic that somewhat limits its applications in vivo. However, this hurdle can be easily overcome by carboxyalkylation of the amino group of chitosan¹. Reports also suggest that bioactive glass ceramics and nanophase ceramics such as titania, influence the cell adhesion, proliferation, differentiation and colonization on surface of implants². Therefore in this project, we address the preparation and characterization of CBCS/BG 45S5 and CBCS/TiO₂ composite scaffolds, relevant to tissue engineering applications.

EXPERIMENTAL METHODS

In this work N-(2-Carboxybenzyl)chitosan (CBCS) was synthesized via a Schiff reaction of chitosan with 2-carboxybenzaldehyde, followed by reduction of the imine derivative with sodium borohydride. Meanwhile, 0.5, 2.5 and 5% TiO₂ nanoparticles and 2.5% Bioglass 45S5 (BG45S5) were added during the carboxyalkylation reaction, in order to obtain different CBCS composites. The porous structure of scaffolds was obtained by freeze-drying technique. The carboxyalkylation was determined by UV and H¹NMR spectroscopies. The prepared biocomposites were characterized using SEM, FTIR and XRD. The swelling, degradation and in-vitro biomineralization of the composite scaffolds were also studied.

RESULTS AND DISCUSSION

The primary λ_{max} is visible in case of CBCS at 231 nm and corresponds to $\pi \rightarrow \pi^*$ transition indicating the incorporation of 2-carboxybenzaldehyde into chitosan backbone, in agreement with the H¹NMR spectra, where the characteristic multiple peak of aromatic protons (7.6–7.8 ppm) appeared. All the CBCS composite sponges revealed high compressive strength values, suggesting that both the benzoic rings and the inorganic fillers can attribute significant mechanical stiffness to the chitosan matrix. Interconnected pores (150–300 μ m) can be observed in all biocomposites by SEM (Fig. 1) appropriate for scaffolds applications.

Fig. 1 SEM pictures of a) CBCS b) CBCS/BG 45S5 2.5%.

Both CBCS/TiO₂ and CBCS/BG composite scaffolds showed significant decline in the degradation rate after 1 and 2 weeks immersion in PBS compared to pristine CBCS scaffolds. Degradation of chitosan can result in acidic degradation products, which may be neutralized by alkali groups leaching out from Bioglass thus reducing the degradation rate. In addition, our results suggest that the composite scaffolds indicated increased swelling ratio, with increase of the concentration of the inorganic fillers. XRD study confirms the mineral deposition of minerals on the surface of both CBCS/BG 2.5% and CBCS/TiO₂ 2.5% composite scaffolds after 7 days incubation in SBF solution (Fig. 2).

Fig. 2. XRD pattern showing characteristic peaks of HA at 36.7°, 38.3° and 43° (upper part)

CONCLUSION

CBCS was successfully synthesized and identified by UV and H¹NMR spectra. Composite materials were prepared by adding TiO₂ nanoparticles at different concentrations and Bioglass 45S5 during the modification reaction. Porous scaffolds were obtained using the lyophilization technique and they were characterized. They all showed interconnected pores and high mechanical properties. In addition, swelling, degradation and bioactivity studies of the composite scaffolds were performed. The developed composite scaffolds were bioactive and showed controlled swelling and degradation rate by the addition of inorganic fillers.

Release of Propranolol hydrochloride from Polyethyleneglycol Modified Lactone Polymers

Sanja Asikainen, Minna Malin and Jukka Seppälä

Research Group of Polymer Technology, School of Chemical Technology, Aalto University, Finland,
sanja.asikainen@aalto.fi

INTRODUCTION

Biodegradable lactone polymers, especially poly(ϵ -caprolactone) (PCL), poly(lactic acid) (PLA) and their copolymers, have been widely studied for biomedical applications. Copolymerization can be used to tailor polymer properties and drug release from polymer matrix. Water soluble polyethylene glycol (PEG) block in lactone polymers increases the hydrophilicity of polymer.¹

The aim of this study was to investigate how copolymer composition and hydrophilic co-initiator affect the release of hydrophilic drug propranolol hydrochloride and the hydrolytic degradation of polymer.

EXPERIMENTAL METHODS

Materials Polymerization

Three different polymers were used in this study. PLCL (P(CL30-LLA70)) from Purac was used as reference polymer. Polymer of DL-lactide and copolymer of DL-lactide and ϵ -caprolactone were polymerized in bulk in a batch reactor by using 0.03 mol-% Sn(II) octoate as an initiator and 0.04 mol-% polyethylene glycol (PEG, 20 000 g/mol) as a co-initiator. The polymers were homopolymer PEG-PDLLA and copolymer PEG-P(CL30-DLLA70) having monomer ratio of 30 mol-% ϵ -caprolactone and 70 mol-% DL-lactide. The polymerization temperature was 160 °C and polymerization time was 4h. Polymers were used without further purification.

Preparation of samples

10 w-% of propranolol hydrochloride was blended into polymers in a corotating twin screw microextruder and melt pressed to receive cylinder-shaped devices having dimensions 5x2mm.

Thermal analysis

Glass transition temperatures were measured by differential scanning calorimetry (DSC). The analysis was performed on the temperature range of -90 °C to 200 °C at heating rate of 10 °C/min. The glass transition temperatures were determined from the second heating scan.

Molecular weight determination

Molecular weights were determined by room temperature size-exclusion chromatography. Chloroform was used as a solvent and eluent for polymers. Monodisperse polystyrene standards were used for primary calibration.

In vitro release experiments

Samples were weighted and immersed individually in 30 ml phosphate buffer solution (pH 7.4) at a temperature of 37 °C. The test specimens were removed from test tubes at different intervals and weighted after drying 24 h in vacuum at room temperature. The

amount of released propranolol HCl was determined from buffer solution using UV-spectrometer (Unicam Helios β v.1.30). The spectra were collected in the range of 200 to 350 nm. The maximum absorption was at 294 nm.

RESULTS AND DISCUSSION

No propranolol peak was seen in the DSC measurements of the drug blended with polymers. Therefore, it can be assumed that propranolol HCl was dissolved in the polymer matrices. Samples with propranolol HCl had slightly lower T_g compared to neat polymers (Table 1) which may be due to the effect of drug solubility to polymer. The effect was more significant with polymers containing PEG, which may indicate that hydrophilic PEG enhances solubility of hydrophilic propranolol HCl.

Table 1. Glass transition temperatures of polymers and drug blends.

	Neat polymer	Polymer + Drug
PEG-PDLLA	44 °C	40 °C
PEG-P(CL30-DLLA70)	10 °C	5 °C
P(CL30-LLA70)	22 °C	21 °C

Molecular weights of copolymers decreased slower compared to that of homopolymer during first month, which also affected the drug release rate. When molecular weight reached 40 % of its initial value the release rates became closer to each other.

For the first month, the release rate from P(CL30-LLA70) was faster compared to PEG-P(CL30-DLLA70). After 4 weeks PEG-P(CL30-DLLA70) started to swell remarkably and simultaneously the release rate increased. Homopolymer (PEG-PDLLA) showed faster release rate for the first month, but after that copolymer (PEG-P(CL30-DLLA70)) released drug faster.

CONCLUSION

Copolymerization and hydrophilic co-initiator can be used to tailor drug release properties of polymer. PEG enhanced the solubility of hydrophilic drug into the polymer matrix and affected drug release especially by increasing polymer swelling.

Titanium oxide coated cobalt-chromium-molybdenum; improving the osteogenic response of mesenchymal stem cells *in vitro*

N Logan^{1*}, A Cross³, S Collins², A Trayner², I Parkin³, L Bozec¹ and P Brett¹

¹ Biomaterials and Tissue Engineering, University College London, Eastman Dental Institute, UK.

² Corin Group, Cirencester, UK.

³ Department of Chemistry, University College London, UK
niall.logan.11@ucl.ac.uk

INTRODUCTION

Titanium (Ti) and its alloys are accepted as the current gold standard implant material for orthopaedic applications¹. Despite this, other materials, such as cobalt-chromium-molybdenum (CCM), are often used due to their superior mechanical properties. Whilst CCM provides additional mechanical strength, it does not have the biocompatibility of Ti². The objective of this study was to investigate if coating the surface of CCM in a layer of titanium oxide (TiO₂), could increase the bioactivity of the material, by masking the underlying bulk alloy with the same oxide layer as found on Ti.

EXPERIMENTAL METHODS

Human mesenchymal stem cells (MSCs) from 3 donors were used for the experiments. CCM discs of 15mm diameter, 1mm thickness, were ground and polished to achieve a smooth, featureless topography. Half of the CCM discs were then coated in anatase TiO₂ (CCMT) by way of atmospheric chemical vapour deposition (CVD). Discs of pure Ti were used as a positive control and uncoated CCM as a negative control. All discs underwent UV sterilisation before cell culture experiments. MSCs were cultured using DMEM supplemented with osteogenic additives, at standard culture conditions of 37°C/5%CO₂ in a humidified atmosphere. The osteogenic activity of the cells was assessed by monitoring proliferation (2x10³ cells per disc) and fluorescent microscopy analysis of both bone alkaline phosphatase (b-ALP) and hydroxyapatite, after 4 and 21 days, respectively (n=3) (12.5x10³ cells per disc). To ascertain the adhesion capabilities of the substrates, the expression of the focal adhesion protein, vinculin, was analysed by fluorescent microscopy after 3 and 24 hours in osteogenic culture (n=10) (5x10³ cells per disc). Images were quantified by a pixel based method using ImageJ software. Statistics were performed using the student's t test with p < 0.05 considered significant.

RESULTS AND DISCUSSION

MSC proliferation in OM was not inhibited and a minor rise in cell numbers through day 1 – 7 was observed on all substrates. By day 18, the amount of cells present had reduced on all three substrates, due to the creation of a mineralised tissue formed through MSC osteogenesis. Throughout the experiment, the CCMT substrate promoted osteogenic proliferation at a rate more comparable to that on the Ti substrate than the CCM.

The perceived intensity of b-ALP, an early stage marker of osteogenesis, was enhanced in MSCs on both CCMT and Ti surfaces after 4 days. b-ALP was observed in MSCs on the CCM substrate, but did not appear to exhibit the same level of expression as found on both CCMT and Ti.

Hydroxyapatite (HA) is one of the key components in the extra cellular matrix of bone tissue and is a late marker of osteogenesis. After 21 days in culture, HA was positively identified on all three substrates. Nodules of HA were observed on all three substrates, with the largest nodules found on the Ti substrate. The CCMT substrate stimulated the formation of bigger nodules of HA than CCM. This implies there was an enhanced level of osteogenic differentiation occurring on the CCMT substrate compared to CCM.

Vinculin is a focal adhesion protein involved in linking cell adhesion membranous molecules, and plays a role in the adhesion of the cell to the substrate. Fluorescent microscopy analysis showed an increase in the expression of vinculin on both CCMT and Ti surfaces compared to CCM, although this was only statistically significant for Ti vs CCM at 24 hours (p<0.05). Furthermore, MSCs on CCMT and Ti appeared to have a greater number of focal adhesions per cell. This analysis implies that the CCMT and Ti substrates may promote superior adhesion of MSCs, through heightened vinculin expression and greater numbers of focal adhesions per cell.

CONCLUSION

From the work in this study we have demonstrated that it is possible to improve the osteogenic behaviour of human MSCs on CCM by coating the substrate with a durable layer of TiO₂ by way of atmospheric CVD. This infers that TiO₂ coatings may be a promising method of improving other bio inert biomaterials.

Autophagy Modification by Intracellular Controlled Release of Rapamycin

Junpei Nagata, Makoto Matsui, and Yasuhiko Tabata

Department of Biomaterials, Fields of Tissue Engineering, Institute for Frontier Medical Sciences,
Kyoto University, Japan, yasuhiko@frontier.kyoto-u.ac.jp

INTRODUCTION

Autophagy plays an important role in maintaining the functional homeostasis of cells. Harmful intracellular harmful components, such as denaturalized protein aggregates and damaged mitochondria, are physiologically eliminated via autophagy. The intracellular accumulation of the components due to autophagy dysfunction causes neurodegenerative disorders¹ or tumorigenesis². If autophagy can be activated, the harmful accumulation will be suppressed to normalize the cell quality. To modify the autophagy activity, the mammalian target of rapamycin (mTOR) was inhibited by rapamycin. In this study, rapamycin was incorporated into nanospheres of poly(L-lactic acid) (PLA) for the controlled release. When cells were incubated with PLA nanospheres incorporating rapamycin or free rapamycin, the autophagy activity was compared. The cellular internalization of nanospheres and the controlled release of rapamycin from the nanospheres were examined.

EXPERIMENTAL METHODS

PLA with a weight-averaged molecular weight of 5,000 and rapamycin were dissolved in the mixed solution of acetone and ethanol (4/1 v/v). The mixed solution was emulsified in aqueous poly(vinyl alcohol) (PVA) solution, followed by the complete evaporation of organic solution to prepare PLA nanospheres incorporating rapamycin. The size of nanospheres was measured by a dynamic light scattering method, and the percentage of rapamycin incorporated was determined by high performance liquid chromatography (HPLC). *In vitro* rapamycin release was evaluated in phosphate-buffered solution (PBS), while the amount of rapamycin released was quantified by HPLC. Human hepatocellular carcinoma (HepG2) cells were cultured with PLA nanospheres incorporating coumarin-6, and then the nanospheres internalization was assessed by fluorescence microscopy. To evaluate autophagy activity and accumulation of ubiquitinated proteins, HepG2 cells were cultured with PLA nanospheres incorporating rapamycin or free rapamycin in the absence or presence of a proteasome inhibitor, MG-132 for 4 days, followed by lysing to extract cells proteins. The proteins extracted were evaluated by the antibodies of microtubule-associated protein 1 light chain 3 (LC3), and ubiquitin in western blotting assay for the evaluation of autophagy activity and ubiquitinated protein accumulation, respectively.

RESULTS AND DISCUSSION

The size of PLA nanospheres incorporating rapamycin ranged from 200 to 500 nm. The size increased with an increase in the concentration of PLA or PVA used in nanospheres preparation. The percentage of rapamycin incorporated into the nanospheres was about 100%. The

in vitro release test indicated that rapamycin was released over one week. PLA nanospheres were internalized into HepG2 cells within one hour and retained in the cells for 4 days. The western blotting assay revealed that autophagy was induced by incubation with free rapamycin or rapamycin-incorporated nanospheres for 1 day (**Figure 1**). However, after 4 days incubation, the induction of autophagy was observed only for the nanospheres incubation. On the other hands, the ubiquitinated protein accumulation was suppressed by incubation with free rapamycin or rapamycin-incorporated nanospheres for 1 day, whereas the accumulation suppression was observed only by 4 days incubation with the nanospheres. It is possible that rapamycin released from PLA nanospheres induced autophagy, resulting in the enhanced degradation of ubiquitinated proteins.

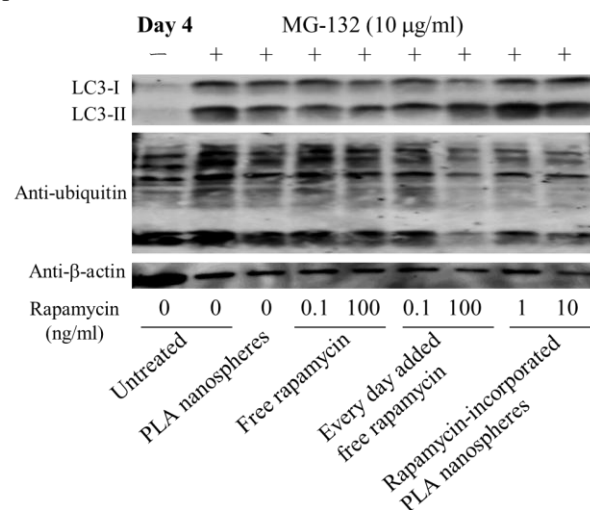

Figure 1. Western blotting of LC3 and ubiquitinated proteins in HepG2 cells incubated with PLA nanospheres incorporating rapamycin or free rapamycin in the presence of MG-132. The concentration of PLA nanospheres is 1, 10 μg/ml.

CONCLUSION

PLA nanospheres incorporating rapamycin with the size range from 200 to 500 nm released rapamycin over one week. The nanospheres were internalized in HepG2 cells to induce autophagy and allowed to intracellularly degrade ubiquitinated proteins for 4 days. Incorporating rapamycin into PLA nanospheres is promising to modify autophagy activity through rapamycin release.

INTRODUCTION

Since the beginning of the 1970s, controlled release technology has known great advancement, and motivated numerous researchers in materials science. These systems overcome the drawbacks of traditional drug dosage form, and offer more effective and favorable methods to optimize drug delivery in optimum dose to specific sites or to prolong delivery duration. Our research project deals with the synthesis of pH-controlled drug delivery systems for bone implant, allowing the local release of Gentamicin Sulphate (GS), an antibiotic communally used to prevent infections during orthopaedic surgeries. By systemic therapy, antibiotics may not be delivered efficiently and adequately without side effects. The goal of this project is to develop biomaterials allowing the controlled release, at the level of the site of implantation of these biomaterials (over an adjustable period of time), of an active molecule (GS) fixed covalently on the surface of the latter thanks to chemical anchoring of spherical particles (in particular of nanoparticles) functionalized by the active molecule. A cleavage reaction of the active particle-active molecule bond, activated by the contact of material with the physiological medium or by a modification of the pH, induces controlled release of the bioactive molecule in its native form.

Fig. 1. Representation of the bioactive biomaterial

EXPERIMENTAL METHODS

α -norbornenyl poly(ethylene oxide) macromonomers were synthesized by anionic ring-opening polymerization of ethylene oxide and were ω -functionalized with a carboxylic acid (NB-POE-COOH) or the GS (NB-POE-GS). Macromonomers were characterized by ^1H NMR, Size Exclusion Chromatography (SEC) and MALDI TOF. Nanoparticles are obtained by Ring-Opening Metathesis CoPolymerization (ROMP) of norbornene with NB-POE-COOH and NB-POE-GS. Their colloidal stabilities were shown by Dynamic Light Scattering measurements. Titanium discs ($\varnothing = 5 \text{ mm}$; $h = 3 \text{ mm}$) were activated by functionalization with amine groups using aminosilane molecules (APTES). The NPs were covalently linked onto the titanium surface through the formation of an uncleavable amide bond between the carboxyl group of the NPs and the amide group of silane molecules available onto the surfaces of the disks activated by NHS and DCC. The grafting was characterized by Scanning Electron Microscopy (SEM) Fluorescence microscopy and μ -imagery. The *In vitro* evaluation was carried out by Minimum Inhibitory Concentration (MIC) measurements after GS release at acidic

pH. GS release kinetic profiles have been established by fluorescence spectroscopy.

RESULTS AND DISCUSSION

α -norbornenyl macromonomer was obtained with a size of about 4000 g.mol⁻¹ and a narrow distribution (PDI < 1.1). The ω -functionalization was carried out with high functionalization yields. Nanoparticles are synthesized with total conversions and diameters were about 350 nm.

Two controlled densities of NPs - corresponding to two densities of drug (0.15 and 1.0 $\mu\text{g}\cdot\text{cm}^{-2}$) - were anchored on the biomaterial surfaces and these densities were measured by three methods: scanning electron microscopy observations, μ -imagery using radio-labelled nanoparticles and fluorescence microscopy, using FITC-labelled nanoparticles. FITC-labelled biomaterials were also used to establish GS release kinetics as a function of pH (pH 4, 5, 6 and 7).

Fig. 2. GS release kinetic curves as a function of pH

The GS release efficiency was proved by *in vitro* bacterial inhibition tests using *staphylococcus epidermidis* as bacterial strain. GS was released from grafted titanium discs. A delivery only at acidic pH, (pH = 6, 5, 4) has been observed.

CONCLUSION

In this work was presented the synthesis of a bioactive biomaterial and their characterization. We also demonstrated the *in vitro* activity of such materials. *In vivo* experiments on rabbits have been done and produced so far encouraging results.

Design of a new composite structure based on resorbable synthetic and natural polymers for anterior cruciate ligament reconstruction

Coline PINESE¹, Xavier Garric¹ Benjamin Notellet¹ Jean Coudane¹ Christian Gagnieu²

¹ Artificial Biopolymers department/ Max Mousseron Institute of Biomolecules, Montpellier I University, France,

² National Institute of Applied Sciences, France, colinepinese@gmail.com

INTRODUCTION

Following accidents, anterior cruciate ligament (ACL) damages are increasingly, becoming a common public health problem. As ACL have poor regeneration ability^{1,2}, it can be removed and replaced by autologous grafts. However, current available solutions have several limitations encouraging research on degradable biomaterials alternatives³. To comply with the requirement of ligament regeneration, ligament reinforcement must be strong enough to support knee physiological strains, and must degrade while allowing the new ligament regeneration.

The aim of this study is to design a new composite composed of two parts:

- 1- A degradable and elastomeric scaffold to serve as temporary mechanical support
- 2- A collagen-GAG matrix to promote cell colonization and ligament tissue formation and maturation.

EXPERIMENTAL METHODS

Novel block copolymers PLA-Poloxamer based have been synthesized by ring opening polymerization. They were then spun for designing a tubular knitted fabric. In parallel, a collagen and glycosaminoglycans (GAGs) porous three-dimensional matrix has been developed to promote cell adhesion and proliferation. Knitted reinforcements associated with collagen-GAG matrix are designing as a composite structure. Subcutaneous implantation of composite structures was performed for 3 months in rats

RESULTS AND DISCUSSION

The main objective is to show the ability of a degradable and polymeric scaffold to provide a structural support with similar mechanical properties to those of ligament tissue.

Figure 1: Copolymere tubular fabric

Figure 1 shows the tubular fabric

	Copolymers tubular fabric	Ligaments
Young's Modulus (MPa)	67 MPa	50-150 MPa
Toe regions strain (%)	27,20%	7-16 %
Stress at failure (MPa)	22,5 MPa	16-36 MPa

Table 2: Copolymers tubular fabrics and ligament mechanical features

Table 1 show that main mechanical features of copolymers tubular fabric are similar to those of ligament tissue.

The second aim is to promote early neotissue formation.

Figure 2: Composite structure subcutaneously implanted after one month

The figure 2 show that the inflammation is moderate after a month and composite structures are fully integrated allowing a new tissue formation composed of oriented collagen.

CONCLUSION

Fully integrated, the composite structure allows neotissue formation while gradually losing its mechanical properties after 3 months. The ability of composite structure to provide a structural support for ligament regeneration with mechanical properties similar to native tissues in dynamic environments, and their ability to support a new tissue formation make them of a particular interest.

INTRODUCTION

The increasing antibiotic resistance of some bacteria strains and the risk of infections in acute and chronic wounds and burns have encouraged new approaches for the prevention of biofilm-associated infections, among them the use of silver. Unlike antibiotics, silver interferes with multiple components of bacterial cell structure and functions, so being less affected by specific micro-environmental variations. Recently, silver wound dressings have become widely accepted in wound healing centres and are commercially available. In this work, novel antibacterial wound dressings have been developed through a silver deposition technology based on the photochemical synthesis of silver nanoparticles.

MATERIAL AND METHODS

Conventional cotton gauzes were treated with 0.5 wt/v % of silver nitrate, according to a patented technique based on the *in situ* synthesis and deposition of silver nanoparticles¹. Plain gauzes and gauzes treated with 4 wt/v % Ag were adopted respectively as negative and positive control. Samples were analyzed by a field emission scanning electron microscope (FE-SEM) in order to verify the distribution of the silver coating on the cotton fibres. Thermogravimetric analysis (TGA) was adopted to measure the amount of silver deposited on the substrates. The antimicrobial capability of the silver-treated samples was determined by evaluating the efficacy of the silver coating in inhibiting the bacterial colonization of *Staphylococcus aureus* on the material, through agar diffusion tests and bacterial enumeration. Samples of untreated and silver-coated cotton gauzes were also characterized through SEM analysis of bacterial cells adhered onto the samples, after fixation of bacteria with glutaraldehyde and paraformaldehyde.

RESULTS AND DISCUSSION

The presence of silver on the substrates was verified through TGA analysis and resulted different between the treated samples. The result of the SEM showed a homogeneous silver coverage of the fibres, also with the lower silver concentration tested. No significant difference in the antibacterial properties was observed in the width of the bacterial inhibition growth areas induced by the silver treated samples between the different concentrations of silver tested. These data were confirmed by the results obtained by the bacterial enumeration and by SEM analysis of the bacterial adhesion on the cotton fibres, confirming a considerable reduction of the bacterial adhesion and proliferation.

Figure 1. SEM analysis of distribution of the silver coating on the cotton fibres: neat cotton fibres (a);

cotton fibres treated with 0.5 wt/v % silver (b); cotton fibres treated with 4 wt/v % silver (c); cotton fibres treated with 0.5 wt/v % silver at higher magnifications (11.74KX).

Figure 2. Agar diffusion tests on *S. aureus*: untreated sample (a); sample treated with 0.5 wt/v % silver (b); sample treated with 4 wt/v % silver (c).

Figure 3. SEM analysis on bacterial cells adhered and proliferated on the cotton gauzes: untreated gauze (a); gauze treated with 0.5 wt/v % silver (b).

CONCLUSION

The results obtained demonstrated an impressive reduction in bacterial proliferation and adhesion. Thanks to the simplicity of the technology, the ease of preparation of the devices, the economic feature and the antibacterial effectiveness, these silver treated gauzes can represent an alternative to common medical treatments to contain the risk of wound contamination.

INTRODUCTION

Silver nanoparticles (AgNPs) have attracted intensive research interest because of their important bactericidal effect. AgNPs have been incorporated in fabrics, polymers, medical devices and burn dressings to eliminate microorganisms.

In this study a nano-silver antibacterial coating on hydrogel fibers was analyzed. Hydrogel blends obtained by different percentages of silver-treated and untreated fibers were compared to determine the best cost/antibacterial efficacy ratio in the final product.

EXPERIMENTAL METHODS

The substrates used were superabsorbent fibers based on crosslinking copolymers of acrylic acid (Oasis, Technical Absorbents Ltd, UK). Deposition on AgNPs was obtained through a well-known technique developed and optimized by University of Salento and based on the *in situ* photo-reduction of silver nitrate [1]. Three blends with different Treated/Untreated fibers ratios were prepared and named Blend A, B and C, with ratios of 1:1, 1:2 and 1:3 respectively. Untreated fiber (sample NT) was used as negative control and 100% treated fiber (sample T) was used as positive control.

The antimicrobial activity of the silver-treated substrates on *E. coli* and *S. aureus* was evaluated through agar diffusion tests and through optical density readings at 600 nm in Luria-Bertani Broth (LB). The swelling properties in phosphate buffered saline (PBS), simulated body fluid (SBF), chemical simulated wound fluid (cSWF), and deionized water (DI water) were investigated. Samples were analyzed by scanning electron (SEM) microscopy to study the morphology of silver coating and the distribution of AgNPs clusters.

RESULTS AND DISCUSSION

Diffusion tests in agar were performed according to the Standard "SNV 195920-1992". The inhibition to bacteria growth was evaluated by measuring the width of the inhibition zone surrounding the sample. Results of this test are shown in Table 2.

	<i>S.Aureus</i>	<i>E.Coli</i>
Sample T	3.5 ± 0.3	4.8 ± 0.3
Blend A	3.2 ± 0.3	4.0 ± 0.3
Blend B	1.8 ± 0.3	2.0 ± 0.3
Blend C	1 ± 0.3	1.2 ± 0.3
Sample NT	0 ± 0	0 ± 0

"Table 2: Inhibition zone (mean ± SD in mm)".

The results reported in Fig. 1 show the antibacterial effect of silver treated hydrogel fibers and its blends. The results obtained by the swelling tests are shown in Fig. 2.

"Figure 1: Bacteria concentration (CFU)/mL ± SD"

The swelling degree significantly decreased with the increasing of the ionic strength of the swelling solution but can be considered good for applications such as exudate absorptive materials. SEM revealed a homogeneous coating as Fig. 3 clearly shows.

"Figure2: Swelling ratios in different fluids "

"Figure3: SEM images Sample T 3000x,inset 20000x"

CONCLUSION

The materials obtained demonstrated good swelling properties, uniform deposition and good antibacterial effects, even in the blends containing the lower percentage of silver treated fibers, thus indicating the effectiveness of the silver deposition technology and its potential use in the field of antimicrobial device for biomedical applications.

Optimization of Silicone as Implant Material for the Application in the Middle Ear: Incorporation of Functionalized Nanoporous Silica Nanoparticles

Tanja Heemeier¹, Mandy Jahns¹, Songül Noyun¹, Laura Doniga-Crivat², Silke Besdo², Peter Behrens¹

¹Institute for Inorganic Chemistry, Leibniz University of Hannover, Germany

²Institute for Continuum Mechanics, Leibniz University of Hannover, Germany

Tanja.Heemeier@acb.uni-hannover.de

INTRODUCTION

Silicone as implant material is applied in many different medical applications because of its biocompatibility and biostability under the experimental conditions¹. The goal we pursue is to develop a silicone pad in order to optimize the contact between a middle ear prosthesis and the tympanic membrane. Such a prosthesis is applied when a patient lost the auditory ossicular chain due to infections. Up to now a small piece of cartilage is placed between the tympanic membrane and the headpiece of the prosthesis. The major disadvantage of this body's own material is that it degenerates gradually and its properties differ from patient to patient. However, the silicone pad, as a long-term stable material with steady properties, shall protect the tympanic membrane against forcing of the prosthesis. Additionally, an optimal sound transmission has to be ensured. For reinforcement and adjustment the silicone mixture is equipped with different fillers^{2,3} like functionalized hydrophobic nanoporous silica nanoparticles (NPSNP). If desired these NPSNP could be used as a local drug delivery systems as well.

EXPERIMENTAL METHODS

The silicones SILUPRAN[®] 2420 and 2445 served as base material and were mixed with functionalized hydrophobic NPSNP to adjust the mechanical properties for the desired application. The NPSNP with approx. 40 nm diameters were synthesized by using tetraethoxysilane, diethanolamine and cetyltrimethylammonium bromide in a water/ethanol mixture. The functionalization was carried out by the reaction with alkenyltrimethoxysilanes as well as different alkenyl- and alkylchlorosilanes. For optimization of the functionalization degree (FD) and the hydrophobicity the reaction conditions and concentrations were varied. Afterwards different amounts of functionalized hydrophobic NPSNP were mixed with the silicones in a SpeedMixer[™] DAC 150SP and cured at 120 °C.

RESULTS AND DISCUSSION

The synthesis of hydrophobic vinyl-functionalized NPSNP was successful. The FD of vinyl groups was determined with C/S analysis. With the variation of functionalization agents and their concentrations different FDs were obtained and tested in silicone mixtures. The comparison of SEM images of pure SILUPRAN[®] 2445 and SILUPRAN[®] 2445 with incorporated functionalized hydrophobic NPSNP shows no differences so that the nanoparticles added seem to be distributed homogeneously. Rheological measurements

(Fig. 1) of these samples show a slight increase of the storage modulus G' when functionalized NPSNP were incorporated compared to pure SILUPRAN[®] 2445. Thus, the incorporated nanoparticles have a positive reinforcing effect on the network.

Fig. 1: Rheological measurements of SILUPRAN[®] 2445 with and without functionalized NPSNP.

These results and further investigations regarding more hydrophobic NPSNP and higher filler contents may help to find a silicone mixture with suitable mechanical properties for the silicone pad. Additionally, tensile testings for characterisation of the silicones are planned.

CONCLUSION

Nanoporous silica nanoparticles were vinyl-functionalized and hydrophobized with different functionalization degrees. Then, these nanoparticles were incorporated into silicone mixtures which showed slightly reinforcing behaviour. To find the optimal filler content for the application as silicone pad in the middle ear further investigations need to be done. The incorporated nanoparticles can also be used as local drug delivery systems to promote healing.

Temporary implant surfaces equipped with an anti-adhesive plasma fluorocarbon polymer film

Birgit Finke¹, Holger Testrich², Henrike Rebl³, J. Barbara Nebe³, Rainer Bader⁴, Uwe Walschus⁵, Michael Schlosser⁵, Klaus-Dieter Weltmann¹, Jürgen Meichsner²

¹Leibniz Institute for Plasma Science and Technology, Greifswald, Germany ²Institute for Physics, University Greifswald, Germany ³Dept. of Cell Biology and ⁴Dept. of Orthopedics, Rostock University Medical Center, Rostock, Germany ⁵Medical Biochemistry & Molecular Biology, University Greifswald, Germany; finke@inp-greifswald.de

INTRODUCTION

Metallic implants, especially made from titanium and its alloys, are state of the art in orthopedic and trauma surgery. Temporarily used implants such as intra-medullary nails, screws or external fixators for fractures support the mechanical stabilization of the bone consolidation but should not integrate into the bone because of their removal after fracture healing. An anti-adhesive coating could be very useful for these temporary implants to avoid protein and cell attachment as well as ingrowth into the surrounding tissue at last.

Gas-discharge plasma processes are successfully applied for the modification of titanium surfaces and could be very valuable for the improvement of implant performance [1]. A new surface functionalization strategy was developed in close collaboration with cell biologists. The plasma polymerization of octafluoropropane (C_3F_8) in a mixture with hydrogen (H_2) as precursor leads to the desired surface properties on Ti6Al4V.

Here, we present optimized plasma fluorocarbon polymer (PFP) films for both plasma discharges. Physico-chemical properties of the PFP-films were determined and the biological response *in vitro* and *in vivo* was tested.

EXPERIMENTAL METHODS

Discs (1 cm diameter) and platelets ($5 \times 5 \times 1 \text{ mm}^3$) from polished, chemically pure titanium alloy Ti6Al4V were used as substrates. They were coated with ~300 nm thin films applying continuous wave low-pressure microwave (MW) or radio frequency (RF) discharge plasmas. The PFP films were optimized by variation of the C_3F_8/H_2 ratio, power and pressure strongly correlated with cell culture investigations to guarantee minimal cell adhesion. Film properties were analyzed by XPS, FT-IR, water contact angle measurements, AFM, as well as mechanically testing, e.g. the determination of total wear debris with artificial bone per 1 million cycles. Film stability was checked by sonication (10°) in distilled water. Human osteoblasts (MG-63 cells) were cultured on the samples. Adhesion and cell cycle phases were calculated by flow cytometry. *In vivo* biocompatibility was studied after intramuscular implantation of untreated Ti6Al4V and PFP-coated platelets in male LEWIS rats. The inflammatory tissue response was analysed after 7, 14, and 56 days.

RESULTS AND DISCUSSION

A closed pinhole-free, strongly cross-linked (Fig.1), mechanical stable and very smooth PFP film could be obtained. Sonication of these films showed good resistance against hydrolysis and delamination. Using XPS, an F/C ratio >1 was found and Ti6Al4V could not be detected by XPS. An advantageous medium hydrophobicity exists with a water contact angle of about 110° . A C1s high resolution spectrum for a C_3F_8/H_2 mixture (70/30 ml) is shown in Fig. 1.

Fig. 1: C1s high resolution XPS spectrum of the PFP coating

Cell adhesion and cell spreading were drastically reduced on PFP coated Ti6Al4V *in vitro* in both discharges.

In vivo investigations revealed only a weak tissue reaction in comparison to untreated Ti6Al4V.

CONCLUSION

These optimized gas-discharge plasma-based PFP surface modification could be an option to improve the clinical handling of temporarily used Ti6Al4V implants.

niklas.burbli@acb.uni-hannover.de

INTRODUCTION

Within the Cluster of Excellence Hearing4all a main requirement is the optimization of the long-term biointegration and functionality of the cochlear implant. Our approach is the chemical modification of the electrode surface to improve the contact of the cochlear electrodes to the nerve fibers on the one hand and to minimize the impedance of the electrical contact on the other hand¹. For this purpose, the platinum surface of these electrodes shall be equipped with a coating based on Carbon Nanotubes (CNTs).

Carbon Nanotubes represent a remarkable material with a chemically inert structure and a unique set of properties like high aspect ratio, high mechanical strength and excellent electrical conductivity. There are promising results for various biomedical applications of CNTs and especially CNT-based coatings of neural interface electrodes^{2,3}.

EXPERIMENTAL METHODS

As-received CNTs were purified via acid-treatment to remove residual catalyst and to get carboxylic acid-functionalized CNTs. Stable aqueous dispersions of the purified CNTs were obtained via ultrasonication.

Tailored gold- or platinum-coated silicon wafers (1.5x1.5 cm²) were coated with the aqueous CNT-dispersions via several methods, e.g. doctor blading method, spray or drop coating.

Characterization of the purified CNTs and CNT-coated films was carried out by SEM, Raman and IR spectroscopy. The purity and composition of the CNTs were additionally investigated by EDX and TG measurements. Thickness and topography of the films were determined with a confocal microscope.

Electrochemical characterization of the CNT-coated and non-coated substrates was performed via impedance spectroscopy scans by using a potentiostat/galvanostat (Versastat 4, Princeton Applied Research). A standard three-electrode electrochemical cell configuration with a Pt wire as counter electrode and an Ag/AgCl reference electrode was applied.

Cell culture experiments of the CNT-films were performed with NIH3T3 fibroblasts. The morphology and GFB expression were determined by transmission light and fluorescence microscopy.

RESULTS AND DISCUSSION

Long-time stable aqueous CNT-dispersions were successfully obtained via acid-treatment and following ultrasonication. A reduction of catalyst residue in the CNT-solid was determined with TG and EDX measurements. Raman and IR spectra show structural changes and the effective carboxylic acid-functionalization of the CNTs.

CNT-coatings have been prepared with a thickness below 100 nm via spray coating and a thickness of about half a micron via doctor blading method and drop coating. SEM images show a homogeneous covering of the substrate with CNTs (Fig. 1).

Fig. 1: SEM image of CNT-coating on Au substrate (left) and fluorescence microscopic image of NIH3T3 fibroblasts on CNT-coated glass substrates (right).

The cell culture experiments with NIH3T3 on CNT-coatings indicate a good biocompatibility (Fig.1).

Fig. 2: Impedance spectroscopy measurements of CNT-coated and uncoated Au-substrates.

The impedance spectroscopy scan (Fig.2) shows the CNT-coating leads to decreased impedance at frequencies below 10² Hz.

CONCLUSION

Purification and functionalization of the CNTs lead to stable aqueous dispersions. These have been used to prepare CNT-films via variable coating methods. Cell culture experiments indicate good biocompatibility of the CNT-films. The electrochemical characterization of as-prepared electrodes shows a decrease of the impedance at frequencies below 10² Hz compared to a non-coated Au electrode.

INTRODUCTION

Installing multifunctionality on biomaterials is a powerful approach to increase their bioactivity. In particular, this strategy could be applied to metallic substrates to improve and accelerate osteointegrative processes¹. The aim of this work was to introduce an innovative methodology to synthesize polyurethane-polyurea nanocapsules (PUUa NCs) functionalized with cyclic RGD peptides (Fig. 1), which show great cell-binding activity and allow the encapsulation of hydrophobic drugs. Different PUUa NCs RGD-decorated were coated on Ti surfaces, and their effect on the adhesion of osteoblast like cells investigated. Moreover, the encapsulation of roxithromycin and its antibacterial effects were studied.

Figure 1: Schematic structure of PUUa NCs

EXPERIMENTAL METHODS

The NCs were covalently immobilized on Ti samples via a two-step protocol. First, PUUa NCs were synthesized by successive polycondensations between diisocyanate and diamino/diol monomers, followed by an aqueous emulsification². Subsequently, PUUa free isocyanate groups were reacted with Ti amino groups. To this end, Ti samples were previously activated with oxygen plasma and aminosilanized. The presence and distribution of the capsules was analyzed by SEM and fluorescence microscopy. The influence on cell behaviour was investigated using SAOS-2 cells by cell adhesion assays. The encapsulation of roxithromycin

was studied by HPLC, and evaluated in antimicrobial assays.

RESULTS AND DISCUSSION

The functionalization of Ti with the NCs was optimized by using distinct crosslinking units until an homogenous particle distribution was observed by SEM and fluorescence microscopy. RGD-nanocapsules significantly improved the adhesion of Saos-2 cells compared to controls (Fig. 2). Moreover, the presence of the PUUa-RGD capsules supported very good levels of spreading, with clear actin filaments and cytoskeletal organization, and the formation of focal adhesions. Encapsulation of roxithromycin (antibacterial, anti-inflammatory) was also explored.

Figure 2: Cell adhesion on coated Ti after 4 h of incubation

CONCLUSION

The immobilization of PUUa NCs functionalized with RGD peptides onto Ti is a feasible and very promising strategy to increase the bioactivity of Ti and accelerate osteointegrative processes. Encapsulation of distinct drugs using these systems opens new prospects for applications in biomaterials and regenerative therapies.

INTRODUCTION

The aim of our work is the optimization of the long-term biointegration and function of cochlear implants in the inner ear. By chemical modification of the electrode surface or by integrating delivery systems for active agents, the contact between the platinum sections of the cochlear electrode and nerve fibers can be improved. The loading and controlled release of drugs and neuronal growth factors is possible by introducing porous coatings on the substrate like nanoporous silica or porous platinum¹⁻³. Due to the porosity of the platinum coatings the impedance can also be reduced by the increased surface, what is favourable for the signal line of the cochlear implants⁴. We investigated the chemical and electrochemical preparation of nanoporous platinum films on metallic surfaces like gold- or platinum-coated silicon wafers. The focus of our investigations about porous platinum is lying on its biocompatibility as well as on the decrease of the impedance for applications in the inner ear.

EXPERIMENTAL METHODS

Porous platinum coatings were chemically deposited on gold- and platinum-coated silicon wafers by dip coating from surfactant-containing H_2PtCl_6 and PtCl_4 solutions. The surfactants used were Pluronic® F127 and C_{16}EO_8 , which were simultaneously removed during thermal reduction of the platinum.

For electrochemical platinum deposition from an aqueous surfactant-containing Pt^{4+} solution, a three electrode setup was used. Working electrodes were gold- or platinum-coated silicon wafers, as counter electrode a platinum wire was applied. The reference electrode was an Ag/AgCl system in saturated KCl-AgCl solution. Two different methods, direct and pulse potential electrodeposition were investigated at a constant potential of -0.5 V .

The coatings were characterized by SEM, EDX, confocal microscopy and impedance measurements. The cell culture tests of the chemical deposited platinum coatings were performed with NIH3T3 fibroblasts.

RESULTS AND DISCUSSION

The chemically deposited films consisted of a network of platinum nanoparticles which formed pores with diameters between 50 and 100 nm, shown in Fig. 1. Cell culture experiments of the chemically deposited platinum coatings with NIH3T3 fibroblasts indicated good cellcompatibility. As shown in Fig. 1, the fibroblasts exhibit a good cell proliferation on the stable platinum coating, thus a high cell density exists.

Fig. 1: SEM image (left) and image of NIH3T3 fibroblasts cell culture tests (right) of nanoporous platinum coatings by chemical deposition.

Impedance measurements of the chemically and electrochemically deposited platinum coatings showed a decrease of the impedance in comparison to the uncoated substrates, shown in Fig. 2.

Fig. 2: Impedance measurements of uncoated and platinum-coated gold wafers.

CONCLUSION

We were able to deposit porous platinum coatings in two different ways. The chemical deposited porous platinum coatings by dip coating and subsequently calcinations showed good cellcompatibility in cell culture experiments. Both, chemically and electrochemically deposited porous platinum coatings exhibit decreased impedances.

INTRODUCTION

Bacterial infections are the most current complication which could occur during the fitting of a prosthesis in orthopaedic surgery. It can be the cause of morbidity and mortality and take place in 0.7 to 2.2% of the cases despite antibioprophyllaxis. Bacteria responsible for this kind of infections are *Staphylococcus Epidermidis* or *Staphylococcus Aureus* and mostly, it happens in per-operative conditions. Even if antibioprophyllaxis considerably decreases the rate of per-operative infection, it presents risks of allergy, side effects or bacteria resistance. Moreover, standard antibiotic protocols present little efficiency because of immuno-incompetent zone around implant, reduced sensitivities of bacteria growing in a biofilm and difficulties of achievement of the drug at the site of infection. That is why local antibiotic treatments are an excellent alternative to deal with these problems.

In a recent contribution to this field, we have presented a new biomaterial having applications as implant in orthopaedic surgery and allowing the release of an antibiotic (the Gentamicin Sulphate) only in case of infection [1, 2]. When methicillin-resistant bacteria are involved, glycopeptide antibiotics, as Vancomycin (VAN), are the drugs of choice to cure the infection. That is why we have explored a new route, with the use of this antibiotic. In this work, we propose to synthesize titanium alloy coated with vancomycin by covalently grafting drug functionalized polymeric NPs onto its surface.

Fig. 1. Representation of the bioactive biomaterial

EXPERIMENTAL METHODS

α -norbornenyl poly(ethylene oxide) macromonomers were synthesized by anionic ring-opening polymerization of ethylene oxide and were ω -functionalized with a carboxylic acid (NB-POE-COOH) or the VAN (NB-POE-VAN). Macromonomers were characterized by ¹H NMR, Size Exclusion Chromatography (SEC) and MALDI TOF. Nanoparticles are obtained by Ring-Opening Metathesis CoPolymerization (ROMP) of norbornene with NB-POE-COOH and NB-POE-VAN. Their colloidal stabilities were shown by Dynamic Light Scattering measurements. Titanium discs ($\varnothing = 5$ mm ; h = 3 mm) were activated by functionalization with amine groups using aminosilane molecules (APTES). The NPs were covalently linked onto the titanium surface through the formation of an uncleavable amide bond between the carboxyl group of the NPs and the amide group of silane molecules available

onto the surfaces of the disks activated by NHS and DCC. The grafting was characterized by Scanning Electron Microscopy (SEM). The *In vitro* evaluation was carried out by Minimum Inhibitory Concentration (MIC) measurements on VAN functionalized macromonomers and particles. Antibacterial activity of the final materials was also characterized.

RESULTS AND DISCUSSION

α -norbornenyl macromonomers were obtained with a size of about 4000 g.mol⁻¹ and a narrow distribution (PDI < 1.1). The ω -functionalization was carried out with high functionalization yields. Nanoparticles are synthesized with total conversions and diameters were about 350 nm.

A controlled density of NPs was anchored on the biomaterial surfaces and this density was measured by scanning electron microscopy observations.

Fig. 2. SEM observation of the VAN functionalized biomaterial

The efficiency of the vancomycin functionalized biomaterials was proved by *in vitro* bacterial inhibition tests using *staphylococcus aureus* as bacterial strain.

CONCLUSION

In this work was presented the synthesis of bioactive biomaterials functionalized with Vancomycin and their characterization. We also demonstrated the *in vitro* activity of such materials. *In vivo* experiments on rabbits are now in progress.

INTRODUCTION

Hyaluronan (HA) is one of the most important biopolymers in the biomaterials field. Chemical modification can tailor HA towards specific uses as drug delivery system or in tissue engineering. Since its introduction¹ EDC/NHS has been the standard method for amidation of HA. Here we compare systematically ligation of amines to HA in water via EDC/NHS and DMTMM using an array of substrates including small, large and functional molecules: adipic acid dihydrazide (ADH); amino acetaldehyde dimethyl acetal (AADA); glycine ethyl ester hydrochloride (Gly); bovine serum albumine (BSA); doxorubicin (Dox) hydrochloride; poly(N-isopropylacrylamide) (pNIPAM)

EXPERIMENTAL METHODS

Syntheses were performed using DMTMM or EDC/NHS as condensing agent 1/1 to HA (4/1 for ADH, in order to compare with reference 1).

EDC/NHS Syntheses. After combining solutions of HA and the respective amine EDC+NHS in powder were added, and pH was corrected to 5.5. After 45 minutes pH was raised to 7.3 and the reaction let to proceed at room temperature for 5 days.

DMTMM Syntheses. After combining solutions of HA and the respective amine DMTMM in powder was added, pH was corrected to 6.5 and the reaction let to proceed at room temperature for 5 days.

For both methods products were precipitated and washed with ethanol, and characterized via FT-IR, ¹H-NMR, UV, rheology. Molar degree of substitution (DSmol) was calculated via NMR and when possible via UV.

RESULTS AND DISCUSSION

The generation of the NHS ester of HA requires acidic pH, while the nucleophilic attack of the amine is only efficient at neutral or alkaline pH, where the NHS ester of HA is hydrolytically labile². The optimal conditions of coupling are therefore a non-trivial compromise. DMTMM conjugation was effective also in absence of pH control. For all the substrates tested DMTMM yields were superior at parity of feed ratio (table below).

Moiety	DSmol DMTMM	DSmol EDC/NHS
ADH	35%	18%
AADA	65%	49%
Gly	53%	22%
BSA	0.63%	0.16%
Dox	2.62%	2.24%
pNIPAM	4.5%	undetectable

Rheological features of pristine HA were modified upon functionalization, with the trend of the curves in good

agreement with DSmol and FT-IR³. The figure below compares the mechanical spectra of HA-ADH synthesized with both methods. For the EDC/NHS derivative loss modulus G'' is higher than storage modulus G' in the whole frequency range analysed, indicating a scarcely or non-crosslinked polymer. By contrast DMTMM derivative displays higher moduli and G' always over G'' all over the frequency range. Both features are signatures of a covalently crosslinked network, which is obtained owing to the higher ligation efficiency of DMTMM.

CONCLUSION

DMTMM is more efficient than EDC/NHS for ligation of amines to HA in water. Unlike EDC/NHS the reaction does not need accurate pH control to proceed. The advantages of DMTMM activation are particularly useful for the scale-up of preparations from the lab to the industrial scale, which is a critical step for the translation biomaterials in the clinical use³.

The materials synthesized display a wide range of physico-chemical and rheological properties, and are suitable for a plethora of different applications in the biomedical field. DMTMM-mediated ligation is a new promising chemical tool to synthesize HA-based biomaterials, controlled release systems and polymer therapeutics.

Silver nano-coatings on silk sutures for the prevention of surgical infections

De Simone Serena¹, Gallo Anna Lucia², Paladini Federica², Sannino Alessandro², Pollini Mauro²

¹Dhitech Scarl, Technological District Hi-Tech, via Salvatore Trinchese 61, 73100 Lecce, Italy

²Department of Engineering for Innovation, University of Salento, via Monteroni, 73100 Lecce, Italy.

serena.desimone@dhitech.it

INTRODUCTION

Surgical wounds are frequently complicated by infections of different severity, so giving rise to a range of clinical problems and prolonging hospitalization with increased healthcare costs¹. The definition of preventive strategies results essential for the management of 'Surgical Site Infections' associated to bacterial colonization and the onset of significant complications. In recent years, silver nanoparticles have been proposed as antimicrobial agent² in several commercial products for healthcare³. The aim of this work is the development of low-cost silver coatings on standard non-absorbable silk surgical sutures by adopting a patented⁴ technology based on the *in situ* photo-reduction of a silver precursor.

EXPERIMENTAL METHODS

The non-absorbable multifilament silk sutures (0.3 mm diameter) were dipped in a silver solution containing 0.5 wt/v % of silver nitrate and then exposed to UV lamp in order to induce the synthesis of silver clusters on the surface of the suture. After the treatment, the samples were washed in deionized water to remove the unreacted salt. The coated sutures were characterized in terms of antibacterial capability, quality of the coating, stability, durability and cytotoxicity. The morphology of the silver coating and the distribution of the silver clusters on the substrates were evaluated through scanning electron microscopy. The amount of silver deposited on the suture was quantified by energy dispersive X-ray spectroscopy. Tensile tests were carried out on silver treated and untreated samples to verify if the silver treatment affected the mechanical properties of substrate. The antibacterial activity of the treated sutures was measured by agar diffusion tests on *Escherichia coli* and *Staphylococcus aureus*, according to Standard 'SNV 195920-1992'. The percentage of antibacterial efficacy (ABE%) was calculated through bacterial enumeration and the bacterial adherence on the surgical suture surface was also quantified after 24 hours of incubation at 37°C for both the bacterial strains. Cytotoxicity tests were performed through MTT test on a selected cell population.

RESULTS AND DISCUSSION

The microbiological characterization demonstrated the good efficacy of the silver deposition technology adopted in reducing the microbial colonization of medical device. An evident zone of inhibition to bacterial growth against Gram positive and Gram negative bacteria (Fig. 1). The evaluation of the ABE% of the Ag/silk resulted 81% and 78%, on *S. aureus* and *E. coli* respectively. The percentages in the reduction of bacteria adhered to the substrate were 34% and 35% for *E. coli* and *S. aureus* respectively.

Fig 1. Antibacterial test on *S. aureus* (Fig. a) and on *E. coli* after 24 h (Fig. b) for untreated and treated suture

The results of MTT test demonstrated that the presence of the silver particles did not affect the cell viability (Fig. 2).

Fig 2. Cytotoxic effect of silver sutures on fibroblasts.

CONCLUSION

The technology adopted for the deposition of silver is characterized by the excellent adhesion of the silver coating to the substrate. The antimicrobial capability of the silver treated materials was assessed on Gram positive and Gram negative bacteria in terms of reduction of bacterial viability and proliferation, and also of bacteria adhesion on the substrate. Moreover, the silver coating did not affect the mechanical properties of the materials and did not exhibit effect of cytotoxicity. The antibacterial-coated sutures developed may be considered as an interesting alternative in surgical practise for the prevention of the risk of infections with advantages also in terms of cost/effectiveness ratio.

INTRODUCTION

Adult mesenchymal stem cells (hMSCs) are being extensively investigated for their use in tissue regeneration. However, as they are found in very low numbers in adult tissue, expansion and quality testing *in vitro* is required to produce the desired MSC numbers for therapeutic delivery. The controlled differentiation and therapeutic uses of stem cells are dependent on providing the correct chemical cues and on mimicking their complex micro-environment or niche^[1]. Components of the niche such as the laminin glycoprotein play a crucial role in modulating stem cell behaviour via the activation of integrin pathways. These pathways influence the phenotypic fate of the cell by enhancing adhesion, and altering migration and differentiation.

In this study poly(ϵ -lysine) dendrons functionalised with the laminin mimicking peptide sequence YIGSR have been used to decorate the surface of polyurethane (PU) films. The aim is to control the *in vitro* morphology of hMSC preventing their uncontrolled differentiation into fibroblast-like cells and their consequent phenotypic change.

EXPERIMENTAL METHODS

Dendrons were synthesised from Fmoc-protected amino acids by solid-phase synthesis using a 4x molar excess of reagents. The dendron consisted of a root molecule of arginine, then 3 branching generations of poly(ϵ -lysine) and a final functionalisation of the uppermost branching generation with the YIGSR peptide. The dendrons were characterised by ATR/FT-IR and mass spectrometry.

PU films^[2] (1 cm discs) received from Milan University were plasma etched at 400 Pa pressure, 60 W air plasma for 5 minutes prior to treatment with NHS/EDC and dip-coating in a solution of the YIGSR-modified poly(ϵ -lysine) dendron (PLLYIGSR) and allowed to air dry. Contact angle goniometry and ATR/FT-IR were used to verify the dendron coating.

Human MSC (Lonza, UK) were seeded at a density of 4×10^4 onto each material and incubated in chemically defined media (CDM) (Lonza, UK) at 37 °C for 4 days. Prior to fixing in 3.7% paraformaldehyde and staining with DAPI, the cells were incubated for 1 h in CDM containing 5-Chloromethylfluorescein Diacetate

(CMFDA). Cell viability, adhesion and morphology were observed using confocal microscopy.

RESULTS AND DISCUSSION

Mass spectrometry of the unbound functionalised dendron confirmed the presence of the YIGSR peptide at a characteristic peak at 594.31247 m/z.

A reduced internal contact angle was recorded on the PU disc functionalised with PLLYIGSR (57°) when compared to the non-functionalised PU surface (83°) supporting the surface functionalization of the material. The material surface decoration was further confirmed by the observed cell morphology. hMSCs identified on all surfaces were viable prior to fixation as shown by the fluorescent green CMFDA staining in Fig 1. Cells seeded onto the functionalised surface formed spheroids (Fig 1(b)), in contrast to those seeded on to TCP, which presented a flat spindle-like morphology (Fig 1(a)), indicative of fibroblast like colonies associated with the de-differentiation of MSC.

Figure 1. hMSC seeded onto TCP (a) and functionalised PU material (b).

CONCLUSION

Poly (ϵ -lysine) modified PU films were successfully functionalised to achieve increased stem cell binding with the ability to promote spheroid formation. These spheroid cultures have previously been shown to ensure continued stemness *in vitro* and offer the potential to expand hMSC in a controlled environment for tissue engineering applications.

Synthesis and Characterization of Chitosan/Hydroxyapatite Biocomposite Scaffolds for Potential Bone Repair Applications

Vitor César Dumont^{1*}, Nádia S. Vieira Capanema¹, Alexandra A. Piscitelli Mansur¹ and Herman Sander Mansur

^{1*}Center of Nanoscience, Nanotechnology and Innovation-CeNano²I, Department of Metallurgical and Materials Engineering, Federal University of Minas Gerais, Brazil, vitorcdumont@gmail.com

INTRODUCTION

Basically, the major goal of tissue engineering is to restore diseased or damaged tissue to its original state and function, reducing the need for transplants and joint replacements. Thus, one of the challenges faced by the research community in tissue engineering is related to the development of appropriate scaffold materials that can act as templates for cell adhesion, growth and proliferation¹⁻². In this sense, the scaffolds must present an adequate pore size and interconnectivity to promote cell in-growth, good biocompatibility, and controlled degradation kinetics to match the ratio of replacement by new tissue. Also, the scaffolds should provide an initial biomechanical support until cells generate the extracellular matrix¹⁻². In the last 2-3 decades a large number of biomaterials have been produced to behave as synthetic scaffolds that may guide and stimulate the tissue growth but no definitive solutions have been found yet for all kinds of bone tissue repair³. Among them, synthetic bioceramic materials based on calcium phosphates particularly tricalcium phosphate (TCP) and hydroxyapatite (HAp) have widely been studied and clinically used for bone tissue engineering due to their well-known osteoconductive and osteoinductive properties. However, when compared to cortical and cancellous bones, the synthesized calcium phosphates typically present unsatisfactory mechanical properties, especially in porous forms¹⁻⁴. One feasible solution is based on the combination of organic and inorganic components, forming hybrid materials, referred to as composites (or nano-composites). Thus, in this study it is reported the synthesis and characterization of the biocomposites based on polymer chitosan (Chi) and hydroxyapatite (HAp). It was investigated the effect of the relative concentration of the biopolymer (chitosan) to inorganic (HAp) components on the properties and structures of the scaffolds produced.

EXPERIMENTAL METHODS

Hydroxyapatite (HAp) was prepared by the precipitation method in alkaline aqueous media based on the procedure reported by our group⁴. Membranes were produced by cast method of chitosan (small, medium and high molecular mass) solutions prepared in water concentration at 1 % in acetic acid. The Chi/HAp biocomposites were synthesized by blending different proportions of the HAp to chitosan (ranging from 1 to 10 m/m%). Each component and the composites scaffolds were extensively characterized by Fourier Transform Infrared Spectroscopy (FTIR), Scanning and Transmission Electron Microscopy (SEM/TEM), Atomic Force Microscopy (AFM), X-ray diffraction (XRD), Thermogravimetry Analysis (TGA),

Differential Scanning Calorimetric (DSC) and swelling assays.

RESULTS AND DISCUSSION

Typical XRD results of the synthesized HAp bioceramic after drying at 110°C and thermal treatment at 900°C are shown in Fig.1 (curves a and b, respectively). It can be observed major peaks associated with the HAp crystalline pattern (ICDD - 96-900-3549) which is more evident after the sintering⁴ (Fig.1b). Similarly, FTIR spectra of HAp after drying at 110 °C and sintering at 900°C are shown in Fig.2 (curves a and b, respectively). It may be observed the major peaks related to HAp chemical groups (hydroxyls, phosphates), and also the presence of carbonates common to HAp produced by water precipitation methods. Chitosan FTIR spectra have indicated the presence of major chemical groups (amine, hydroxyls and acetyls). The morphological aspects, swelling and mechanical properties of Chi/HAp biocomposites were affected by the ratio of components.

Fig.1. XRD patterns of the HAp after drying at 110°C (a) and thermal treatment at 900°C (b).

Fig.2. FTIR spectra of the HAp after drying at 110°C (a) and thermal treatment at 900°C (b).

CONCLUSION

Homogenous scaffolds of Chi/HAp biocomposites were produced and characterized. Their morphological aspects, swelling and mechanical properties were significantly affected by the ratio of components HAp/Chi. Thus, these Chi/HAp biocomposites may be considered as potential alternatives as biomaterials in the future for bone repair and substitutes.

Synthesis of morphology controlled calcium phosphate nanobiomaterials for biomedical applications

P.J.T Reardon^{1,2}, J. Huang¹, J. Tang^{2*}

¹ Department of Mechanical Engineering, UCL, London

^{2*} Department of Chemical Engineering, UCL, London Philip.reardon.09@ucl.ac.uk

INTRODUCTION

The performance of calcium phosphate (CaP) biomaterials depends greatly on morphology and size. For example, CaP nanoparticles can provide enhanced bioactivity.¹ Wire-like CaP can be used as biomaterial reinforcement due to excellent mechanical properties and recently porous CaP nanomaterials have shown high loading and favourable release properties for drug delivery.^{2,3} The use of microwave dielectric heating for chemical synthesis allows material production with altered morphologies, increased yields, narrow size distribution, and considerably reduced synthesis times. Therefore, this energy efficient 'green' process is used in the current study, to prepare biodegradable calcium phosphate nanomaterials with varied size, morphology and textural properties for biomedical applications.

EXPERIMENTAL METHODS

Briefly, ethanol or ethanol/water solutions containing either $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ or H_3PO_4 were prepared and mixed at room temperature and pressure, then irradiated in a microwave solvothermal process. In vitro protein loading and release measurements were carried out with Bovine serum albumin (BSA), Lysozyme, Fibrinogen and myoglobin using a UV-Vis spectrometer, the amount of loaded/delivered protein was calculated by the depletion method.¹ Material characterisation was performed using XRD, FESEM, TEM and nitrogen adsorption analysis as previously reported.^{4,5}

RESULTS AND DISCUSSION

Figure 1 TEM micrographs of CaP (a) nanorods (60°C), (b) nanoplates (200°C).

Using a microwave assisted process, nanoplates and nanorods with controllable pores are synthesized without the use of any toxic surfactants by varying synthesis temperature (Figure 1). HA/monetite content and dimensionality were manipulated by changing the ratio of the $\text{H}_2\text{O}/\text{EtOH}$ solvent mixture. High aspect ratio (ca. 54) nanowires containing ca. 38 wt% HA were obtained with a 60/40 $\text{H}_2\text{O}/\text{EtOH}$ volumetric ratio (Figure 2a). Importantly, the quantity of HA in the high aspect ratio nanowires/needles was controlled by varying the stoichiometric ratio of the reactants, demonstrating that one dimensional materials with close to 100% HA can be achieved when the Ca/P ratio is increased to 1.67 (Figure 2b). Loading of proteins on CaP has been found to be the highest for the nanoplate

Figure 2 SEM micrographs of nanowires/needles obtained using Ca/P ratios of (a) 1.4 and (b) 1.67

samples. Interestingly, BSA loading was 2.5 times higher than a commercial hydroxyapatite nanomaterial even if the former has approximately half the surface area of the latter (Figure 3).⁴ Furthermore, the delivery period differed, lasting 8 times longer, indicating the morphology controlled nanostructured CaP could be a promising candidate for drug delivery with increased loading capacity and longer release period.

Figure 3 Protein delivery from nonomaterials of different morphology and a CaP standard.

CONCLUSION

The findings highlight that reaction parameters can be varied in tandem with microwave irradiation to tailor the morphology and composition of calcium phosphate materials, which are of very high importance in developing excellent materials suitable for bone tissue engineering and drug delivery.

Dextran as a Versatile Scaffold for Hydrogel Formation with Hyaluronic Acid

Nick Dibbert¹, Bastian Dieter¹, Gerald Dräger¹ and Andreas Kirschning¹

¹Institute of Organic Chemistry, Leibniz University Hannover, Schneiderberg 1b, 30167 Hannover

Nick.Dibbert@oci.uni-hannover.de

INTRODUCTION

The major goal in the research of biopolymers is to generate a three-dimensional, biomimetic and biodegradable network. These networks are applied in artificial tissues for skin-transplantation, *in vivo* drug-release or as artificial muscle fibres.¹ In the case of myocardial infarction, a less-invasive injectable biopolymer serves as a favourable matrix for cell delivery and regeneration of damaged tissue.² There are two major strategies to construct a three-dimensional biopolymer network, either ionic interactions or covalent linkages, the latter approach is favoured in our case due to its stability. So as the condensation of hydrazide functionalized hyaluronic acid with oxidized dextran.

EXPERIMENTAL METHODS

General procedure for oxidation³: To a 0.6M solution of dextran in dest. water, NaIO₄ was added in the dark and stirred for 12 h. The solution was ultrafiltrated for 3 d against water and lyophilized for 3 d. 100 mg oxidized dextran was dissolved in 5 mL dest. water and treated with 10 mL of a 0.25M solution of NH₂OH·HCl and 0.05% methyl orange. The mixture was stirred for 12 h and titrated with 0.09M NaOH solution till the end point⁴.

General procedure for decoration³: A 0.053M solution oxidized dextran (OxDex) was treated with a primary amine (Rutjes linker⁵, ethylene diamine, N-Boc-ethylene diamine, spermine, aniline) and stirred for 12 h.

General procedure for hydrogelation⁶: 25 µL of a 2 mg/100 µL solution of the hydrazide compound (hyaluronic acid hydrazide) were mixed in a silicon mask with 25 µL of a 3 mg/100 µL solution of the aldehyde compound (OxDex).

RESULTS AND DISCUSSION

To form a hydrogel that can be decorated with the RGDfK pentapeptide a preparation of the dextran was necessary. The idea was to oxidize dextran to a point where it can be modified with a linker molecule (**Scheme 1**) while having enough free aldehydes for hydrogelation.

Scheme 1. General strategy.

First of all we could define a range between 0.5 and 1.4 eq NaIO₄ where the chemical properties, in terms of solubility and forming stable hydrogels are ideal for our application. To get an idea of how the primary amine reacts with the polymer, experiments with various amounts of aniline were carried out as described and the remaining aldehydes were titrated.

Scheme 2. Suggested structure after decoration.

These titrations with aniline showed that for every equivalent of aniline two equivalents of aldehydes were consumed. This may suggest the structure as shown in **Scheme 2**.

Further titration experiments showed that there is a range between 0.01 eq and 0.3 eq of primary amine where enough aldehydes are present for a stable hydrogel formation. With greater than 0.3 eq of the primary amine, the polymer becomes insoluble in aqueous media.

Unfortunately, ultrafiltration of the decorated dextran leads to cleavage of the substrate and decomposition of the polymer. This may suggest that the reaction of the primary amine is reversible within the ultrafiltration.

CONCLUSION

We demonstrate a method to oxidize dextran reproducibly and determine the degree of oxidation. We also demonstrate a difference in the ability for hydrogelation between unfunctionalized and functionalized dextran

Adsorption of Col I on poly(NaSS) grafted Ti6Al4V surfaces improves MC3T3-E1 osteoblast-like cells mineralization

Helena Felgueiras^{1*} and Véronique Migonney¹

¹Laboratory of Biomaterials and Specialty Polymers, LBPS-CSPBAT CNRS UMR 7244, Institut Galilée, Université Paris XIII, 93430 Villetaneuse, France. felgueiras.helena@gmail.com

INTRODUCTION

Titanium (Ti) and its alloys are very common in the orthopedic field. These materials possess excellent corrosion resistance, low toxicity and “acceptable” compatibility with the living tissue, making them ideal bone substitutes. Nonetheless, their long term success remains a challenge (implant loosening). Based on the knowledge that the implant surface is the main responsible for the observed host response, our laboratory developed a strategy to overcome this problematic. It consists in the grafting of bioactive polymers bearing anionic sulfonate groups onto the metallic surfaces. Previous studies on model surfaces established the distribution of these groups instigates specific proteins’ adsorption (fibronectin, vitronectin...), which leads to favorable cell response including differentiation [1-5].

The purpose of the current investigation was to attest on the ability of the grafted poly(sodium styrene sulfonate) (poly(NaSS)) to induce osteoblastic differentiation on Ti6Al4V materials and, at the same time, to infer about the MC3T3-E1 maturation in the presence of proteins of interest such as albumin (BSA), fibronectin (Fn) and collagen type I (Col I), individually pre-adsorbed on Poly(NaSS) grafted and non grafted surfaces.

EXPERIMENTAL METHODS

13 mm diameter Ti6Al4V discs (CeraVer, France) poly(NaSS) grafted and non grafted [2,3] were used. The presence of sulfonate groups on the grafted surfaces was probed using X-ray photoelectron spectroscopy (XPS), Fourier Transformed Infrared (FTIR) and toluidine blue colorimetric method. Contact angle measurements were also conducted.

Prior to the cell culture experiments, 10% fetal bovine serum (FBS) in culture medium, 4000 µg/mL BSA in PBS, 20 µg/mL Fn in PBS and 10 µg/mL Col I in 0.1M acetate buffer (Sigma) were pre-adsorbed onto the surfaces for 1h. MC3T3-E1 osteoblastic cells (ATCC) were seeded at 5x10⁴ cells/mL and cultured from 5 min to 28 days. The cells viability, morphology, attachment strength, proliferation, differentiation and mineralization were followed.

RESULTS AND DISCUSSION

Poly(NaSS) grafting ($\approx 1.63 \times 10^{-5}$ g/cm²) led to an increase in the hydrophilicity of the surfaces which is due to the presence of the anionic sulfonate groups. Cell attachment was improved in the case of poly(NaSS) grafted surfaces and this was related to a better availability of the RGD domains of adsorbed Fn and Col I. Fluorescent images confirmed these observations. Significant cytoplasmatic expansion was observed on Fn pre-adsorbed substrates whereas Col I led to an increased attachment strength.

The presence of sulfonate groups augmented the osteoblastic maturation, both early differentiation and mineralization.

Fig.1. Production of alkaline phosphatase (ALP, early differentiation) by MC3T3-E1 cells.

Pre-adsorbed Col I onto grafted substrates enhanced significantly the alkaline phosphatase levels (Fig.1) as well as the calcium and phosphate production. BSA did not reveal any significant effect on the cells behavior.

CONCLUSION

In vitro tests using MC3T3-E1 osteoblastic cells confirmed the poly(NaSS) grafted Ti6Al4V potential for long term implantations by enhancing osteointegration. Col I pre-adsorbed on poly(NaSS) demonstrated a clear aptitude to induce osteoblastic maturation

Enhancement of integrin-mediated cell attachment by pre-adsorbed model proteins on poly(NaSS)-functionalized Ti6Al4V substrates: a QCM-D study

Helena Felgueiras^{1*}, Sven Sommerfeld², N. Sanjeeva Murthy², Joachim Kohn² and Véronique Migonney¹

¹Laboratory of Biomaterials and Specialty Polymers, LBPS-CSPBAT CNRS UMR 7244, Institut Galilée, Université Paris XIII, 93430 Villetaneuse, France and ²New Jersey Center for Biomaterials, Rutgers University, 145 Bevier Road, Piscataway, New Jersey 08854, USA felgueiras.helena@gmail.com

INTRODUCTION

The adsorption of proteins from blood and other body fluids onto a biomaterial surface is a complex phenomenon triggered seconds after the biomaterial exposure to the biological environment. Proteins that reach the surface provide an adhesion network of ligands for the attachment of cells *in vivo* and *in vitro*. Their orientation, conformation and packing density define the way bioactive sites are presented to specific receptors of the cellular membrane, the integrins, and characterize the observed host response [1-4].

The effect of albumin (BSA), fibronectin (Fn) and collagen type I (Col I) pre-adsorbed on poly(sodium styrene sulfonate) (poly(NaSS)) physisorbed Ti6Al4V substrates on the attachment of MC3T3-E1 cells was studied. Three other substrates, Ti6Al4V, gold and poly(DTE carbonate), were used for comparison. Antibodies against specific receptors on the cellular membrane were used to understand the role of protein conformation on protein-cell interactions.

EXPERIMENTAL METHODS

Protein adsorption and cell attachment were followed in real time using a quartz crystal microbalance with dissipation (QCM-D, QSense). The four substrates, Ti6Al4V, poly(NaSS) physisorbed on Ti6Al4V, poly(DTEc) and gold, as well as the proteins, BSA, Fn and Col I, used in this study were prepared as described in [5].

MC3T3-E1 osteoblastic cells were followed for 2h at static conditions on all sensors, both in the presence and absence of each protein (1h pre-adsorption). Anti-integrins $\alpha_5\beta_1$ and $\alpha_2\beta_1$ were selected to test the MC3T3-E1 attachment mechanisms on Fn and Col I pre-adsorbed sensors, respectively. Cytoskeleton organization and focal adhesions were observed by fluorescent microscopy (ZEISS AxioLab, Germany). On the Ti6Al4V sensors, antibodies against the RGD sequence and heparin binding domains were used to probe the Fn conformation. Base line was established with PBS. The results were analyzed using the Sauerbrey equation ($\Delta f = -C \cdot \Delta m$, Δf change in frequency, Δm change in mass, C constante = $17.7 \text{ ng/cm}^2 \cdot \text{s}$).

RESULTS AND DISCUSSION

Ti6Al4V substrates with physisorbed poly(NaSS) displayed the highest protein adsorption, and

provided the best conditions for cell attachment. Interestingly, although the protein deposition on the poly(DTEc) sensors was the lowest, a large amount of cells was detected. In addition, poly(NaSS) substrates were found to have a large influence on the protein conformation, particularly with respect to some important Fn binding domains, suggesting more active binding sites are exposed to cells in its presence.

On the same substrates, MC3T3-E1 cells attachment was found to be integrin dependent. Cells cultured for 2h in the absence of antibodies against α and β integrins exhibited abundant focal adhesions. By blocking important integrins ($\alpha_5\beta_1$ and $\alpha_2\beta_1$), the major transmembrane components of focal adhesions, inhibition of cell attachment was detected (Fig.1); this was accompanied by differences in cytoskeleton organization.

Fig.1. Inhibition of MC3T3-E1 cell attachment by the presence of $\alpha_2\beta_1$ anti-integrins on regular and poly(NaSS) coated Ti6Al4V sensors, pre-adsorbed with Col I.

CONCLUSION

Presence of sulfonate groups favored protein adsorption and cell attachment. On these altered surfaces, integrin-mediated attachment was predominant and played a major role in cell cytoskeleton organization. Poly(NaSS) was also found to have a large influence on Fn protein conformation, exposing more active binding sites.

Predicting Change in Constitutive Behaviour of Degrading Polymers

Hassan Samami, Jingzhe Pan

Department of Engineering, University of Leicester, UK, hs257@le.ac.uk

Introduction

Bioresorbable polymers such as Poly lactic acid (PLA) and poly glycolic acid (PGA) have been successfully used in many medical implant devices such as resorbable sutures. Hydrolysis degradation is a time dependent process which causes a significant change in the structural and mechanical property of bioresorbable polymers when they are implanted in a biological environment such as human body. This time dependent process occurs due to the attack of water molecules to the molecular chains of the polymer. Structurally, bioresorbable polymers are either amorphous or crystalline that could remain totally amorphous or undergo an increased crystallinity during the hydrolysis time. In the design of a bioresorbable device, it is important to predict the change in mechanical proprieties during degradation.

Micromechanical Model

This study shows that the constitutive law of a degrading polymer can be analytically obtained from the initial condition and the current average molecular weight of a polymer using only one empirical parameter. A chain scission is treated as an effective cavity as revealed by an atomistic study [1]. A degrading amorphous polymer is modelled by a continuum solid with increasing number of cavities that are randomly distributed.

Fig 1: Formation of two inclusions within a degrading polymer

The cavities are inhomogeneities that are free from any stress field but can disturb the applied stress field [2]. Unlike the atomistic study [1], the cavities are assumed to be spherical and have a common radius. This radius is the only fitting parameter in the model that is unique to each polymer. The average molecular weight can either be taken from an experimental measurement or from the mathematical model developed by Pan and co-workers [3]. An analytical constitutive law predicting the Young modulus as well as the Poisson's ratio for the degrading polymer is then obtained using the Mori-Tanaka (MT) theory [4]. This theory takes into account of the elastic interactions between the cavities, which is important toward the later stage of the degradation.

Results and Discussion

The results of the Mori-Tanaka (MT) model are compared with the experimental data obtained by Tsuji [5] in Fig 2. It can be seen that the model can fit the data fairly well.

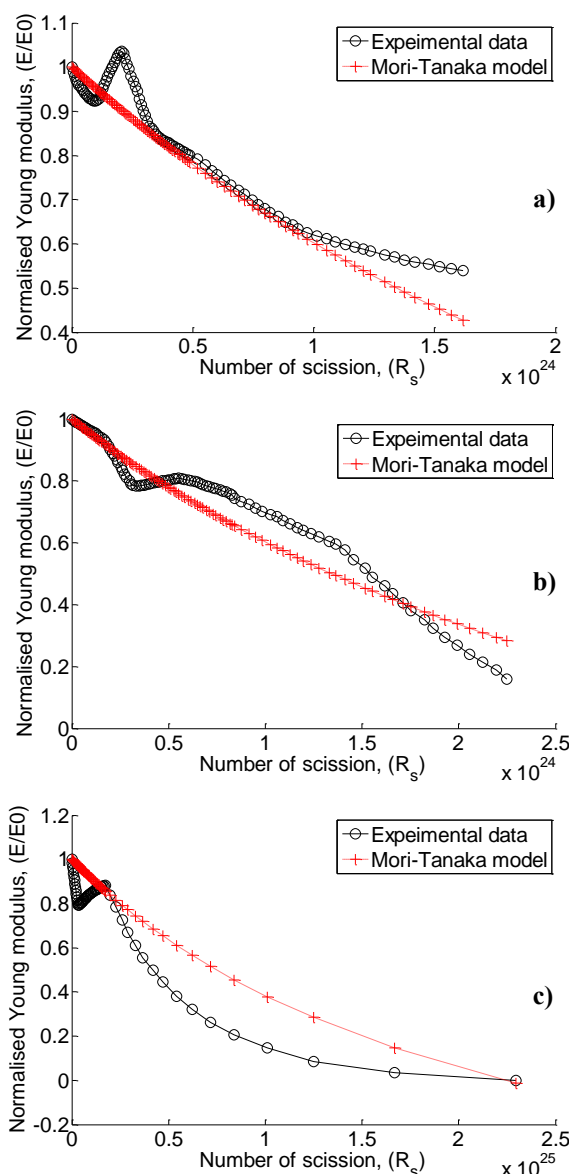

Fig 2: Change in Young modulus of amorphous non-blended films during 24 months of hydrolysis degradation

a) PLLA, b) PDLA, c) PDLLA

Conclusion

The Mori-Tanaka theory for solids with cavities are shown to be able to capture the trend of experimental data of Young's modulus of degrading amorphous polymers.

Nitric oxide releasing polyester blends for topical skin vasodilation

Victor Baldim and Marcelo Ganzarolli de Oliveira*

Institute of Chemistry, University of Campinas, Brazil, mgo@iqm.unicamp.br

Keywords: Drug Delivery, Interfaces, Synthesis

INTRODUCTION

Nitric oxide (NO) is a signalling molecule involved in vasodilation, wound healing, immune response and neurotransmission. Reduced endogenous NO production plays a fundamental role in the pathogenesis of peripheral vascular diseases such as chronic leg ulcers and Reynaud's syndrome. Therapies with macromolecular NO donors have been used for the controlled release of NO in different quantities¹. We have already synthesized a polysulfhydrylated polyester (PSPE) and showed that its S-nitrosation leads to a polynitrosated polyester (PNPE)², capable of releasing NO spontaneously. In this work, we prepared a set of blends between PSPE and polycaprolactone (PCL), a well known polyester used for biomedical applications³. The S-nitrosothiol (S-NO) concentration of their nitrosated derivatives was measured by chemiluminescence and the topical skin vasodilation they promoted was evaluated by laser Doppler flowmetry.

EXPERIMENTAL METHODS

Synthesis of PSPE – PSPE was prepared by the acid-catalysed polycondensation reaction of thyoxyglycerol with mercaptosuccinic acid². The reaction proceeded under reflux, N₂ flow and magnetic stirring, at 120 °C for 14 h.

Polymer blend preparation - Solutions of PCL/PSPE in THF were prepared in the mass ratios: 100/0 (PCL), 85/15 (PSPE15), 75/25 (PSPE25) and films were prepared by solvent casting in Petri dishes. Films were characterized by DSC, TGA, XRD, SEM/EDS.

S-nitrosothiol quantification - Films of PSPE15 and PSPE25 were S-nitrosated by immersion in acidified NaNO₂ solution during 20 min at room temperature, protected from light leading to polynitrosated films (PNPE15 and PNPE25, respectively), whose NO charges were quantified by chemiluminescence (NOA, Sievers)⁴.

Skin blood flow measurement –Vasodilation promoted by the topical application of PNPE15 and PNPE25 films in forearm skin of a volunteer for 10 min was measured by Laser Doppler flowmetry (Transonic System Inc.)⁴.

RESULTS AND DISCUSSION

The PNPE films obtained are homogeneous and flexible. Their different S-nitrosothiol charges can be confirmed visually by the intensity of the orange colour developed (Fig. 1). This colour is due to the S-NO groups whose concentration is c.a. 0.14 $\mu\text{mol}/\text{cm}^2$ (Fig.1). Spontaneous homolytic cleavage of the S-NO bonds release free NO, which diffuses through the *stratum corneum*, reaching the dermal microcirculation.

The concentrations of S-NO groups achieved, proved to be sufficiently high for promoting a 6 to 10-fold dose response increase in blood flow, 10 min after the application of the films (Fig.2).

Figure 1. Solvent cast films of PCL, PNPE15 and PNPE25 (above) and their corresponding S-nitrosothiol groups concentrations measured by chemiluminescence (below).

Figure 2. Skin blood flow measured by laser Doppler flowmetry in the forearm of a volunteer before (basal) and after topical application of PNPE15 and PNPE25 films.

CONCLUSION

PNPE films can be charged with different NO doses and lead to dose-dependent skin vasodilation in topical application. Therefore these materials may allow a new approach for the topical treatments of ischemic skin diseases.

Structural Integrity Assessment of a Polymer-based Knee Implant

Y. Fong^{1*}, P. Reed², F. Pierron² and M. Browne¹

^{1*}Bioengineering Science Research Group, University of Southampton, United Kingdom, Y.K.K.Fong@soton.ac.uk

²Engineering Materials Research Group, University of Southampton, United Kingdom

INTRODUCTION

The state of the art total knee replacement (TKR) system employs a cobalt-chromium (CoCr) alloy femoral component¹. Although excellent success rates of above 94% at nine years across the main brands are associated with current systems, deficiencies, such as stress shielding and release of metal ions have been identified²⁻⁴. Recently, younger patients are being treated with TKR; with an increased life expectancy, these patients are likely to impose increased demands on the TKR. To address these issues, a novel TKR system has been proposed, which employs an injection moulded PEEK-OPTIMA[®] femoral component.

Before a new implant can be introduced and released into the market, it has to undergo preclinical testing to ensure it is safe for implantation. However, past experience has shown that a lack of rigorous preclinical testing could lead to extremely poor performance and early device recall. In the case of polymer based orthopaedic implants, there is an additional issue to consider in that standard testing tends to focus on high modulus, metallic implants, which do not exhibit the time and temperature dependent properties of polymer-based materials.

The aim of this study is to assess the effects of typical experimental variables on the performance of a PEEK-OPTIMA[®] based implant. As part of this work, multi-parameter tests will study the effects of test frequency, waveform, environment and temperature on the fatigue life of test coupons of PEEK-OPTIMA[®]. In the present work, the effect of frequency is examined.

EXPERIMENTAL METHODS

Tension-tension fatigue tests were carried out on a servohydraulic machine (Instron 8872) in ambient laboratory environment with sample dimensions specified in BS EN ISO 527-2:2012.

PEEK-OPTIMA[®] samples were tested at 2 Hz (n = 1), 5 Hz (n = 3) and 10 Hz (n = 20), with a R-ratio of 0.1, at 80 % yield. The number of cycles to failure was recorded in each case. Tests that did not fail were terminated at 5 million cycles.

An infrared camera (FLIR Cedip SC5000) was used to monitor the sample temperature from the beginning of each test until it either stabilised or failed. Samples were spray painted in matt black. An unloaded sample was placed next to the sample of interest as a control, such that temperature measurements could always be corrected against the room temperature.

For samples tested at 10 Hz, five different frequency ramping times were used – 0 s (n = 11), 30 s (n = 1), 60 s (n = 1), 90 s (n = 1) and 240 s (n = 6). As a result of the anomalous behavior observed from one of the samples, further tests (n = 3) were carried out at 10Hz to study the effect of cooling on the fatigue life of PEEK-OPTIMA[®].

RESULTS AND DISCUSSION

All samples tested at 2 Hz and 5 Hz ran out; whereas, nineteen out of twenty samples tested at 10 Hz without cooling survived a mean of $2,486 \pm 640$ cycles. One 10 Hz sample ran out. Where cooling was applied in the 10 Hz tests, the fatigue life was significantly enhanced (range: 64,918 to 4,018,741 cycles).

The rate of heating in the samples increased with increasing test frequency, as well as decreasing ramping time. The maximum temperature in the 2 Hz, 5 Hz and 10 Hz uncooled samples were found to be 8.0 °C, 17.7 °C and 67.0°C above ambient, respectively. The mean temperature of the 2 Hz and 5 Hz samples were seen to have stabilised at 2.3 °C and 6.0 °C above ambient, respectively.

In the absence of cooling, heat could not be dissipated from the 10 Hz samples quickly enough, causing the samples to soften, and exhibit a ductile fracture surface; whereas cooling tended to produce a smooth, flat fracture surface.

CONCLUSION

The fatigue life of PEEK-OPTIMA[®] was found to be frequency dependent and results to date suggest that the material fatigue behaviour is not compromised at 5 Hz and below. At 10 Hz, samples underwent softening and ductile failure. However, this effect was eliminated when cooling was applied. Further work will determine whether a frequency effect emerges between 2 and 5 Hz when variable amplitude loading is applied.

Fabrication of hydroxyapatite thin film with entirely c-plane surface

Masanobu Kusunoki^{1*}, Yasuhiro Sakoishi¹, Katsuya Asano¹, Naoki Fujita¹, Takayuki Makino¹, Daisuke Okai²

^{1*}Faculty of Biology-Oriented Science and Technology, Kinki University, Japan, kusu@waka.kindai.ac.jp

²Department of Material Science & Chemistry, Graduate School of Engineering, University of Hyogo, Japan

INTRODUCTION

Hydroxyapatite [HA: $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$] is useful in chromatography¹ because it adsorbs proteins via two types of interactions, with affinity for a calcium ion and ionic bonding for the phosphate group. The interactions based on electrical anisotropy correspond to the crystallographic anisotropy of HA. In chromatography, granular HA with surfaces of both a positively charged a-plane and a negatively charged c-plane is generally used. If we could obtain single surface with either the a- or c-planes, the separation efficiency could be improved and the apparatus size could be reduced. This also applies to bio-sensor such as quartz crystal micro balance² (QCM) and surface plasmon resonance³ (SPR), which monitor interactions between proteins as adsorption or decomposition. In this study, we investigated a method for fabricating HA films with entirely c-plane surfaces.

EXPERIMENTAL METHODS

The HA film was deposited by pulsed laser deposition. A KrF excimer laser with a wavelength of 248 nm and energy density of 2.5 mJ/mm² was used for HA abrasion. A sintered HA pellet was used as the abrasion target. Oxygen was supplied through a humidifier to a vacuuming chamber as atmospheric gas. The gas pressure was set to be 10 Pa. The film was deposited on a quartz substrate in a circular area of diameter 8 mm. The substrate was heated with a heater temperature of 700°C. The rate of film deposition under these conditions was 6.2 nm/min. The film was not annealed after the deposition. The crystal orientation of the HA film was controlled using a c-axis-oriented ZnO template layer, because ZnO has a hexagonal crystal structure. Since HA also has a hexagonal crystal structure, we expected hetero-epitaxial growth of the HA film on the ZnO template.

RESULTS AND DISCUSSION

Figure 1 shows a 2θ-X-ray diffraction pattern of the deposited HA film. The approximate thickness of the HA, ZnO, and Au films was 500, 200 and 10 nm, respectively. Only [002] and [004] peaks are observed for HA, indicating that a perfect c-axis HA film was obtained on the flat substrate surface. The ZnO film also showed c-axis orientation with the [002] peak. The c-axis-oriented ZnO film would be obtained regardless of the Au [111] film being placed under the ZnO template in this sample. For instance, the c-axis-oriented ZnO aligns directly on the quartz substrate. Au was placed here because we expected that the c-axis-

Fig. 1 X-ray diffraction of c-axis-oriented HA film deposited on ZnO template layer. Au [111] film placed under the ZnO template assuming that act as electrode of biosensor.

oriented HA would be applied to chromatography as well as bio-sensors such as QCM or SPR. The Au layer could act as the electrodes of the sensors. The HA film surface was fairly smooth as observed under an optical microscope.

CONCLUSION

A HA film having an entirely c-plane surface was fabricated with the aim of improving the performance of chromatography and bio-sensors. X-ray diffraction of 2θ-θ showed hetero-epitaxial c-axis orientation of the HA film on the ZnO template layer. The technique can be applied to new devices employing the crystallographic anisotropy of HA.

A Parametric Study of a Mathematic Model for Degradation of Bioresorbable Polymers

X. Chen and J. Pan

Department of Engineering, University of Leicester, Leicester, UK, xc26@le.ac.uk

INTRODUCTION

Bioresorbable polymers have been used in human body as drug delivery stands, surgical sutures and bone fixation devices. To estimate the degradation rate and change in mechanical properties of these polymers a mathematical model has been established by Pan and his co-workers¹ based on the observed degradation pathway in experiments. The complexity of the degradation mechanism dictates that a large number of material parameters have to be used in the model. This work shows how the parameters affect the prediction of the model and therefore indicates a potential experimental method to measure these parameters.

MATHEMATICAL MODEL

The degradation model contains a list of material parameters. Among these χ_1 and χ_2 are used as partitioning parameters which take values between zero and one. χ_1 and χ_2 reflect the effect of carboxylic end groups on long and short chains working as catalysts for the hydrolysis reaction. k_1 and \bar{k}_2 represents reaction constants for non-catalytic and auto-catalytic hydrolysis reactions respectively. This work focuses on the effect of these parameters on the model prediction. Other parameters such as diffusion coefficient of oligomers were fixed in this study.

RESULTS AND DISCUSSION

Considering a sample of thickness 0.3mm, Fig 1 shows that two sets of these parameters predict almost identical molecular weight reduction as function of time. However when the sample thickness is increased to 2mm, as shown in Fig 2, the same sets of parameters predict very different molecular weight as functions of time. This suggests that the set of material parameters can only be determined uniquely using samples of different thicknesses.

Figure 1 Calculated average molecular weight as functions of time for two different sets of parameters for sample thickness of 0.3mm.

Figure 2 Calculated average molecular weight as functions of time for two different sets of parameters identical to those used in Fig 1 for sample thickness 2mm.

CONCLUSION

The mathematical model by Pan and his co-workers can be used for the design of bioresorbable devices. The model contains a large set of material parameters. This work shows that the set of parameters cannot be uniquely determined from degradation data that is obtained using samples of one thickness.

Patient Specific Implants Using a Novel Rapid Template Approach

A. Chan¹, P. Boughton¹, J. van Gelder², N. Young³ and A. Ruys¹

¹ Biomedical Engineering, Faculty of Engineering & IT, University of Sydney, Australia, acha3105@uni.sydney.edu.au

² Sydney Spine Institute, Neurosurgery Sydney Adventist Hospital, Australia

³ Department of Radiology, Centre for Biomedical Imaging Research and Development, University of Sydney, Australia

INTRODUCTION

Patient specific implants aim to provide improvements in functional outcomes by meeting anatomical constraints. Conventional modular implants can be inappropriate for patients with significant trauma or degeneration and can lead to risks of implant malpositioning and malfunction. While custom implants can result in shorter operative times and faster recovery, key remaining challenges include commercial viability, delivery timeframe and quality assurance of individually fabricated implants¹.

3D printing provides the accuracy and flexibility to fabricate anatomically specific implants however are accompanied with heavy regulatory loads. The exposure of print materials to oxidising temperatures results in the loss of optimal mechanical properties and limit implants to non-load bearing applications². 3D printed implants must also undergo sterilisation prior to surgery, leading to considerable delays.

The objective of this work is the development of a rapid-fabrication system for post-forming patient specific implants from terminally sterilised packaged precursors, whether bone cement or thermosensitive biomaterials or scaffolds. Forming implants from sterile packaged precursors using 3D printed templates eliminate delays associated with sterilisation and maintains superior biomaterial properties. Functional gradients can also be induced within the biomaterial to mimic the mechanical properties of the native tissue structure. This system has been investigated with bone cement for cranioplasty and soft tissue scaffolds as functionally graded meniscal replacements.

EXPERIMENTAL METHODS

Scaffold Design: A soft tissue aliphatic polyester scaffold was designed to suit the size and shape of the medial meniscus. Scaffold porosities and tensile moduli were used to determine the level of volumetric transformation required to acquire the circumferential tensile properties of the meniscus. Increased scaffold heights were defined for the outer meniscal rim.

Implant Fabrication: Anatomical geometries were derived from CT scans and processed using *ScanIP*. Implant models were developed into templates on Solidworks then rapid prototyped using fused deposition modelling. Implants were formed by packaging precursor materials in low density polyethylene (LDPE) envelopes then conformed within the template.

Model Analysis: Scaffold confinement within the meniscal template was simulated on Abaqus FEA using properties derived from previous work³. Porosity change was analysed using elemental volume.

RESULTS AND DISCUSSION

Implant Fabrication: Anatomical shapes were successfully translated onto implants and scaffolds using cranial and meniscal templates. Total lengths and widths differed by 3.74% and 0.19% for cranioplasty, and 2.5% and 1.96% for meniscal scaffolds respectively. Implant thicknesses were significantly thinner than model values for both applications. This was attributed to impeded material conformance within the template due to packaging constraints. Standard LDPE packaging imparted tension in the transverse direction, leaving a pleated texture on cranioplasty implants. LDPE films provided improved packaging conformance however removal from the template was significantly harder and packaging was prone to breakage. Future developments will improve packaging conformance through texturing and applying a stronger vacuum across the template.

Model Analysis: A macroscopic function gradation in porosity was observed across the meniscal scaffold. Excessive constraint led to the precursor partially conforming to the female template form. While thermal conditions were not included in the analysis, these values suggest a functional gradient can be induced during implant fabrication. This presents the possibility to fabricate meniscal implants that are anatomically specific to the patient with respect to geometrical and biomechanical properties of the native meniscus.

CONCLUSION

In this study, the development of a system to rapidly post-form patient specific implants has been applied in cranioplasty and meniscal applications. Anatomical geometries and functional gradients were successfully translated onto a range of materials. Optimisations in packaging and shaping techniques are recommended to account for buckling instability of packaging and introducing target scaffold functional gradations or heterogeneities. While this rapid fabrication system requires refinement, these developments have demonstrated promising potential in fabricating patient specific implants for a number of applications.

Use of Ivory to Assess Composite Dentine Bonding

Saad Liaquat¹, Paul Ashley¹, Laurent Bozec¹, Anne Young¹

¹Eastman Dental Institute, UCL, London, UK, Saad.liaquat.11@ucl.ac.uk

INTRODUCTION

A current goal in dentistry is to develop a dental composite that can bond to human teeth without the need for the current complex acid etching procedures (e.g with phosphoric acid gel), and /or need for an adhesive (e.g Ibond). The aim of the study was to evaluate and compare the shear bond strength of two commercial (Z250, Gradia), and one experimental conventional composite (C-HEMA). In addition, a commercial (Vertise Flow), and experimental (C-4 META) potentially self- adhesive composite was studied.

Access to extracted human teeth for testing of composite bonding, however, is limited. Ivory was used as a substitute for human dentin in tensile adhesion measurements in 1979¹ and more recently to check the push out bonding of an adhesive system². In this study ivory is used (to access the shear bond of dental composites) in addition to human dentine to enable increased sample number, and thereby confidence in differences observed with dentine pre-treatment, and material type.

EXPERIMENTAL METHODS

Ivory Tusk & human teeth were cut to expose dentine surface. Cut sections were mounted using slow-setting viscous self-curing resin. Ivory dentine grinding & polishing was carried out using P120, & P500 paper until sound dentine was exposed. For Human dentine, grinding was stopped when superficial dentine was exposed.

All dentine surfaces were either treated with 37 % phosphoric acid gel etchant, or Ibond total etch for 0 or 20 s. Composite pastes were subsequently placed in a brass tube of 3 mm internal diameter, & 6 mm long placed on the dentine surfaces. Shear bond strength was determined using an Instron Universal testing machine with a "Flat-edge shear fixture", and 1 kN load cell at cross head speed of 1 mm/min (Table 1 & 2). Each test was performed in triplicate.

RESULTS AND DISCUSSION

From the combined results (Table 1 & 2) it can be seen that the biggest factor increasing bond strength is use of the adhesive Ibond (average of 28 vs 9 MPa). Acid etching can increase bonding both with (26 to 32 MPa) and without (7 to 12 MPa) use of adhesive. Addition of adhesion promoting monomers such as 4-META³ into the composites can improve bonding but only when no adhesive is employed (6 to 14 MPa increase). In comparison, differences in average bond strengths with ivory and human dentine were minimal demonstrating

that ivory is a good substitute for human dentine irrespective of treatment or material type (Table 1 & 2).

CONCLUSION

Ivory dentine can be used as a substitute for human dentine in adhesion tests. Additionally adhesive monomer 4-META in composites can increase bonding. Use of a separate adhesive, however, is more effective.

INTRODUCTION

Mechanical properties of metallic materials can be controlled by not only alloy design¹ but also constructing appropriate structure². A porous implant material with adequate pore structure and appropriate mechanical properties has long been sought as the ideal bone substitute³, because it exhibits low Young's modulus and bone ingrowth. The mechanical properties of porous materials change from day to day; the bone ingrowth into the pores makes the Young's modulus and the strength significantly increase after implantation. Therefore, it is necessary to implant the porous devices showing lower strength than that of living bone. In this case, the strength must be insufficient in the initial stage.

The purpose of the present study was to increase the strength of porous implants by heat-injection of biodegradable plastic into the pores. In addition, compressive strength was also investigated.

EXPERIMENTAL METHODS

Sodium chloroacetate ($\text{ClCH}_2\text{COONa}$, 98 % purity, Sigma Aldrich) was heated at 160 °C for 20 h under vacuum. NaCl was removed from the product polymer by stirring in distilled water for 5 h. The resultant powder of polyglycolide (PGA) was rinsed with ethanol twice and vacuum-dried at 80 °C. The compact of PGA powder and porous Ti (porosity: 60 %, $\phi 3 \times 5$ mm) were put in a die made of stainless steel and pressed up to 2 MPa at 210–240 °C by using a high frequency induction heating equipment.

Compression test was carried out at an initial strain rate of $1.66 \times 10^{-4} \text{ s}^{-1}$ for the porous Ti and the porous Ti-PGA composites.

RESULTS AND DISCUSSION

The resultant powder was determined as polyglycolide (PGA) by X-ray diffraction. Temperature scan between 30 and 250 °C was performed at a heating rate of $10 \text{ }^\circ\text{C min}^{-1}$ in differential scanning calorimetry. There is an endothermic peak, related to melting, with onset temperature of 167.8 °C, peak temperature of 205.4 °C and finish temperature of 215.0 °C.

Figure 1 shows (a) appearance and (b) cross-section of porous Ti-PGA composite prepared by heat-injection. All pores on the surface were filled by PGA. Furthermore, the PGA penetrated to the centre though few small cavities could be confirmed. The filling fraction was measured to be approximately 70 %.

The 0.2 % proof stresses were obtained from the stress-strain curves (Table 1). All stress-strain curves showed typical and smooth ones for ductile metals even in the composites. The porous Ti shows a proof stress of about 40 MPa. The compressive strength drastically

increased by filling the pores with PGA, it reached more than 90 MPa. This strength is comparable to that of cortical bone. In addition, the strength increased with increasing in injection temperature.

Fig. 1 Appearance (a) and cross-section (b) of porous Ti-PGA composite.

Table 1 Compressive strength in porous Ti and porous Ti-PGA composites.

	Injection temperature (°C)	0.2 % proof stress / MPa
Porous Ti	-	40
Ti-PGA	210	66
	225	93
	240	108

CONCLUSION

1. Porous Ti-polyglycolide (PGA) composites could be prepared by using a heat-injection method. The PGA penetrated to the centre of the porous Ti showing 60 % porosity.
2. Compressive strength was drastically improved by filling the pores with PGA. The strength increased with increasing in injection temperature.

Mechanical Properties and Surface of Ultrafine Grained Titanium for Dental Implants

Carlos Nelson Elias^{1*}, Daniel J. Fernandes¹, Jochen Roestel²

¹Instituto Militar de Engenharia, Brazil, elias@ime.eb.br (presenting author)

²Conexão Sistemas de Prótese, jochen@conexao.com.br

INTRODUCTION

The area of human implants has undergone rapid and dramatic developments in the past years. This was greatly enabled by new materials with enhanced biocompatibility. Although implants have been used by humans since ancient times, there were many rejection problems and it is only recently that osseointegrated implants have become widely used. The corrosion resistance to body fluids as well as the mechanical strength, fatigue endurance, and impact toughness are important requirements of a biomaterial, especially for implant applications. Biomaterials are usually classified [1], in terms of their interaction with the body, into: biotolerant materials (e.g., stainless steel, CrCo alloy, and polymethyl-methacrylate) release substances in nontoxic concentrations, which may lead to the formation of a fibrous connective tissue capsule; bioinert materials (e.g., alumina and zirconia) exhibit minimal chemical interactions with adjacent tissue; and bioactive materials (e.g., hydroxyapatite, bioglass) stimulate a biological response from the body, such as bonding to either a soft tissue, like cartilage, or hard like bone.

The main application of unalloyed cp Ti (ASTM grade 1 to 4) is for dental implants. This metal is not, however, used for orthopedic application owing to its low mechanical properties. This work focuses on dental implants and in the introduction of ultrafine grained titanium (UFG Ti), obtained by severe plastic deformation (SPD) processing, for which properties were evaluated [2]. In particular, its strength was found to match that of Ti-6Al-4V alloy, commonly used in high strength structural implants.

EXPERIMENTAL METHODS

In this study samples for mechanical tests and implants were machined from bars of cp Ti G2, 4, 5 and cp Ti G4 cold hardening. The implants were subjected to surface treatments with double etching (HCl and H₂SO₄ solution) with the same concentration and for the same temperature and time interval.

Tensile test and surface morphology analysis was done.

RESULTS AND DISCUSSION

Figure 1 shows the surface morphology of dental implant surfaces after acid etching. It can be seen that the surface is homogeneous with uniformly distributed microcavities. Roughness in the nanometer scale is on Ti G4 cold hardening surface. Figure 1 does not show a significant micro morphology difference between Ti G4 and Ti G4 cold hardening after acid treatment. This result suggests that the use of dental implant made with Ti G4 cold hardening can be subjected to the same machining processes and surface chemical treatment as cp G4 without significant changes in biocompatibility.

Only at high magnification it is possible to observe that Ti G4 cold hardening has higher number of nanoscale surface features than Ti G4 and G5. It is expected that the interactions between the cells and the nanoscale surface are improved in the early stages after implantation. According to Meirelles et al [3], the nanoscale surface features improve the osseointegration mechanism.

The stress-strain curves are shown in Figure 2. It can be seen that the mechanical strength increases in the following order: Ti G2, Ti G4, Ti G5 and Ti G4 Hard.

Figure 1: Surface morphology of dental implants after acid etching. (A) Ti alloy G5. (B) cp Ti G4. (C) cp Ti G4 cold hardening.

Figure 2: Tensile test of cp Ti and Ti alloy.

Figure 2 shows that all cp Ti and Ti 5 samples are ductile, i.e., have a high plastic deformation before fracture. The curves show that when the applied stress is higher than the yield strength, permanent deformation occurs and the ductility decreases. Ti 4 cold hardening is the strongest metal.

CONCLUSION

The results of the present work show that:

- The surface morphology of Ti G4 cold hardening has micro and nanoroughness, which can improve the dental implant osseointegration.
- The Ti G4 cold hardening is stronger than cp Ti and Ti G5.

Preparation and Characterization of Novel Composite Agarose Films for Wound Healing

Alma Akhmetova^{1*}, Matthew Illsley², Timur Saliev¹, Talgat Nurgozhin¹, Sergey Mikhlovsky¹, and Iain Allan²

¹Department of Translational Medicine, Longevity and Global Health/Center for Life Sciences, Nazarbayev University, Kazakhstan

INTRODUCTION

Wound healing is a complex process that requires multipurpose approach. The common properties for desired products usually include absorption, stimulation of regeneration process, pain free removal, and no toxicity. In these terms agarose is a promising biomaterial for wound healing applications. It does not require additional crosslinking agents and forms a gel at room temperature. The transparent nature of this polysaccharide can allow monitoring of the wound state. Absence of toxicity and inertness of agarose may prevent unnecessary reactions at the wound site. Its slow degradation rate is beneficial for the end product properties such as longer shelf life.

To aid absorption of wound exudate, bacteria, and necrotic tissue, activated carbon (AC) was incorporated into agarose films. We developed and studied mechanical properties of agarose films of various concentrations. For the first time activated carbon particles were incorporated into agarose films and triple-layered films were developed.

EXPERIMENTAL METHODS

To prepare agarose films, agarose powder for general use was dissolved in distilled water which was brought to boiling. 0.5%, 1%, 1.5%, and 2% concentrations of agarose solutions were prepared. Each solution was poured into a plastic Petri dish (87x12 mm) and left to set for about 3-5 minutes. Then, 6-7 circles (27x3.3mm) were cut out and placed into plastic weighing boat. Samples were dried overnight in a vacuum oven at 60°C. Activated carbon particles were added to the agarose and distilled water and brought to boil. The above steps were repeated to prepare films.

The mechanical strength and elasticity of agarose films were assessed using texture analyser. Young's modulus of elasticity, tensile strength, and elongation at breaking point were measured and analysed. Solvent absorption capacity of the prepared films was tested following standard gravimetric procedure. Moisture content and swelling capacity of films were measured. All measurements were conducted in triplicates.

RESULTS AND DISCUSSION

The increase in concentration greatly affected mechanical properties of agarose films resulting in a curl of the edges and rigid structure. These films were prone to easy breakage. One-layered agarose films of

0.5% and 1% were elastic and straight. Activated carbon was added in 1:1 ratio to agarose. In the resulted films, incorporated AC particulates were found to detach from the agarose layer. To overcome this problem, the AC layer was sandwiched between two agarose layers with the inner AC layer having a lesser diameter than the surrounding agarose layers.

Figure 1 - Moisture content ratio of one-layered and three-layered agarose films, and three-layered agarose-activated carbon-agarose films.

Triple-layered, agarose-activated carbon-agarose, films almost immediately absorbed much higher volume of the solvent (Figure 1). The swelling ratio was twice larger in comparison to films containing only agarose. These results indicate that activated carbon particulates are freely available within agarose cascade. However, the equilibrium in both experiments was not reached for three-layered films. Therefore, the continuation of the experiments is required.

CONCLUSION

The prepared agarose films of low concentration were straight and elastic and suitable for easier application to the wound site. These films were non-adherent and, therefore, can be directly used to the wound enabling pain-free removal. Incorporation of activated carbon into agarose layer was successful only when the agarose-activated carbon layer was covered completely with two agarose layers. Inclusion of AC enabled much higher absorption capacity and swelling of the films.

INTRODUCTION

Calcium phosphate based bone substitutes have the unique capacity to be resorbed *in vivo* according to bone remodeling kinetics and replaced by natural bone. Thus injectable calcium phosphate cements (CPCs) are under intense investigation since they offer additional advantages compared to ceramics and open up new applications in the field of drug delivery systems using minimally invasive surgery in pathological osseous sites. In this context, bisphosphonate (BP) antiresorptive drugs can be combined with CPCs¹, however, the way to introduce BP in a CPC has a critical influence on the setting kinetics. We have also explored the potential of gallium-doped calcium phosphate materials². It was shown that gallium (Ga) reduced the resorption activity, differentiation and formation of osteoclasts, in a dose-dependent manner without inducing any adverse effect on osteoblastic cells. For this reason, we are interested in investigating whether gallium can be combined with injectable CPCs for the development of a local delivery system of this ion in fragilized osseous sites. Meanwhile we are also interested in improving the bioactivity of these CPCs by the addition of autologous blood as a source of fibrinogen and growth factor in their liquid phase.

EXPERIMENTAL METHODS

The formulations were optimized from an apatitic-type CPC, with α -TCP as main component (78%), BP or Ga is introduced via (10%) calcium deficient apatite [BP-CDA or Ga-CDA]. The liquid phase consisted in a Na_2HPO_4 solution or blood. The BP used for our study was Alendronate. BP-CDA was obtained by suspending CDA in a solution of Alendronate, Ga-CDA was obtained by a pH controlled co-precipitation process between gallium nitrate, calcium nitrate and diammonium hydrogen phosphate. The products obtained were characterized by ³¹P MAS NMR, CPC setting by high frequency impedance and mechanical properties by texture analyser.

RESULTS AND DISCUSSION

Three approaches to incorporating Alendronate in the cement were investigated: BP (i) dissolved in the liquid phase (ii) added to the ground solid phase (iii) chemically combined with a component of the solid phase. As phosphonates are considered as retardant agents for the setting of Portland cements, the later approach has been shown to be the most promising particularly via the chemical association between CDA

and BP as previously demonstrated. In this study we have also compared the setting time obtained by using Gilmore needles method with high frequency impedance measurements³. ³¹P NMR has also been used to characterize the chemical transformation of α -TCP to CDA during the setting process. As for BP, the best approach to incorporating Ga in a CPC consists to combine it with a component of the solid phase. After changing the constitution of the solid phase of cement including incorporation of inhibitors of bone resorption, we also decided to change the liquid phase of the cement. For this, we replaced the aqueous liquid phase by blood. Our starting point is related to two commercial cements: a long setting time cement LST (initial setting time 15 min.) and a short setting time cement SST (initial setting time 8 min.). In the case of LST/blood cement, there is a competition between the precipitation of crystalline particles of CDA and the polymerization of fibrin during blood clotting.

In the case of SST/blood cement, the precipitation process can be achieved more easily and we obtain an injectable self-hardening cement which matches the control as shown Fig.1.

CONCLUSION

Here we demonstrate the feasibility of such medical device based on doped-calcium phosphate cement incorporating inhibitors of bone resorption in order to stimulate bone ingrowth. One can of course imagine to incorporate both gallium and bisphosphonate in the same cement which nevertheless raises the question of whether we are still dealing with a medical device. We also believe that the replacement of the aqueous liquid phase by blood is a promising way due to the presence of many circulating cells promoting bone healing. Preliminary "*in vivo*" experiments supports this assertion.

Robotic Deposition of 3D Scaffolds Using β -tricalcium Phosphates Inks for Bone Regeneration

Raquel Costa Richard¹, Renata Nunes Oliveira^{1*}, Rossana Mara da Silva Moreira Thiré¹

^{1*} Department of Materials Engineering, Federal University of Rio de Janeiro, Brazil, nunes@metalmat.ufri.br

INTRODUCTION

Several approaches have attempted to replace extensive bone loss, but each of them has their limitation¹.

Even though health bone is able to self-regenerate, this regeneration is limited to a gap of a few millimeters. Therefore, filling the bone defect with a porous scaffold helps to enhance bone regeneration since the scaffold serves as a template for cell ingrowth as well as for extracellular bone matrix formation². It has been shown that three-dimensional (3D) scaffolds with interconnected macroporous, reproducing the shape of the patient's bone defect, help to improve the biocompatibility of the scaffolds after surgical procedure³.

The goal of the present study was to synthesize beta-tricalcium phosphate (β -TCP), beta-tricalcium phosphate substituted by magnesium (β -TCMP) and biphasic calcium phosphate substituted by magnesium (BCMP) via hydrolysis and to produce scaffolds for bone regeneration using robocasting technology.

EXPERIMENTAL METHODS

Calcium deficient apatites (CDA's) powders, with and without magnesium, were obtained by hydrolysis, calcined and physico-chemically characterized. Colorimetric cell viability assay, calcium nodule formation and the expression of alkaline phosphatase, osteocalcin, transforming growth factor beta-1 and collagen were assessed using a mouse osteoblastic cell line (MC3T3-E1).

Direct-write assembly of cylindrical periodic scaffolds ($\Phi = 8\text{mm} \times H = 5\text{mm}$) was done via robotic deposition with a robotic deposition device (Aerotech 3200, Stillwater, OK) using β -TCP, β -TCMP and BCMP colloidal inks. The sintered scaffolds were characterized by scanning electron microscopy and uniaxial compression test.

Statistical analysis of the mechanical compression data were performed by one-way ANOVA at 95% confidence interval using the software Origin 8.0[®] (OriginLab Corporation, USA). Multiple comparisons between groups were performed by the Tukey test.

RESULTS AND DISCUSSION

According to XRD spectra, β -TCP was obtained after calcining Mg-free CDA; β -TCMP or BCMP were obtained after calcining Mg-substituted CDAs, depending on the Mg/Ca molar ratio of the CDA. MTT assay showed that the β -TCP, β -TCMP and BCMP obtained promoted cell proliferation, indicating non-cytotoxicity. Calcium nodule formation results indicated that the degradation products of the β -TCP, β -TCMP and BCMP were conducive to bone formation. The amount of mineralized nodules was higher in the β -TCP, followed by β -TCMP and BCMP samples. The same behavior was observed for bone formation markers (ALP and osteocalcin) and for bone resorption

markers (TGF- β 1 and collagen) activity in MC3T3-E1 cell line. This behavior can be explained for the fact that the presence of Mg ions retards the dissolution of CaP^4 . The 3D structures obtained from the β -TCP, β -TCMP and BCMP inks were cylinders (8mm x 5mm) composed of 21 layers, with two perimeter rims surrounding a parallel array of rods (0.33mm) with an inter-rod spacing of, approximately, 460 μm . Figure 1 shows the macro and microstructure of a β -TCP sintered scaffold.

Studies with trabecular bone have been registered a wide variation of strength which is usually in the range of 4 to 12 MPa⁵. The mean compressive strength values of β -TCP, β -TCMP and BCMP scaffolds were 18.67 (± 4.14), 12.24 (± 2.67) and 7.63 (± 2.36) MPa, and the maximum compressive strength values were 26.58, 15.81 and 10.63 MPa, respectively.

Figure 1- Macro (a,b,c) and microstructure (d) of β -TCP sintered scaffold.

CONCLUSION

According to the cell viability assay, the powders induced cell proliferation. Calcium nodule formation and bone markers activity suggested that the materials present potential value in bone tissue engineering. The scaffolds built by robocasting presented interconnected porous and exhibited mean compressive strength between 7.6 and 18.7 MPa, compatible with trabecular bone.

Evaluation of Bone Replacement Materials in a Rabbit Cranial Defect Model using MicroCT and Hard Tissue Histology

Gerlind Schneider^{1*} and Dirk Linde¹

¹Department of Otorhinolaryngology / Friedrich Schiller University Hospital, Jena, Germany

^{*}gerlind.schneider@med.uni-jena.de

INTRODUCTION

For functional and structural restoration of bone deficiencies, various resorbable and nonresorbable alloplastic materials have been introduced, including metals, polymers and ceramics.

However, an optimal artificial replacement for craniofacial bone has not been found yet, and the search for improved reconstruction methods and alternative materials is going on. To assess and compare biocompatibility and osseointegration of these materials, adequate animal test models are indispensable.^{1,2}

EXPERIMENTAL METHODS

In a rabbit cranial defect model ("Jena skull model")¹, biocompatibility and osseointegration of polymeric and composite (3D printed tricalcium phosphate + polymer) bone replacement materials were evaluated at different time points after implantation. Calvaria including implants and surrounding tissue were explanted and embedded in methacrylate resin².

The samples were scanned with a nanotom® (phoenix|x-ray) microCT scanner and proceeded for histological examination by sawing-grinding technique³. Avizo® Fire (vsg) software was used for visualisation and processing of µCT data.

Qualitative and morphometric evaluation of osseointegration, fibrous encapsulation, and inflammation was performed on undecalcified histologic preparations of the explants, and on 3D reconstructions plus virtual slices derived from corresponding 3D microCT datasets.

RESULTS AND DISCUSSION

The obtained 3D microCT data enabled comprehensive qualitative and quantitative assessment of osseointegration and biodegradation of radioopaque composite implants.

Prerequisite for visualization and discrimination of materials by µCT is a significant difference of their Hounsfield values. Due to this limitation, radiolucent polymeric implant materials and soft tissue could not be distinguished from embedding resin (figure 1).

In contrast, histologic preparations of undecalcified hard tissue and implant materials enabled detailed visualization and examination of all tissues and implant materials (figure 1). The substantial disadvantage of hard tissue histology is the inevitable loss of information due to small number of slices and large gaps between specimens yielded by this method.

Figure 1: Explants from rabbit cranial defect model containing composite implant: histologic preparation (upper part) and virtual slice of µCT scan (lower part)

CONCLUSION

To obtain comprehensive and quantifiable information about biodegradation, biocompatibility and osseointegration of alloplastic bone replacement materials, microCT scans as well as histologic evaluation should be performed.

A New Analytical Model of GAAS MESFET With Different Laws of Mobility

Y.Saidi , Z.Fares

Department of Physics, Faculty of Sciences, Mentouri University, Constantine, Algeria
e-mail: saidiyas09@yahoo.fr

1-Introduction

We present in this paper an analytical model of the current –voltage (I-V) characteristics for submicron range GaAs JFET and MESFET transistors. This model is take into account the two-dimensional analysis of the charge distribution in the active region and incorporates a field depended electron mobility, velocity saturation and charge build-up in the channel. In this framework an algorithm of simulation based on mathematical expressions obtained previously

2-Calculation of drain current in channel

To calculate the drain current expression as a function of the drain voltage, we must make some approximations [2,3]:

- voltage for various values of the gate voltage, we use some reasonable approximations (1):
- One neglects the current flow in the y-direction; this approximation is valid for the components with the length and short gate.
- An abrupt junction Schottky barrier.
- A channel of uniform doping N_d (x, y) = N_d , N_d is constant.
- Neglecting edge effects, the overflow area depopulated on the sides of the gate

3 - Effect of mobility variable

The characteristics current -voltage depend with the variations on the electron mobility according to the electric field. In area of weak electric fields, free carriers are in thermal equilibrium with the network and their average speed is proportional to the electric field:

$$V(E) = \mu_n E.$$

μ_n is the mobility of electrons at low electric field.

But, when the electric field is high, the electron transfer intervals induced in the GaAs, a decrease of

witch descript the variations of the mobility with the electric field in the submicron GaAs and several approximate analytical expressions have been proposed for this function. The mobilities law used in our I-V model are expressed by :

- For the weak electrical fields where $E < E_0$:
$$\mu = \mu_n \quad (4)$$
- For the high electric fields beyond E_0 ($E \geq E_0$) [3,4]

4) Results and discussions

The numerical calculation of the current of drain according to the biasing calls upon the expressions (8), (9), (10) established previously. The study was carried out on a submicronic gate GaAs MESFET.

In the linear regime, we notice a good coincidence between experiment values and theory and those that, for various acts of mobility, especially in the case of constant mobility, demonstrating the independence of the mobility of electrons in the field power, low drain voltages and also the close correlation between experience and the model proposed in the linear regime.

Conclusion:

In this study we have developed an analytical model to calculate the I-V characteristics of short gate length GaAs MESFET which takes into account the one-dimensional analysis of the charge distribution in the active region and incorporates a field depended electron mobility, velocity saturation and effect of these parameter to the current voltage expressions. The model compares favourably from a submicron GaAs MESFET . More ever, comparisons between the analytical models with different values of mobility proposed shown the effect of mobility it affects directly the output characteristics (I-V) of GaAs MESFET.

INTRODUCTION

Self-assembled nano-structure on the surface of bone/dental implants has attracted significant interest in the last few decades. In this context, anodic TiO₂ nanotubes have been shown to have a beneficial effect on osteoblast differentiation and bone formation around implant [1-2]. However, there is uncertainty about the interfacial adhesion to substrate as a surface coating for medical implants [3]. In this study, the effects of anodising conditions on the morphology, composition and interfacial adhesion of the nanotubes grown on titanium alloy were investigated with various electrolytes, pH values and voltage sweep rate.

METHODOLOGY

Samples of Ti-6Al-4V alloy were polished using silicon carbide papers followed by an alkaline cleaning. The nanotubes were grown by anodisation under 0-20V, in 0.2-0.5 wt% ammonium fluoride (NH₄F) with 0.5-1M NH₄H₂PO₄ or 0.5-1M (NH₄)₂SO₄, for 60-120 minutes at room temperature. The experiments were performed at a range of pH and voltage sweep rate. The resulting samples were analysed using a field emission scanning electron microscope (JEOL JSM-7500F) combined with an Oxford Instruments system (AZtec) whereby an Energy-Dispersive X-Ray Spectroscopy (EDS) was also performed with the aim of quantifying the elements present in the surface coating. The adherence of the coating, prepared under various conditions, was tested using a pull-off test on a universal mechanical test machine. The interface failure mechanisms were examined afterwards using high resolution SEM.

RESULTS AND DISCUSSION

TiO₂ nanotubes of an average diameter of 30-100 nm were formed on the surface, with the aim of enhancing the attachment of human cells for its use as biomaterial. In the sulphate containing electrolyte, the nanotubes formed on the β -phase of the alloy were fully dissolved due to the high solubility of vanadium oxide (Fig. 1) while for the samples from the phosphate containing electrolyte, the β -phase had a thin layer of TNTs as shown in Fig. 2.

The pH played a crucial role in the growth of the nanotubes in terms of growth rate and wall thickness which in turn influenced the elements present on the nanotubes. The presence of fluoride and phosphorus ions in small amount (From EDS) is expected to have

antibacterial properties while helping in the initial attachment of bone cells [4]. The adherence of the nanotubes to the surface was obtained, highlighting the effects of coating thickness, residual stress and coating

Fig. 1: TNTs obtained from sulphate containing electrolyte

Fig. 2: TNTs obtained from phosphate containing electrolyte

CONCLUSION

The presence of the micro and nanostructure on the surface at the same time was observed which will be beneficial in attachment and proliferation of human cells which can improve osseointegration. At the same time the appropriate thickness of the nanotubes layer, with a good adherence, was determined. It is envisaged that the nanotubular structure could act as a carrier for bactericidal or bone growth catalyst drugs to improve the anti-bacterial properties and bioactivity of an implant.

ACKNOWLEDGEMENTS

I would like to thank the University of Plymouth for sponsoring the project and all three supervisors who helped at every step in the study.

INTRODUCTION

In recent decades, calcium phosphate bone cement (CPC) research has focused on the improvement of injectability, mechanical strength and resorption¹ in an attempt to accelerate a good cell response at early implantation times. The preparation of α -tricalcium phosphate (α -TCP) has required heating to very high temperatures^{2,3} and time-consuming ball-milling to achieve the required reactivity^{4,5}. Therefore, the development of alternative synthesis pathways is eagerly awaited. A new bottom-up approach that makes pure α -TCP has the potential to improve the field of calcium phosphate bone cements. This research takes on the challenge, with attention to microstructural characteristics, to develop a nano-sized building block of resorbable bone cements – by heating amorphous calcium phosphate (ACP) precursor – that upon mixing with water transforms into calcium-deficient apatite.

EXPERIMENTAL METHODS

Amorphous calcium phosphate precursors (ACP) were synthesized from calcium nitrate tetrahydrate ($\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$), ammonium phosphate dibasic ($(\text{NH}_4)_2\text{HPO}_4$) and ammonium hydroxide solution (NH_4OH , 26% NH_3 basis). A 0.30 M calcium nitrate solution was formed by dissolving $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ in deionised water together with 30 ml ammonia solution and then combined with a 0.24 M ammonium phosphate solution. The resulting precipitate was immediately filtered and rinsed with water (then lyophilized), or treated with ethanol (then oven-dried). The powder was heated between 675 and 800 °C for 10 or 20 min in a cylindrical tube furnace. Particle size was measured in a scanning electron microscope and by Rietveld analysis. Phase composition and bonding in the crystallized powder was assessed by X-ray diffraction and Fourier-transform infrared spectroscopy. Biocompatibility of powders was investigated *in vitro* with a lactate dehydrogenase cytotoxicity assay on mesenchymal stem cells.

RESULTS AND DISCUSSION

All precipitated precursors showed the typical X-ray diffraction pattern for the amorphous phase⁶, a broad maximum at approximately 30°. The morphology of heated ACP powders is shown in Figure 1. The individual spherical particles (approximately 50 nm) have joined to form longer particles, and these connect to create a nano-sized pure α -TCP structure.

Figure 1. Morphology of (a) ACP and (b) processed at 775 °C.

Pure α -TCP, after hydrolysis to CDHA, demonstrated the highest biocompatibility (25% cytotoxicity) whereas the α -TCP with low amount of β -TCP (7–15%) showed an increased cytotoxicity (up to 40%).

CONCLUSION

Nano-sized pure α -TCP (50–100 nm) was obtained from an amorphous calcium phosphate precursor, treated with ethanol and heated above 700 °C. A lower purity α -TCP was obtained when ACP was rinsed in water and slowly cooled. Pure α -TCP showed the highest biocompatibility and this could be related to the 100% conversion to a calcium-deficient hydroxyapatite cement. A lower biocompatibility arose in the presence of β -TCP. Highlight: The first time a nano-sized pure α -TCP has been made and offers great promise for imparting greater functionality for use in regenerative medicine of hard tissues.

Single Cell Tracking of Haematopoietic Stem Cells in 3D Biomimetic Gradients

Michael Ansorge¹, Jiranuwat Sapudom¹, Tilo Pompe¹

¹Institute of Biochemistry, Universität Leipzig, Germany
tilo.pompe@uni-leipzig.de

INTRODUCTION

The interaction of stem cells with their microenvironment determines cellular dynamics and cell fate decisions. This highly regulated entity is called 'stem cell niche'. The control mechanisms are based on cues of the extracellular matrix and neighbouring cells, such as biophysical factors, like matrix topology and stiffness, as well as biochemical factors, like matrix composition and growth factor presence.

We engineer defined biomimetic microenvironments for *in vitro* cell culture to dissect the specific signalling mechanisms in the stem cell niche. Reconstituted collagen matrices complemented with local gradients of signalling molecules are used to study cell fate in heterogeneous populations of primary haematopoietic stem and progenitor cells by label-free 3D single cell tracking.

EXPERIMENTAL METHODS

3D collagen I matrices were engineered with defined topological and mechanical properties as characterized using confocal laser scanning microscopy with a newly developed topology analysis and atomic force spectroscopy.¹

Gradients of signalling molecules (SDF-1, Dkk-1) were formed using biofunctionalized hydrogel microbeads to facilitate protein release over several days. Release characteristics were investigated with confocal laser scanning microscopy and fluorimetry in combination with fluorescence correlation spectroscopy to quantify local gradients around matrix-embedded microbeads.

Primary murine hematopoietic stem cells (CD150⁺ CD48⁻) were cultivated over several days inside the biomimetic scaffolds. Quantitative 3D single cell tracking was performed using brightfield microscopy and automated cell detection and tracking.

RESULTS AND DISCUSSION

The efficacy and accuracy of our new single cell tracking technology facilitate the *in vitro* long-term

study of label-free primary cells in 3D biomimetic matrices. By that we were able to quantify migration and proliferation characteristics of haematopoietic stem and progenitor cells within local gradients of SDF-1 and DKK-1, which mimic important regulating cues of the haematopoietic stem cell niche in the bone marrow. Change in directionality, positioning and dynamics of migratory behaviour could be correlated to the proliferative activity and local gradient fields of the signalling molecules. By comparing the heterogeneity of single cell behaviour and population-wide averages we could reveal the distinct impact of signalling molecule gradients on the behaviour of hematopoietic stem and progenitor cells.

CONCLUSION

Our label-free automated 3D single cell tracking tool allowed to analyse haematopoietic stem cell dynamics in biomimetic microenvironments of signalling gradients and to reveal regulating cues of the bone marrow niche. The combination of both technologies - biomimetic gradients and single cell tracking - provide an advantageous approach for in-depth *in vitro* studies of signalling mechanisms on a variety of biological and biomedical questions.

Electrochemical dissolution of stainless steel endodontic files fractured in the middle and apical thirds of the root canal

Caroline Amaral¹, Fabiola Ormiga¹ and José Ponciano Gomes²

¹Department of Metallurgy and Materials and Department of Endodontics, Federal University of Rio de Janeiro, Brazil, caroline.chavadian@metalmat.ufrj.br

²Department of Metallurgy and Materials, Federal University of Rio de Janeiro, Brazil

INTRODUCTION

Under excessive stresses and tensions, the endodontic instruments may fracture in the middle or apical third of the root canal^{1,2}. Several methods have been described for removing fractured instruments from root canals^{3,4,5}, however these methods have some limitations, such as weakening and perforation of the root. In this context, a method to dissolve the fractured instruments was recently proposed⁶. The aim of this study was to investigate the process of active dissolution of stainless steel files in the middle and apical third of simulated root canals in solutions containing chloride and fluoride.

EXPERIMENTAL METHODS

Redox curves and anodic polarization curves were performed in [NaF 12g / L NaCl + 175.5 g / L] solution at pH 5.0 to evaluate the process of dissolution of the stainless steel alloy. The polarization of immersed files was performed to calculate the weight loss and length loss after the test. The tested files were observed using an optical microscope. The polarization of fragments a size 20 stainless steel K files was performed for 60 minutes in the middle and apical thirds of simulated root canals. Radiographic analysis of the simulated root canals was used to verify fragment dissolution. A size 10 file was used to verify the possibility to bypass the fragment before and after the tests.

RESULTS AND DISCUSSION

The stainless steel alloy suffered localized dissolution in [NaF 12g / L NaCl + 175.5 g / L] solution. The redox curve showed the stability of the solution to -0.2 V_{SCE}, but above this potential, the solution was unstable due to oxidation reactions. The progressive consumption of the files was observed in the total polarization time of 7 min (Figure 1). Ten fragments of size 20 files were partially dissolved in the middle and apical thirds of the simulated root canals (Figures 2 and 3). Radiographic analysis obtained before and after polarization tests showed loss of weight and thickness of the size 20 file (Figure 2 and 3 ab ab), allowing the bypassing of the fragment by a size 10 file (Figure 2 c and 3 c).

Figure1. Current values registered during the polarization of immersed a size 20 stainless steel K files

and optical microscope analysis (1) file as received, (2) file submitted to polarization for 3.5 minutes and 7 minutes.

Figure2. Current values registered during the polarization of a size 20 K- file fragment in the middle third of simulated root canal and radiographic analysis (a) before polarization (b) after polarization and (c) fragment bypassed by a size 10 K file.

Figure3. Current values registered during the polarization of a size 20 K- file fragment in the apical third of simulated root canal and radiographic analysis (a) before polarization (b) after polarization and (c) fragment bypassed by a size 10 K file.

CONCLUSION

The method tested in the present study allowed a partial dissolution of fragments of stainless steel K- files in the middle and apical thirds of simulated root canals in a period clinically acceptable.

Photochemical nitric oxide release from a Flutamin derivative incorporated in Pluronic F127 hydrogel

Patricia Taladriz-Blanco and Marcelo G. de Oliveira

Institute of Chemistry, University of Campinas, UNICAMP, SP, Brazil, patricia.taladriz@iqm.unicamp.br

Keywords: Hydrogels, responsive biomaterials, drug delivery

INTRODUCTION

Nitroaniline derivatives are known to release nitric oxide (NO) when irradiated with visible light.¹ This property offers the perspective of using these compounds for obtaining a controlled release of NO in medical applications. Pluronic F127, a triblock PEO-PPO-PEO copolymer with thermo-responsive behaviour, undergoes reversible micellization and gelation with heating. In the gel state, the hydrophobic nuclei of the micelles act as concentrating microenvironments for drugs with low solubility in water, including free NO. In this work, we have incorporated a Flutamin derivative, N-(3-aminopropyl-3-(trifluoromethyl)-4-nitrobenzenamine (ATN), in Pluronic F127 matrices. The resulting hydrogels were shown to be thermally stable and to release gaseous NO upon irradiation with visible light. These properties may allow the use of these hydrogels for delivering NO locally in topical applications.

EXPERIMENTAL METHODS

ATN was synthesized on the bases of procedures already described elsewhere.¹ Aqueous solutions of Pluronic F127 30wt% and 10wt% were prepared by the cold method.² ATN was dissolved in the F127 solutions to a final concentration of 0.19 mM. Solutions were kept in the dark until use. F127/ATN samples were irradiated at 15 °C and 37 °C using a 150 W Xenon Arc lamp through a 400 nm cut-off optical filter. The photochemical NO release from the F127/ATN solutions, below and above CMT, was characterized by chemiluminescence using an NO Analyser (NOA 280i, Sievers, Boulder, CO, USA).

RESULTS AND DISCUSSION

Fig. 1 shows the total amount of NO photochemically released from the F127/ATN formulations. It can be seen that at 10wt% and 5 °C, where F127 is below its critical micelle temperature (CMT), the total NO released in 10 min is 0.15 mmol (Fig 1, bar A) while at 37 °C, where F127 is above CMT, the amount of NO released in the same time is ca. 4-fold higher (Fig. 1, bar B). An enhanced NO release was also obtained at 30wt% at 15 °C, where F127 is above the critical micelle concentration (CMC). These results show that the enhanced NO release is associated with the presence of micelles. As the photochemical NO release from ATN implies the formation of a phenoxyl radical after NO ejection, this result can be assigned to the facilitated hydrogen abstraction from the methylene groups of the PPO blocks in the micelle nuclei, which blocks radical pair recombination, increasing the yield of the

photochemical NO release. This effect is absent below CMT or CMC. In addition, we have seen that above the gelation temperature, the amount of NO released is decreased (Fig. 1, bar D vs. bar B). This result suggests that viscosity constraints imposed on the diffusion of the phenoxyl radical in the gel state, favours radical pair recombination, decreasing the yield of photochemical NO release. Together, these two effects can be used as a tool to modulate the photochemical release of NO from these formulations in different applications. Although the inclusion of Flutamin in vesicles or β -CD, was already shown to increase the photodegradation of Flutamin relative to water³, the results presented in this work underscore a new effect of the F127 matrices, where the hydrophobic nuclei of micelles act as nanoreactors, increasing the yield of NO released in homolytic bond cleavages such as the photocleavage of the nitro group of ATN.

Figure 1. Bar graph showing the total amount of NO released from F127/ATN per min of irradiation with visible light.

CONCLUSION

F127/ATN comprise thermally stable formulations. F-127 micellization and gelation can be used as a tool for controlling the photochemical delivery of NO from the photodecomposition of ATN through the irradiation with visible light. The potential applications of such formulations may include the topical applications for increasing dermal vasodilation in ischemic tissues or for obtaining microbicidal actions on infected lesions.

Electrospun Human Hair Keratin Matrices Affect Human Fibroblast Behavior Through Topographical Cues

Wan Ting Sow¹ and Kee Woei Ng^{1*}

¹School of Materials Science and Engineering, Nanyang Technological University, Singapore,

*Email: kwng@ntu.edu.sg

INTRODUCTION

Natural polymers such as proteins and polysaccharides are potential materials as templates for tissue regeneration due to their natural bio-inductive abilities to improve cell-material interactions. However, most of these materials still present some shortcomings due to their animal origins¹.

From this perspective, hair keratin emerges as an attractive protein of human origin to be used as templates for tissue regeneration because it can be easily extracted from the unlimited supply of human hair².

In this work, we extracted keratin from human hair, fabricated it into fibrous matrices via a scalable technique, electrospinning and evaluated their potential as fibrous templates for supporting cell growth³. We prepared two types of keratin matrices, with random and aligned fibres, to study the effect of topography on cellular response.

EXPERIMENTAL METHODS

Keratin was extracted from human hair using 0.125M Na₂S solution. Subsequently, solutions of keratin were electrospun with 0.5 wt% of poly(ethylene) oxide added to improve processability³. Random and aligned fibres were generated via a flat collector platform and rotating drum, respectively. The resulting fibrous matrices were characterised using Scanning Electron Microscopy (SEM) to view their morphology and Fourier Transformed Infrared Spectroscopy (FTIR) to evaluate their chemical properties. Investigation of cell behaviour on keratin fibrous matrices was conducted using primary human dermal fibroblasts (HDFs). Cell viability was analyzed through evaluating cell metabolic activity using the AlamarBlue assay while cell proliferation was quantified using the Picogreen assay. These cell quantification results were evaluated statistically using the Student's t-test and the sample size was n=3. Live/Dead staining was also done to view the morphology and distribution of HDFs on keratin fibrous matrices.

RESULTS AND DISCUSSION

Our results showed that keratin fibrous matrices with beadless morphology were electrospun with a mean fiber diameter of $0.70 \pm 0.09 \mu\text{m}$ for random fibres and $0.74 \pm 0.10 \mu\text{m}$ for aligned fibres (Fig 1).

Fig. 1: SEM images of keratin fibrous matrices with A) random and B) aligned morphology.

FTIR analysis indicated that the chemical properties of fibrous matrices resembled those of extracted keratin, revealing that electrospinning did not significantly affect protein quality.

Results from cell studies showed that proliferation and metabolic activity of HDFs on keratin matrices were comparable to the positive control and significantly higher on aligned keratin fibres compared to random keratin fibres on day 3 after cell seeding (Fig 2). Besides, our live/dead staining revealed that HDFs cultured on the keratin matrices could form cellular networks according to the architecture of the matrices, implying that the cells were able to respond to the topographical cues rendered by keratin matrices (Fig 3).

Fig. 2: Cell viability of HDF. A) Picogreen and B) Alamar Blue assays showed that proliferation and metabolic activity of HDFs on keratin matrices were comparable to the positive control (Gelatin).

Fig. 3: Fluorescence microscopy images of HDF cultured on keratin matrices over 7 days showing that HDFs exhibited typical spindle morphology and could form cellular networks according to the architecture of the keratin matrices.

CONCLUSION

In this work, we showed that keratin fibrous matrices provide a conducive environment to facilitate the growth of primary HDFs and influence the cell network formation via topographical cues.

³Department of Bio-Organic Chemistry, Radboud University Nijmegen, The Netherlands

INTRODUCTION

A powerful strategy to reduce the complications and side-effects related to the systematic use of antibiotics involves local and sustained delivery of antibiotics at the site of infection. Gelatin micro- and nanospheres have been extensively used for controlled delivery of therapeutic proteins such as growth factors (GFs). These GFs were shown to bind to oppositely charged gelatin matrices through the formation of polyion complexes¹, thereby facilitating sustained delivery of large therapeutic biomolecules. The release kinetics of small biomolecules such as antibiotics from gelatin carriers has, however, not been studied before. We hypothesised that controlled and sustained release of charged antibiotics from oppositely charged gelatin carriers can also be achieved. Therefore, we have studied the release kinetics of various antibiotics of different molecular weight and charge from gelatin micro- and nanospheres, aiming at the development of an injectable delivery system for local and sustained delivery of antibiotics.

EXPERIMENTAL METHODS

Anionic gelatin B micro- and nanospheres of low and high cross-linking densities were prepared using water-in-oil emulsification and two-step desolvation methods², respectively. The morphology of the spheres was characterized by scanning electron microscopy, while their size, size distribution and ζ -potential were determined using dynamic light scattering. Four types of antibiotics of different molecular weight and charge were used in this study (Table 1). 25 μ g of each antibiotic was loaded onto gelatin spheres through diffusional post-loading. The release study was conducted at 37 °C in 1 ml PBS with or without 400 ng/ml collagenase. Release kinetics of moxifloxacin and vancomycin were monitored by high performance liquid chromatography, whereas release kinetics of colistin and gentamicin were determined by liquid chromatography-mass spectrometry and enzyme-linked immunosorbent assay, respectively. Moreover, in order to correlate the release rate of the antibiotics to the degradation rate of gelatin, the bicinchoninic acid assay was used to monitor the degradation rate of gelatin.

Table 1 Molecular mass and charge of gentamicin, moxifloxacin, vancomycin and colistin.

Name	Molecular mass (g/mol)	Charge
Gentamicin	477.6	+
Moxifloxacin	401.4	neutral
Vancomycin	1449.3	neutral
Colistin	1155.4	+

RESULTS AND DISCUSSION

Release kinetics of the antibiotics from gelatin micro- and nanospheres had similar trends. Vancomycin and colistin proceeded without any significant burst. The release of colistin was dependent on the degradation of gelatin, while the release rate of vancomycin did not correlate to the degradation rate of gelatin. Gentamicin and moxifloxacin, however, were released almost completely within 2 days, although charged gentamicin was released slightly slower than neutral moxifloxacin.

Fig. 1 Representative cumulative release of four antibiotics from gelatin B nanospheres with high cross-linking density under enzymatic conditions.

These results seem to indicate that the release of antibiotics from gelatin matrices is influenced most strongly by the molecular weight rather than the charge of antibiotics. Antibiotics of higher molecular mass (colistin and vancomycin) were released in a sustained manner. More specifically, the release rate of charged colistin was controlled by the degradation rate of gelatin, whereas the release kinetics of neutral vancomycin did not correlate with the degradation rate of gelatin, this is most likely due to a lack of electrostatic interactions between vancomycin and gelatin. Antibiotics of lower molecular mass (gentamicin and moxifloxacin) were both released in a burst manner irrespective of the charge of the antibiotics, but the release rate was higher for uncharged moxifloxacin vs. charged gentamicin during the first 2 days, which could be related to the electrostatic interaction between cationic gentamicin and anionic gelatin macromers.

CONCLUSION

Release kinetics of antibiotics from gelatin micro- and nanospheres are strongly dependent on the physicochemical characteristics of the antibiotics. Sustained release was observed for antibiotics of high molecular weight, while antibiotics of low molecular weight were released in a burst manner.

INTRODUCTION

Various studies in the field of tissue engineering prove plasma ability to modify polymeric scaffold surface without altering bulk properties [1-2]. Furthermore, it was demonstrated that cell cultures on plasma modified scaffolds display better proliferation and viability compared to pristine materials [3]. In this work we focus on the use of atmospheric pressure non-thermal plasma for surface modification of electrospun poly(L-lactic acid) (PLLA) non-woven mats [4].

EXPERIMENTAL METHODS

Electrospun mats (30-60 µm thick) have been fabricated by means of an electrospinning apparatus, made in house, composed by a high voltage power supply, a syringe pump, a glass syringe, a stainless-steel blunt-ended needle connected with the power supply electrode, and a rotating cylindrical collector. Modification of scaffold surface characteristics has been carried out exposing the substrate to the plasma region generated by three different non-thermal plasma sources operated at atmospheric pressure: a floating electrode dielectric barrier discharge (FE-DBD), a linear corona discharge (LC) using N₂ as working gas and a DBD roller (DBDR). A high voltage generator capable of producing pulses with a slew rate in the order of some kV/ns has been used. Effects of plasma-treatment on PLLA scaffolds have been evaluated through morphological evaluation, thermo-mechanical analysis and scaffold hydrophilicity measurement. In order to estimate the relative amount of carboxyl functional groups (-COOH) created during plasma treatment, a functionalization with fluorescein isothiocyanate (FITC) have been performed. Mouse embryonic fibroblast cells were cultured on untreated PLLA and treated PLLA surface to investigate the cell morphology.

RESULTS AND DISCUSSION

Morphological characterization attested a damage of the scaffold when treated with the FE-DBD, due to local heating of the substrate, while scaffolds treated with other plasma sources did not show any appreciable morphological alteration. Fluorescence intensity has been measured on both pristine and LC and DBDR treated scaffolds. The fluorescence signal measured for treated sample was 2 to 5 times higher than the value of

the pristine samples; the highest -COOH concentration was registered for the LC treated scaffolds. Moreover, no relevant variation of fluorescence intensity was observed after 48h from the plasma treatment and an hydrophilicity increase was preserved after 72h. Fibroblasts growth and shape-factor have been investigated both on treated and untreated electrospun PLLA scaffolds; while fibroblasts on PLLA resulted small and star-like, those grown on PLLA treated with LC assumed a very elongated shape.

Notably, plasma treatment further exacerbated elongated shape of fibroblast, thus confirming that a surface chemical modification could deeply affect cell biology. In fact, fibroblast shape is a complex phenomenon strictly regulated by transmembrane proteins (like integrins) linking binding domains of the extracellular matrix to the cell cytoskeleton [5], which is highly influenced by cell adhesion and mechanic forces [6]. The increase in carboxyl groups derived from plasma treatment, could be part in re-shaping of fibroblast.

CONCLUSION

Functionalization and biocompatibilization of PLLA electrospun scaffold can be achieved using low temperature atmospheric plasmas. A relevant increase of hydrophilicity and -COOH group concentration at the fiber surface is registered after LC and DBDR plasma treatment without alteration of bulk properties. Furthermore, cell proliferation is promoted on LC modified substrates. compared to pristine scaffolds.

INTRODUCTION

Changes in preclinical drug development are attributing significant importance to *in vitro* and *ex vivo* approaches, as result of financial and ethical considerations [1]. Although Caco-2 cell model represents the gold standard of intestinal drug permeability studies [2], this model do not cover the complexity of interactions between epithelial cells and the overlying lamina propria cells [3]. To reproduce these interactions, a physiologically improved tridimensional cell model seeded on the Transwell® filter was developed. This model comprises intestinal fibroblasts (CCD18-Co) embedded in Matrigel®, Caco-2 (enterocytes-like cells) and HT29-MTX cells (mucus-producing cells) on the apical side of the Transwell®. Raji B cells seeded on the basolateral side, protagonizing the conversion of Caco-2 in M-like cells.

EXPERIMENTAL METHODS

Tridimensional cell culture and TEER measurement

CDD18-Co cells were resuspended on Matrigel®. After gelation at 37°C, Caco-2 and HT29-MTX cell suspension (9:1) was added onto the overlying gel layer. After 14 days, Raji B cells were added on the basolateral side, maintained for 4-6 days. Transepithelial electrical resistance (TEER) was monitored every other day.

Histological sectioning

Samples were fixed with 4% paraformaldehyde and post-fixed with 1% glutaraldehyde. After a graded dehydration in ethanol, membranes were embedded in paraffin. Sections were performed between 5-10µm and stained with haematoxylin and eosin dyes.

Immunofluorescence staining

To identify the different cell in culture, membranes were fixed with 2% paraformaldehyde and permeabilized with 0.2% Triton X-100. Non-specific binding was blocked with PBST containing 10% of FBS. Samples were incubated with mouse anti-human vimentin (1:100, Santa Cruz Biotechnology) and with the secondary antibody goat anti-human AlexaFluor488 (1:1000, Life Technologies) and counterstained with DAPI (1µg/mL).

Permeability transport experiment

After 21 days in culture, permeability studies were carried out during 4h at 37°C with 100µg/mL insulin further quantified by HPLC.

RESULTS AND DISCUSSION

After 21 days, intestinal cells are disposed in a distinct layer supported by lamina propria mainly produced by fibroblasts. Moreover, permeability studies revealed the

efficient transport of insulin, resulting from reversible tight junctions opening.

Figure 1A) Schematic diagram of a 3D coculture of intestinal epithelial cells with fibroblasts incorporated in Matrigel®. **B)** Histological staining showed epithelial cells on the top of fibroblasts embedded in Matrigel®. **C)** Identification of Caco-2 cells and intestinal fibroblasts in coculture labelled by WheatGermAgglutinin (WGA) (C1) and vimentin (C2).

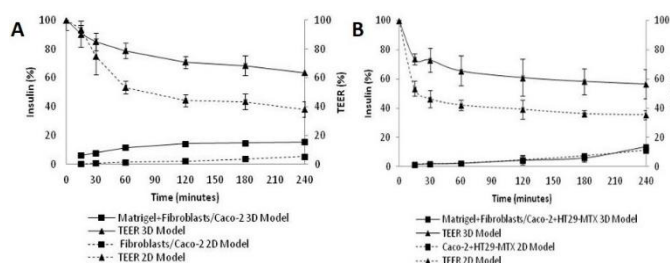

Figure 2A) Cumulative transport of insulin and TEER measurements of insulin across cocultures of Fibroblasts and Caco-2 cells and **B)** cocultures of Fibroblasts, Caco-2 and HT29-MTX cells.

CONCLUSION

Results support the functional character of the 3D model that closely resembles the structure of the native intestinal mucosa.

INTRODUCTION

Infection around dental implants is a relevant health issue since it is not detected until the bone loss induces an implant failure. To avoid this infection it is important to achieve a biological sealing of the implant before bacteria colonize the exposed implant surface¹. In this work, functionalized coatings with RGD peptide² were applied to titanium with either plasma polymerization or silanization³, and compared in terms of its antifouling effect and bacterial and cellular adhesion.

EXPERIMENTAL METHODS

Samples of polished titanium (Ti) grade 2, cleaned with ethanol, acetone and water were activated with argon plasma (0.40mbar, 100W, 5min). Later, they were treated with either: a) low pressure plasma poly(ethylene glycol) polymerization (PEG) from tetraglyme (0.40mbar, 100W, 60min with pulsed mode 20 μ s_{on}, 20ms_{off}), or b) grafting-to titanium of silanized-PEG by dip-coating of PEG-OSiCl₃ (adaptation of the Zhang et al. method³). RGD functionalization was performed by overnight immersion. Coatings were characterized by sessile drop contact angle, FTIR and XPS. Protein adsorption was tested with fluorophore-labelled BSA. Bacterial adhesion assays were done by immersion of the samples in culture medium with bacteria (*Lactobacillus salivarius* (LS) and *Streptococcus sanguinis* (SS)) for 2h followed by seeding and CFU counting. Cell adhesion LDH assays were done with human fibroblasts. For the characterization polished titanium samples were kept as controls.

RESULTS AND DISCUSSION

A more significant decrease was seen in BSA adsorption for the plasma polymerized coatings in contrast to silanized coatings.

Figure 1. Albumin adsorption measured by fluorescence microscopy.

The coatings also present a significant decrease on bacterial adhesion compared to the titanium surfaces. The antifouling character of PEG that is seen in these results can be explained by the inertness of the polymer

backbone and also to its solvated configuration, which has steric repulsion to proteins⁴. The absence of proteins explains the decrease in bacterial adhesion.

Figure 2. Bacterial adhesion to coated samples compared to the titanium control.

Fibroblast adhesion to the coatings is somewhat reduced, but it improves in the functionalized coatings.

Figure 3. Cellular adhesion on the non-functionalized and RGD functionalized coatings.

CONCLUSION

PEG-coated titanium shows an antifouling character and a decreased bacterial adhesion. Cellular adhesion is lower in the coated samples, but it is improved by immobilization of RGD. While both silanized and plasma polymerized PEG show these characteristics, whereas plasma polymerized coatings result into a better antifouling performance and a lower decrease in the cellular adhesion.

INTRODUCTION

The challenge in the development of surrogate extracellular matrices (ECMs) is to design and prepare synthetic materials capable of influencing cell differentiation, proliferation, survival, and migration through both biochemical interactions and mechanical cues. Current efforts in the engineering of synthetic ECMs have focused on "installing" molecular features (peptides, proteins and bio-interactive polymers) within insoluble scaffolds, either by self-assembly or through covalent modifications of polymer or biopolymer networks¹⁻⁵.

Recent studies of engineered synthetic ECMs revealed that molecular features incorporated within insoluble scaffolds play a dual role in cell interaction. The functional moieties act directly on cells while also modifying the hierarchical structural organization and mechanical properties of the resulting material, thus affecting the cellular response indirectly⁶⁻⁸. While the former has been investigated extensively, studies of these structural effects induced by introducing bioactive molecular features are less conclusive. Elucidating the key factors involved in the structure-property relationships of these hydrogels will improve our ability to design and prepare tailor-made scaffolds for a variety of applications.

Here, we present a systematic exploration of the effect of bioactive molecules on the self-assembly of polysaccharide hydrogels and the resulting structures.

EXPERIMENTAL METHODS

Bioactive polysaccharide (hyaluronic acid, chitosan and alginate) hydrogels were prepared by covalently binding a peptide containing the cell adhesion ligand RGD to the polymer chain followed by addition of a gelling agent. In order to study the effect of peptide conjugation on their structural and mechanical properties, the synthesis was conducted with 1:1000 and 1:100 w/w peptide/polymer ratio.

Thorough characterization of the polysaccharides building blocks (both natural and modified) in aqueous solutions and as hydrogels were conducted using small angle X-ray scattering (SAXS), optical tensiometer, zeta potential, and rheology.

RESULTS AND DISCUSSION

The peptide G4RGDS was covalently attached (via EDC chemistry) to the polymer backbone of Hyaluronic acid, alginate and chitosan.

SAXS patterns obtain for all polymer (both natural and modifies in aqueous solution) show conjugation of RDG to HA, alginate and chitosan lead to small yet distinct changes in the scattering pattern i.e. structural differences at nano-scale. Fitting of these scattering curves to a model of a semi-flexible chain form factor combined with a structure factor based on PRISM where the intermolecular interaction is described by a gaussian function⁹ suggest peptide conjugation affects both the polymer chain conformation and the interaction between the chains, regardless of the polysaccharide used. Mechanical testing show peptide conjugation causes differences in the gel's moduli as well.

CONCLUSION

Conjugation of RDG to HA, alginate and chitosan lead to small yet distinct changes in both surface and bulk properties of their aqueous solutions. Preliminary mechanical testing suggests the conformational changes in the solutions are translated to changes in the polymer's young modulus.

Scavenging effect of Trolox released from brushite cements

Gemma Mestres¹, Carlos F Santos¹, Lars Engman², Cecilia Persson¹, Marjam Karlsson Ott¹

¹ Dpt. Engineering Sciences, Uppsala University, Sweden

² Department of Chemistry, BMC, Uppsala University, Sweden

gemma.mestres@angstrom.uu.se

INTRODUCTION

Implantation of a biomaterial in a living tissue causes post-surgical inflammation and may trigger reactions such as the release of pro-inflammatory cytokines, reactive oxygen species (ROS) and destructive enzymes. Antioxidants such as Trolox can be loaded into a biomaterial to cope with inflammation and protect the surrounding tissue during implantation. In this work, Trolox was loaded in calcium phosphate cements, which are commonly used as bone void fillers. The in vivo response to brushite cements has been found to depend on their composition¹. Limiting the initial inflammatory response may be beneficial for some cement formulations, especially when used in conjunction with other implant materials, such as metallic screws.

EXPERIMENTAL METHODS

Brushite cement powder was prepared by mixing 54 wt% β -tricalcium phosphate, 44 wt% monocalcium phosphate and 2 wt% sodium pyrophosphate. Trolox-loaded cement was prepared by adding 0.4 wt% of Trolox to cement powder. The cement paste was prepared by mixing the powder with distilled water at a liquid-to-powder ratio of 0.32 ml/g.

Setting time (Gillmore needles), mechanical properties (universal testing machine) crystalline phases (X-ray diffraction) and morphology (scanning electron microscopy, SEM) of the cements were evaluated. Trolox release was evaluated by immersing 1 cement disc ($\varnothing = 12$ mm, $h = 2$ mm) in 50 ml of phosphate buffered solution (PBS) for 5 days. At regular intervals, 1 ml-aliquots were removed and replaced by 1 ml of PBS. Aliquots were monitored by means of a UV-spectrophotometer. As controls, Trolox (0.08 mg/ml) and cement alone were included. Data were corrected for dilution caused by sampling and Trolox degradation, and finally modelled through Korsmeyer-Peppas equation².

The capacity of Trolox released by the cement to scavenge ROS produced by activated macrophages (Raw 264.7) was evaluated by a luminol amplified chemiluminescence assay³. Aliquots from the drug release study, including Trolox and cement alone, were added to a well plate in contact with a luminol solution. Luminescence was monitored for 60 min at 37°C.

RESULTS AND DISCUSSION

The initial and final setting times of the brushite cement were around 8.5 and 11 min, respectively. After 7 days in 100% humidity, set cements were mainly composed of brushite, constituted by rhomboedric crystals precipitated in random directions. The compressive strength was approximately 25 MPa. Trolox did not

significantly modify any of the previously described physical properties.

The drug release study showed a burst release from brushite cement for the first day, followed by a sustained release between 1 and 3 days after which the concentration of Trolox remained constant until day 5. Nearly 64% of Trolox was released from the cement, the release pattern fitting with a non-Fickian transport. While the extracts from the cement alone did not scavenge ROS, aliquots from Trolox-loaded cement were able to do so, in a similar manner as aliquots containing “pure” (non loaded) Trolox (Figure 1). Moreover, as time passed and more Trolox was released the scavenging effect became more pronounced.

Figure 1. Luminescence measured over time for aliquots of Trolox (0.08 mg/ml), cement alone, and Trolox-loaded cement (22h-time point).

CONCLUSION

With the aim to create a calcium phosphate cement able to limit the acute inflammatory response, Trolox was added into a brushite cement. The presence of Trolox did not modify properties such as setting time, compressive strength or morphology of the cements. Trolox was released for 3 days through a non-Fickian transport. Trolox released from cement was able to scavenge reactive oxygen species produced by macrophages in a dose-dependent manner. The doped calcium phosphate cement is expected to partially protect the surrounding tissues from acute inflammation.

Thermomechanical properties and bioactivity of silicone hybrids containing inorganic biomedical fillers

I.-G. Athanasoulia¹, S.P. Vasilakos¹, P.A. Tarantili¹, Tr. Papadopoulos^{2*}

¹Chemical Engin. School/Polymer Technology lab., National Technical Univ. of Athens, Greece

^{2*}Dental School/Biomaterials lab., University of Athens, Greece, trpapad@dent.uoa.gr

INTRODUCTION

Silicone rubbers (SR) present good biocompatibility, physiological inertness and easy handling, that make them recommended materials in prosthetic applications. However, in some cases, they do not organically unite with tissues, which leads to inflammation and foreign-body reaction after implantation. In order to improve the mechanical, physicochemical and biological properties of silicones, bioactive inorganic particles can be used as modifying additives. Hybrids with hydroxyapatite¹, β -Tricalcium phosphate (β -TCP)², CaO-SiO_2 ³, $\text{CaO-SiO}_2\text{-TiO}_2$ ⁴, were investigated for this purpose. In this work, silica nanoparticles in comparison with bioactive glass were studied for the modification of silanol terminated polydimethyl siloxane (PDMS).

EXPERIMENTAL METHODS

Silanol terminated PDMS, grade DMS-S31 (Gelest Inc.) of molecular weight 26,000 g/mol, was the silicone base elastomer used in this work. The vulcanization reaction system consisted of 10 phr tetrapropoxysilane as a cross-linker and 0.1 phr dibutyl tin dilaurate as catalyst (Sigma Aldrich). Composites were prepared by the sonication technique, using silica nanoparticles (Aerosil R972, Evonic Degussa GmbH) and bioactive glass (Bonalive) particles. The composites were characterized by differential scanning calorimetry (DSC), dynamic mechanical analysis (DMA). In addition, their tensile and tear properties were also tested. An “*in-vitro*” assay of bioactivity was carried out by soaking PDMS hybrids in Simulated Body Fluid⁵ (SBF) at pH 7.4 for 7, 21 and 40 days. The formation of hydroxyapatite was evaluated by FTIR-ATR spectroscopy and SEM/EDAX analysis.

RESULTS AND DISCUSSION

Silica nanoparticles decrease the temperatures of all the investigated transitions (T_g , T_c , T_m) as well as the enthalpies of “cold” crystallization and melting of the elastomer. The addition of bioactive glass into the PDMS matrix does not have any obvious effect on the T_g , T_c and T_m of the elastomer. However, significant decrease was observed in ΔH_c and ΔH_m of PDMS.

Regarding the investigated mechanical properties, from Table 1 it is obvious that the tensile and tear strength of polysiloxane is improved by the incorporation of the examined types of inorganic particles. However, the modulus of elasticity remains unaffected in the case of PDMS specimens reinforced with bioactive glass.

It has been reported that materials which form bonelike apatite on their surface in SBF can form the apatite even in the living body and bond to living bone through the apatite layer⁵.

Sample	Tensile strength (MPa)	Modulus (MPa)	Tear strength (Nt/mm)
PDMS	0.32	1.27	0.114
Aer R972/PDMS	0.63	1.48	0.122
BG/PDMS	0.70	1.27	0.147

Table 1 Tensile and tear test results of 5 phr loaded silica (Aerosil R972) and bioactive glass/PDMS composites.

The evaluation of hydroxyapatite formation on the surface of PDMS hybrid systems was performed by SEM and EDAX analysis. After 21 days and especially after 40 days of immersion in SBF, a large number of microparticles were detected on the surface of all the examined specimens. Using the EDAX technique, the percentage weight of Ca and P and then the molar ratio of Ca/P were calculated (Table 2). Ca and P are present at low percentage up to 21 days and their presence become significant after 40 days of immersion. These results are in agreement with those of FTIR analysis. Within this period of immersion, the Ca/P ratio is close to 1.67, which corresponds to hydroxyapatite. Deviations from this value were attributed to the formation of some defects during apatite growth.

	Ca	P	Ca/P	Ca	P	Ca/P
D	5 phr Aer R972/PDMS			5 phr BG/PDMS		
0	0.12	0.10	0.93	0.2	0.22	0.70
7	0.16	0.22	0.56	0.23	0.40	0.40
21	0.24	0.72	0.26	7.14	4.56	1.23
40	29.87	14.52	1.59	14.12	8.35	1.31

Table 2 The quantitative results using EDAX analysis on the examined PDMS composites versus immersion time in SBF.

CONCLUSION

Bioactive glass is a new alternative for the modification of biomedical prosthetic silicone elastomers, since it clearly enhances biocompatibility of polysiloxane matrix, despite the fact that it does not significantly improves its mechanical performance.

Kartogenin Conjugated Chitosan-Nano/Microparticles for the Intra-Articular Osteoarthritis Treatment

Mi Lan Kang, Ji Yun Ko, Ji Eun Kim, Gun Il Im*

*Department of Orthopedics, Dongguk University Ilsan Hospital, Korea, gunil@duih.org

INTRODUCTION

Recently, a study has been demonstrated that kartogenin (KGN) can induce chondrogenesis of mesenchymal stem cells (MSCs)¹. Intra-articular (IA) drug delivery is very useful in the treatment of osteoarthritis (OA), the most common chronic joint affliction. The conjugation of biodegradable polymers and small molecular weight drugs is an efficient approach to improve therapeutic properties. In this study, kartogenin conjugated chitosan (CS) nanoparticles (NPs) and microparticles (MPs), new polymer-drugs conjugates, were synthesized, characterized and investigated as IA drug delivery systems for regeneration of osteoarthritic joint.

EXPERIMENTAL METHODS

Bioconjugates of KGN and CS (low molecular weight CS (LMWCS) or medium molecular weight CS (MMWCS)) were synthesized by ethyl (dimethylaminopropyl) carbodiimide (EDC)/ N-Hydroxysuccinimide (NHS) catalysis. NPs and MPs were made by ionic gelation method with tripolyphosphate (TTP) using the conjugates of LMWCS-KGN or MMWCS-KGN, respectively. The conjugation of KGN and CS were confirmed by FT-IR and ¹H-NMR. The particles were characterized by DLS and FE-SEM. The amounts of KGN released from NPs or MPs in vitro were determined by HPLC. In vitro activities to induction of chondrogenesis by LMWCS-KGN NPs or MMWCS-MPs were evaluated in pellet culture of MSCs. The chondrogenesis was assessed by real-time PCR and Western blotting on markers such as collagenase type 2 (COL2) and aggrecan (AGC). The retention of fluorescent-labelled LMWCS-KGN NPs or MMWCS-KGN MPs in the joint of OA rats was carried out using the IVIS spectrum.

RESULTS AND DISCUSSION

Because CS has an amine group in its C2 position, it can be reacted with carboxylic group-containing KGN. The degree of KGN conjugated with CS estimated by ¹H-NMR was up to 80 mol%. Average sizes of LMWCS-KGN NPs and MMWCS-KGN MPs

measured by DLS were 150±39nm and 1800±547nm, respectively. The size of particles was not changed after two weeks due to the hydrophobic nature and small molecular weight of KGN. The release profiles showed sustained release of KGN from the particles. The amount of KGN released from LMWCS-KGN NPs was less than 30% of total conjugated KGN with CS for 6 weeks. The released KGN from the particles were induced more effective chondrogenesis than soluble KGN in MSCs. The LMWCS-KGN NPs and MMWCS-MPs were remained in the OA joint up to 3 weeks. Therefore, long-term drug exposure could achieve in the OA joint.

CONCLUSION

The conjugation of amine group of CS and carboxylic group of KGN was successfully carried out with EDC/NHS catalysis. The hydrophobic KGN could reside inside of the CS-KGN conjugated particles during ionic gelation with TPP. In vitro release studies demonstrated that the release of KGN from CS-KGN particles was delayed by the conjugation of KGN with CS. Due to the localized nature of the disease, IA drug injection is an attractive treatment approach for OA. However, the potential benefits of IA therapy for OA are not achieved using currently available medications and delivery vehicles due to the rapid clearance of therapeutic substances from the synovial space. In this study, the designed particles showed long retention time up to 3 weeks. In conclusion, CS-KGN conjugated particles have considerable potential for creating a sustained release KGN delivery system and providing long-term exposure of KGN in OA joint.

INTRODUCTION: Boron (B) is an essential element utilized both in the natural environment and in the manufacturing of several commodities, including (but not limited to) glass & ceramics¹. The potential of B glasses as degradable systems in biomedical applications is of significant importance². B's popularity has grown due to its bioactivity, stimulating effects on bone formation, antimicrobial potentials for infection control & also, as a local drug delivery device³. Various B networks have shown promise, however if these materials are to be utilized to their full potential, greater control over the degradation rate is required. Previous reports have indicated that additions of up to 10mol% lanthanum (La) in a 70mol% B glass are expected to cause network stabilization⁴. Within this study the composition-property relationship of each La-B glass composition was evaluated.

EXPERIMENTAL METHODS: Six glass compositions (Table 1) were melt-quenched ground to a particle size of 45-150 μ m. Property analysis was then completed on each composition. Glass transition temperature (T_g) was determined by means of Differential Scanning Calorimetry (DSC). Volume and density measurements were obtained by a helium pycnometer. B³⁺, Sr²⁺, Na⁺ & La³⁺ ion release profiles associated with each composition was determined by ICP-OES for up to 30 day incubation periods.

Table 1: Mole fraction compositions of La-B glass compositions.

Glass Designation	B2O3	SrCO3	Na2CO3	La2O3
B100	0.7	0.2	0.1	0
LB100	0.7	0.2	0.8	0.2
LB101	0.7	0.2	0.6	0.4
LB102	0.7	0.2	0.4	0.6
LB103	0.7	0.2	0.2	0.8
LB104	0.7	0.2	0	1

RESULTS AND DISCUSSION

Figure 1: T_g for each glass composition (based on La₂O₃ mol. Fraction).

As illustrated in Fig 1 and 2, the 0-10mol% increase in La₂O₃ content had a direct effect on T_g and density, with linear increases from 553-656°C and 2.71-3.53g/cm³, respectively.

Figure 2: Density (g/cm³) for each composition (based on La₂O₃ mol. Fraction)

Figure 3: B³⁺ & Na⁺ ion release (30 day release) as a function of glass composition (La₂O₃ mol. Fraction).

B atoms can coordinate with both 3 and 4 oxygen (O₂) atoms forming triangular or tetrahedral structural units. These combine to form intermediate structural units which ultimately assist in stabilization. Fig. 3 indicated that, B³⁺ & Na⁺ ion release was directly affected by compositional variations. La³⁺ ion release remained constant at 200ppb irrespective of loading while Sr²⁺ release was affected but not in a linear fashion. These results are consistent with what was expected, that La₂O₃ incorporation would cause a modulation of network outputs and an increase in network connectivity and stabilization.

CONCLUSION: B containing glass networks are becoming increasingly important for a range of biomedical applications. Such networks have illustrated potential for bone regeneration & as *in situ* drug delivery devices, however in order to capitalize on the complete utility of these materials, stabilization & control over degradation is required. This data clearly illustrates the presence of a composition-property relationship, as up to 10mol% of La₂O₃ incorporation modulated all investigated glass properties in a linear fashion, thus indicating an increase in network connectivity of the B₂O₃ network.

Osteogenic Differentiation of AdMSCs on 17 β -Estradiol Releasing Chitosan-Hydroxyapatite Scaffolds

Gülseren Irmak¹, T.Tolga Demirtaş¹, Damla Altındal², Mert Çalış³, Menemşe Gümüşderelioğlu^{1,2*}

¹Bioengineering Dept., Hacettepe University, Turkey

^{2*}Chemical Engineering Dept., ³Plastic Reconstructive & Aesthetic Surgery Dept., Hacettepe University, Turkey, gulseren.irmak@gmail.com

INTRODUCTION

Estrogen, substantially participates in the regulation of bone metabolism by inhibiting bone resorption and increasing bone formation¹. In this study, we decided to develop a novel effective 17 β -estradiol (E2) releasing system which consists of chitosan (CH)-hydroxyapatite (HA) scaffold and PLGA nanoparticles to promote osteogenic differentiation of adipose tissue derived rat mesenchymal stem cells (AdMSCs) for bone tissue regeneration.

EXPERIMENTAL METHODS

E2 loaded nanoparticles (Np) were prepared by using emulsion-diffusion-evaporation method. The encapsulation efficiency of E2 into the PLGA nanoparticles was determined by HPLC (Dionex Ultimate 3000, USA). CH-HA scaffolds were prepared according to the combined method of microwave irradiation and gas foaming, previously described by our group². Nanoparticles in aqueous phase were loaded into CH-HA scaffolds by two ways; i) stirring during scaffold manufacturing, ii) embedding after scaffold manufacturing. The morphology of scaffolds was investigated by SEM. Release kinetics of E2 was investigated from PLGA nanoparticle loaded scaffolds. *In-vitro* release studies were carried out in a shaking bath at 37°C and 70 rpm. E2 concentration in the release medium was determined using HPLC at 280 nm. Cell viability of AdMSCs on CH-HA scaffolds was analysed by using MTT assay. The morphology and attachment of AdMSCs onto the scaffolds were observed by SEM. Osteogenic differentiation of AdMSC's cultured on CH-HA scaffolds in the presence of E2 were determined by ALP analysis and RT-PCR. All data were expressed as mean \pm standard deviations of representative of three similar experiments carried out in triplicate.

RESULTS AND DISCUSSION

According to the SEM and TEM photographs of E2 loaded PLGA nanoparticles (approx. 240 nm), they have spherical morphology and narrow size distribution. Encapsulation efficiency for 65:35 PLGA copolymer was determined as 54 %. SEM photographs of PLGA loaded CH-HA showed that, nanoparticles consisting of E2 were successfully loaded and homogenously distributed through the scaffolds.

Release of E2 from CH-HA scaffolds that was containing PLGA nanoparticles loaded by embedding has continued in a controlled manner and 100% of the encapsulated E2 was released during 55 days. However, 92 % of E2 was released during 135 days from the scaffolds loaded with nanoparticles during scaffold fabrication.

Figure 1: *In-vitro* release profiles of E2 from PLGA nanoparticles loaded scaffolds; a) loaded by embedding (CH-HA-Np), b) loaded during manufacturing by stirring (CH-HA+Np).

The results obtained from *in-vitro* culture of AdMSCs suggest that cells established good contacts with scaffolds and also with each other's, proliferated also changed their fusiform morphology to the cubical shape.

Figure 2: SEM photographs of AdMSC's growing on CH-HA scaffolds at the 14th day of culture: CH-HA-Np scaffold: a) 500X, b) 5,000X, c) 15,000X.

For all groups, ALP activities increased rapidly during 2 weeks, however, cells cultured on the CH-HA-Np scaffolds showed significantly highest ALP activity. According to RT-PCR result, OCN expression on that scaffolds that containing nanoparticles were observed at the 7th days of culture and on the 21st day were relatively higher value than that of CH-HA scaffolds, respectively.

We concluded that, scaffolds that containing nanoparticles were significantly enhanced matrix mineralization and osteogenic differentiation of AdMSCs by providing the controlled release of E2.

CONCLUSION

In conclusion, the 3D system carrying and releasing E2 is a novel and promising vehicle for bone tissue engineering *in vivo*.

Understanding the Physiochemical Interactions between Denture Adhesives and the aqueous phase

S. Gill¹, B.J Tighe¹, N. Roohpour², C. Jeffrey²

¹Biomaterials Research Unit, School of Engineering and Applied Science, Aston University, UK

²GSK Consumer Healthcare, St Georges Ave, Weybridge, UK

gills10@aston.ac.uk

INTRODUCTION

Denture adhesives can provide many benefits to denture wearers, in particular enhancing comfort, retention, chewing ability and increasing confidence¹. Most formulation strategies aimed towards this application function to take advantage of the humid environment of the oral cavity, which effectively hydrates the adhesive, producing a mucilaginous layer with high tack and adherent properties. The primary objective of this study is to investigate the physiochemical interactions between different aqueous phases and the hydrophilic polymer groups within the adhesives in order to better understand the adhesion phenomenon involved. Two commonly used hydrophilic polymers in this application are carboxymethylcellulose (CMC) and mixed partial salts of methyl vinyl ether – maleic anhydride copolymer (MVE/MA).

EXPERIMENTAL METHODS

Most commercial denture adhesives involve the in vivo hydration of the polymer system. It was therefore important to investigate the effect of the nature of the aqueous phase on the adhesion mechanism. This was achieved by studying the addition of a range of aqueous phases at progressive ratios (10-50%) to a commercial product, Poligrip Ultra® (Stafford Miller, Ireland), A1. The aqueous phases exemplified here are DI water and electrolyte solutions based on CaCl₂ and NaCl. Adhesion strength (post-mixing) was studied using an adhesive lap joint shear test between Melinex (polyethylene terephthalate) strips. The data is augmented by water binding studies in which the freezable water content and primary water melting point corresponding to each sample was determined. Three adhesion replicates were taken at each point with a range of +/- 15% and six cycles performed in the DSC studies.

RESULTS AND DISCUSSION

Table 1 summarises the results of adhesion strength and water binding properties for A1 when mixed with 10, 30 and 50% aqueous phase. The quoted adhesion strength values were quoted at approximately 30 seconds post-mixing.

The presence of electrolytes and consequent interaction with the carboxyl groups in the adhesive system is found, as expected, to cause differences to the overall water binding properties of the adhesive. The electrolyte rich solutions showed a distinctly different effect on freezable water content than DI water and also lower primary melting points due to the colligative properties of the dissolved electrolytes.

Aqueous phase	Aqueous phase Content (%)	Adhesion strength (kPa)	Freezing water content (%)	Water Tm (°C)
DI water	10	3	0	-
	30	6.1	6.8	-3.8
	50	6.7	27.3	2.5
NaCl (0.9M)	10	7.2	0	-
	30	15.4	4.3	-8
	50	10.3	11.8	-2.9
CaCl ₂ (0.9M)	10	6.2	0	-
	30	9.8	3.4	-7.3
	50	10.3	15.6	-2.1

Table 1: Effect of aqueous phase on adhesion strength, water binding and primary water melting point.

These results show that the presence of electrolytes within the adhesive system has an effect on water structuring; a phenomenon that appears to be linked – although not in a simple and direct manner - to the adhesion capability of the product, A1.

Interestingly at 10% incorporation of all aqueous phases, no freezable water peaks are detected indicating that all the water is strongly associated with the polymer system. Increasing ratios of aqueous phase give increased levels of freezing water, higher Tm values, and also higher levels of adhesion than at the 10% level of aqueous phase. The standard deviations on the adhesion strength values show that the electrolyte-containing aqueous phases produce higher adhesion values at the same levels of aqueous phase incorporation.

CONCLUSION

The lap shear joint test method and DSC studies used provide useful initial insight into the effects of electrolytes within the adhesive system on adhesion strength at a moderate surface energy surface analogous to that of a conventional denture. The DSC results suggest that this is related to effects of aqueous phase constituents on the water binding properties of the system. This initial work forms the basis for more detailed studies of the components of saliva - a complex biological fluid - and adhesion behaviour at oral tissue interfaces.

³Deprt of Mater.Sci.Eng, Institute of Biomaterials and Biomedical Engineering, University of Toronto, Canada.

INTRODUCTION

Orthopaedic biomaterials represent a crucial alternative to regenerate or replace bone tissue when it is severely damaged by diseases such as arthritis or by injury. However, failure of bone implant interface (lack of Osseointegration) leading to implants loosening remains the main drawback. Accordingly, the objective of this project is to enhance the osseointegration of orthopaedic implants since their long-term performance is restricted to 10-15 years with the currently available materials¹. The original approach of this project consists in the biochemical surface modification of biomaterials by grafting specific peptides while controlling their spatial distribution at the micrometer scale. Briefly, two mimetic peptides (RGD, BMP-2) were grafted on the surface of a model biomaterial. They induce respectively the adhesion and the differentiation of Mesenchymal Stem Cells (MSCs) into mature osteoblasts able to synthesize a mineralized extra cellular matrix (ECM)². Furthermore, our strategy is to graft these two mimetic peptides as micropatterns on the surface to create an appropriate distribution for osteoblastic differentiation³.

EXPERIMENTAL METHODS

Aminated borosilicate glass, used as biomaterial model, was used to conjugate RGD and BMP-2 mimetic peptides through SMPB crosslinker. These two peptides were grafted as micropatterns by using the maskless photolithography technique. The designed micropatterns corresponded to square, rectangle or triangle with a constant surface area of 50 μm^2 . The surface chemistry and topography of the material were assessed by using X-ray Photoelectron Spectroscopy (XPS) and Atomic Force Microscopy (AFM). Micropattern visualization was achieved using fluorescent peptides RGD-TAMRA and BMP-2-FITC visible under fluorescent microscopy.

RESULTS AND DISCUSSION

XPS analyses (Table 1) evidenced the grafting efficiency after each step of the peptide immobilization procedure. Even though the initial SMPB grafting is not evident, with only a slight decrease of the nitrogen surface concentration from 3.8 % on the aminated glass

to 3.2 % on the SMPB-grafted sample, surface immobilization of both peptides is confirmed by the increase in the nitrogen surface concentration coming from the peptide groups.

Table 1: Surface composition determined by XPS at grazing angle.

	% C	% O	% N	% Si
NH ₂ -glass	42.1	40.9	3.8	13.9
SMPB grafted	40.2	42.3	3.2	14.3
RGD grafted	46.8	34.5	5.9	12.7
BMP2 grafted	39.1	41.8	5.4	13.2

The peptides grafting were also confirmed by fluorescence microscopy as the use of fluorescent peptides allowed to visualize the different micropatterns (Fig. 1). Indeed, the spatial distribution of the two peptides designed as square, rectangular or triangular micropatterns was clearly evidenced and precisely defined (Fig. 1).

CONCLUSION

The strategy of designing specific peptides micropatterns onto orthopaedic material surfaces seems to be promising for osseointegration enhancement. Our preliminary surface characterization results evidenced efficient peptides grafting as well defined micropatterns. Future works will assess the effect of peptide micropatterning on the behaviour and fate of MSCs through cell proliferation, adhesion, and differentiation assays, as well as ECM mineralization experiments.

³Department of materials science and engineering, University of Sheffield

⁴Scapa Healthcare, Manchester, UK

INTRODUCTION

There are many types of cutaneous wounds with varying causes. They can be classified as acute or ^{1,2}. One of the major differences is that acute wounds proceed through an orderly and timely process of repair, whilst chronic wounds do not ¹. In the US alone it has been estimated that each year over 6 million people develop a wound that becomes chronic ⁵. It is estimated that caring for chronic wounds costs the US healthcare system tens of billions, while they cost the UK National Health Service about 1 billion pounds per year ⁶. The aim of this project is to enhance currently used silicone contact layers in wound dressings. Physical properties and permeability will be enhanced via integration of nanostructured silicone n-vinylpyrrolidone copolymer 'micelles' as well as the incorporation of antimicrobial agents that will be delivered through the same means.

EXPERIMENTAL METHODS

Preparation of PDMS macromonomer

Macro-monomers were prepared under a nitrogen atmosphere using living anionic polymerization. For example, a solution of hexamethylcyclotrisiloxane (0.03 mol, 7g) and lithium isopropoxide (3mol%, 0.4mL 2M solution in THF) in THF (10mL) was injected into a pre-sealed glass tube. The solution was stirred at room temperature for 3hrs and then allyl chloroformate (3mol%) was injected into the solution. The reaction mixture was ultrasonicated for 20 min and then stirred at room temperature for 24hrs. The solvent was evaporated by rotary evaporation and the liquid oligomer was dissolved in chloroform. The solution was washed with water and the organic layer collected. Chloroform was removed by rotary evaporation.

Preparation of PDMS - NVP copolymers

N-vinylpyrrolidone, PDMS functionalised macro-monomer, ACVA and tetrahydrofuran were mixed together in the desired ratio. The resulting solution was pipetted into a 100ml ampule and placed on a high vacuum line. The solution was frozen with liquid nitrogen and vacuum was applied (3×10^{-3} mBar) and then closed. The ampule was defrosted with tepid water, once thawed this process repeated until the ampule was completely degassed. The ampule was sealed using gas/oxygen blowtorch and placed in a water bath at 60°C for 24hrs. The ampule was opened by cracking and the product was removed via pipetting. The solvent was evaporated by rotary evaporation under reduced pressure and the product was precipitated and repeatedly washed with diethyl ether. This was removed by vacuum filtration obtaining a white powder.

Preparation of Silicone - Copolymer contact layer

The silicone matrix components were provided by Scappa healthcare™ and were prepared by adding

'component A' to 'component B' in an equal 1:1 ratio.

Copolymers were dissolved in the minimum volume of hexamethyldisiloxane before being combined with Rhodamine B or antimicrobial agent. This solution was then mixed with 'component A' before being mixed with an equal amount of 'component B'. The membrane were drawn down using 200µm K-bars onto release paper and set in an oven at 60°C for five minutes.

RESULTS AND DISCUSSION

Three membranes were chosen for SEM which where the 0, 0.1 and 10% copolymer, shown from left to right below in figure 1.

Figure 1 shows that as you increase the copolymer content from zero to 10% the surface morphology changes from being smooth to more rough with increasing populations of 'pimples' appearing. Z-stacked images using confocal microscopy were then taken to produce a projected image side on, shown below in figure 2 of a silicone matrix membrane containing 0.1% copolymer and Rhodamine B mix.

It is clear to see that Rhodamine B is encapsulated within the membrane suggesting that the hydrophilic molecule is being held within copolymer micelles.

CONCLUSION

A hydrophilic fluorescent agent (Rhodamine B) has successfully been incorporated into a hydrophobic cross linked silicone matrix and release has been monitored using UV-VIS spectroscopy over a two day period.

Development of new approaches to fabricate scaffolds for deep zone engineered articular cartilage

Anne Canning¹, Paul Roach¹, Ying Yang¹, James Richardson²

¹Institute of Science and technology, University of Keele, United Kingdom

²The Robert Jones and Agnes Hunt Orthopaedic Hospital, Oswestry, United Kingdom

INTRODUCTION

Cartilage has defined zone architecture structure, changing through the thickness¹. The deep zone bridges cartilage and bone with unique vertical channels. Fabricating a scaffold which replicates the zonal architecture has an advantage to produce anatomically and functionally mimicking cartilage tissue². Here we aim to engineer deep zone cartilage by growing bone cells in a channelled polymer gel also presenting partly embedded biodegradable glass fibres³.

EXPERIMENTAL METHODS

The scaffold mould was designed on AutoCAD2012 software and printed on a 3D Makerbot printer. MG63 cells were seeded on 8 samples of poly (NIPAM) gels cast on the mould.

Cell attachment, migration and proliferation was monitored via H&E and TRITC-Phalloidin staining at 7, 14, 21 and 28 days.

The degradation and diffusion of minerals in the gel of Phosphate fibres was measured using Raman microscopy up to 2 weeks in vitro.

RESULTS AND DISCUSSION

An inverse template structure was produced using 3D printing and metal wires, allowing successful casting of a multi-channelled array in poly (NIPAM). Aligned vertical hollow channels of diameter 325 – 395 μm were produced within the gel, also presenting micro-porosity.

Figure 1) a-c AutoCAD design of engineered construct. b-blue cylinders represent pins threaded from top to base, c-dark blue cylinders represent embedded glass fibres, light blue represent removable pins. d-image of 3D printed mould threaded with metal pins.

(figure 1). MG63 cells were seeded on the gels and showed some adhesion and migration within the upper portion of the channels, moving toward the columnar distribution of cells found in deep zonal cartilage (figure 2).

Figure 2) Confocal images of TRITC-Phalloidin stained cells at 28days (c-d). b,d image of fluorescence superimposed on bright field image of channels.

Phosphate glass fibres were thread into the mould and polymer cast to fabricate gels embedded with mineral rich glass fibres with a degradation rate of 28 days in vitro. The degradation and mineral diffusion was successfully measured using Raman microscopy (figure 3).

Figure 3): Principal component analysis at 2800-3100 and 1050-1150 cm^{-1} of embedded fibre in poly (NIPAM) incubated at 37 $^{\circ}\text{C}$ in buffer at PH7.4 at 0 days (a), 3 days (b), 7 days (c), 14 days (d).

CONCLUSION

These results show a promising prototype to be further investigated to form structures with an architecture that resembles that found in osteochondral defects.

Adhesives and their role in the reduction of HCAI, skin and wound infections

Steven L Percival^{1,2,3}, Rebecca Booth³ and Sean Kelly³

¹Institute of Ageing and Chronic Disease, University of Liverpool, Liverpool, UK

²Surface Science Research Centre, University of Liverpool, Liverpool, UK

³Scapa Healthcare, Manchester, UK, email: Steven.Percival@scapa.com

INTRODUCTION

The increasing incidence of healthcare associated infections (HCAI) together with concerns surrounding the appropriate use of antibiotic agents means that there is a significant need for new approaches for both the prevention and treatment of wound infections¹. Acute wounds such as surgical wounds are susceptible to infection and therefore prevention of microbial colonisation and biofilm development is of paramount importance².

In this study we examined the use of a adhesives commonly used to attach biomaterials and medical devices to the body and investigated novel ways to deliver antimicrobial agents directly to the skin/wound interface.

EXPERIMENTAL METHODS

- Three antimicrobial agents (chlorhexidine, benzylkonium chloride and silver) were combined with medical grade adhesives at concentrations of 3-20% and coated on to a polyurethane (PU) backing film at different thicknesses.
- A customised zone of inhibition (ZOI) assay, log reduction assays, antimicrobial efficacy tests and anti-biofilm tests were performed using common clinical bacteria, *Staphylococcus aureus* and *Pseudomonas aeruginosa*.
- 3x3cm² pieces of sterilised adhesive films were placed on a surface inoculated agar plate and incubated for 24 hours. Areas beneath the material were observed for bacterial growth and then plates re-incubated to verify a bactericidal or bacteriostatic effect.
- 55mm diameter circles of sterilised PU film were incubated in 5mls of simulated wound fluid. 100µl of fluid was removed at 4, 24, 48, 72 and 96 hour time points and serially diluted provide log reduction data.
- Confocal laser microscopy was employed to evaluate real time killing of all antimicrobial adhesives.

RESULTS AND DISCUSSION

Overall, all 3 antimicrobial adhesives evaluated demonstrated an antimicrobial effect using the customised ZOI test when compared to the negative control. In the fluid log reduction test model, colony counts from all 3 adhesives also demonstrated a reduction in planktonic bacterial load throughout the time course indicating that the antimicrobials were eluted from the adhesive materials at sufficient levels to cause microbial death.

- Antimicrobial A caused the greatest log reduction over the complete 96 hour time course (8 log against *S. aureus*).
- Antimicrobial C caused the greatest log reduction in bacteria over the full time course. A 5 log reduction was seen with *S. aureus* and a 6 log reduction with *P. aeruginosa*.
- Antimicrobial B had the quickest action against *S. aureus* and demonstrated a 2 log reduction after 4 hours.

CONCLUSION

This proof of concept study provides evidence that adhesives can be used as a vehicle to deliver efficacious levels of actives and antimicrobials directly to the wound interface. These antimicrobial adhesives have potential applications throughout the field of healthcare including biomaterials, wound dressings, incision drapes, internal sealants and device fixation materials.

The utilisation of poloxamer as a model to study the complexity of biofilms and antimicrobial efficacy in biomaterials

Steven L Percival^{1,2,3*}, Rebecca Booth³ and Sean Kelly³

¹Institute of Ageing and Chronic Disease, University of Liverpool, Liverpool, UK

²Surface Science Research Centre, University of Liverpool, Liverpool, UK

³Scapa Healthcare, Manchester, UK

*email: Steven.Percival@scapa.com

INTRODUCTION

Microorganisms found within and on the human body exist in two phenotypic states, the planktonic state, and the attached or sessile/biofilm state. The biofilm model has been highlighted, and widely acknowledged, as an explanation for the myriad of features observed in the non-healing of skin and chronic wounds. Consequently clinicians and researchers consider the biofilm state to be responsible for recalcitrance and the main reason that an infection occurs. Poloxamer is a non-toxic, di-block copolymer, which has previously been investigated for its potential to easily and reproducibly model the biofilm state *in vitro* (Gilbert *et al* 1998; Clutterbuck *et al* 2007; Percival *et al* 2007).

Here we investigate the growth and behaviour of common skin and wound bacteria, in a scaffold of Tryptone Soya Agar (TSA; 'quasi' biofilm) compared to 30% Poloxamer in Tryptone Soya Broth (Poloxamer; true biofilm). The aim of this investigation was to compare the architecture and biofilm development of these skin and wound isolates in order to gain greater knowledge for biofilm control and reduction in microbial dissemination into surrounding tissue.

EXPERIMENTAL METHODS

- 1 x 10⁸ cfu/ml of *S. aureus* or *P. aeruginosa* in Maximum Recovery Diluent (MRD) were inoculated into Poloxamer or molten TSA and 100µl pipetted onto the surface of glass microscope slides.
- Microscope slides were incubated in a moist environment at 35°C. At 24, 48 and 72 hours images were taken using a light and confocal microscope. Macroscopic images were also taken at 48 hours using a stereoscope microscope.
- Viable counts were performed on samples of inoculated agar and poloxamer. Images and counts of bacterial growth were obtained after 4, 24, 48 and 72 hours incubation at 35°C.

RESULTS AND DISCUSSION

- Macroscopic visualisation of *S. aureus* and *P. aeruginosa* grown in agar and poloxamer showed differences in microcolony formation that reflected the presence of high cell densities present in both substrates.
- Microscopic visualisation of inoculated poloxamer and agar demonstrated differences in bacterial microcolony formation after 24 hours incubation and continued throughout the time course.

- The inoculated agar samples showed closely packed spherical individual colonies of cells which increased in density over 72 hours.
- The poloxamer hydrogel samples demonstrated the formation of smaller, less tightly packed microcolonies that were more irregularly shaped. There was also evidence of microcolonies linking together. The growth of these colonies appeared to be slower when compared to agar.
- Overall, viable counts demonstrated that over time the number of *S. aureus* and *P. aeruginosa* organisms initially increased in both agar and poloxamer. Poloxamer biofilms demonstrated a 'steady state' of growth whereas numbers of viable organisms in agar showed a relatively quick increase followed by a decrease after 24 hours.

CONCLUSION

The use of poloxamer hydrogels to model biofilms was found to be a rapid and simple method to study biofilm development and architecture in relation to biomaterials and medical devices. Poloxamer recreates an environment, which mimics biofilm conditions. This investigation gathered qualitative and quantitative data to demonstrate the differences of microcolony formation and proliferation rates in 2 different bacteria, which are commonly isolated from skin, acute, and chronic, non-healing wounds. Future studies will look to examine the effects of various existing and novel antimicrobial and antibiofilm treatments that could be used to treat biomaterial related infections.

The use of the MBEC assay for quantitative and qualitative investigation of biofilm forming isolates isolated from biomaterials

Rebecca Booth³, Sean Kelly³ and Steven L Percival^{1,2,3*}

¹Institute of Ageing and Chronic Disease, University of Liverpool, Liverpool, UK

²Surface Science Research Centre, University of Liverpool, Liverpool, UK

³Scapa Healthcare, Manchester, UK

*email: Steven.Percival@scapa.com

INTRODUCTION

Several *in vitro* methods have been developed to investigate biofilms however few of these lend themselves to high-throughput (HTP) assays. HTP protocols allow the rapid assessment of antimicrobial and anti-biofilm efficacy of novel actives and thus offer the ability to assess large numbers and concentrations of compounds efficiently. The ability to visualise surface biofilms and the effect that an active has on various stages of biofilm formation and maintenance is also desirable, therefore a model which can be used for both qualitative and quantitative assessment is advantageous. In this study we use the minimum biofilm eliminating concentration (MBEC™) assay (Ceri *et al*, 1999) to investigate the biofilm forming capacity of common bacteria that have been isolated from biomaterials, *Staphylococcus aureus* and *Pseudomonas aeruginosa*. The assay was used to generate both qualitative and quantitative data from biofilms formed on the pegs of MBEC™ plates.

EXPERIMENTAL METHODS

- 10⁵cfu/ml of *S. aureus* and *P. aeruginosa* in Tryptone Soya Broth (TSB) was inoculated into 96 well pegged lid plates and incubated on a shaking platform at 35°C for 48 hours to allow the growth of biofilms.
- Peg lids were rinsed in 0.85% saline to remove any planktonic bacteria.
- Pegs were removed, stained with Invitrogen LIVE/DEAD® BacLight™ stain and visualised using fluorescent and confocal laser microscopy.
- Pegs were removed placed in 10mls Maximum Recovery Diluent (MRD) and sonicated for 10 minutes to remove the attached biofilm. The MRD was serially diluted, plated on to Tryptone Soya Agar (TSA) plates and incubated at 35°C. After 48 hours the colonies were counted.
- The pegged lid was stained with 1% crystal violet for 10 minutes. After staining, the pegs were washed 3 times in 0.85% saline, before being placed in ethanol for a further 10 minutes. The resulting ethanol suspensions were measured at an absorbance of 595nm on a plate reader.

RESULTS AND DISCUSSION

- Visualisation of the pegs showed evidence of microcolony formation and the production of extracellular polymeric substance (EPS).
- Colony counts performed on bacteria isolated from MBEC™ pegs demonstrated that there were 10 times more *P. aeruginosa* cells adhered to the peg surface than *S. aureus*.
- Absorbance levels of crystal violet stain released from the biofilm-coated MBEC™ pegs indicated the presence of higher levels of adherent material in the *P. aeruginosa* biofilms in comparison to *S. aureus*. Stained material includes bacterial cells together with EPS. This study has demonstrated the biofilm forming capacity of bacterial strains, which are commonly found colonising biomaterials using a standard biofilm model. The MBEC model was developed to facilitate HTP screening of actives. The evidence gathered during this study indicates that this model can be used to investigate actives, which may be used to prevent, and/or treat biomaterial related biofilm infections. Furthermore, this study has gathered data to show that the MBEC™ model can be used for both quantification and visualisation of biofilms on the surface of the MBEC™ pegs. Using a fluorescent stain, adherent bacterial cells were visualised and the presence of EPS was also indicated. Cell counts revealed the differences in numbers of adherent cells between bacteria and showed very good reproducibility. A study of crystal violet dye retention demonstrated the differences in levels of total adherent material and was also shown to be highly reproducible across a plate.

CONCLUSION

The reproducibility and flexibility of the MBEC™ device supports the use of this model in HTP screening of biomaterial related biofilm infections.

INTRODUCTION

Adhesives are used across a variety of healthcare applications including wound care dressings, medical device fixation such as ostomy fixation and transdermal delivery. The selection of the type of adhesive for these various applications is dependent on a number of factors including position on the body, wear time, contact with wounded skin and breathability requirements. Aggressive adhesives can damage the fragile skin of neonates and the elderly so choosing skin-friendly adhesives which cause minimal trauma to the skin is important. Dressings and other devices which require fixation to the skin for long periods of time (>48 hours) require adhesives to ensure a secure hold, be conformable so as not to restrict movement and ideally breathable to improve patient comfort and compliance. Few studies have been completed to fully understand and compare the various characteristics of skin adhesive materials. In this study we aim to compare the physical and chemical characteristics of 3 types of adhesive used in healthcare; acrylics, silicones and polyurethane (PU) gels.

EXPERIMENTAL METHODS

- Physical and chemical test methods were carried out following industry standard test protocols.
- Moisture vapour transfer rate (MVTR) was measured at 37°C equivalent to 24 hours using upright Paddington cups (BSEN 13726-2:2002).
- Peel adhesion was measured at a constant peel angle using a 25mm width of adhesive material.
- Trauma on removal was investigated using a porcine skin model. Adhesives were applied to the skin surface with constant pressure and then removed following 2 hours to understand the degree of skin trauma caused on removal of an adhesive.

- Effect of adhesive removal on the *in vitro* stratum corneum was visualised macroscopically and also quantified by measuring the absorbance of methylene blue dye released from tissue.

RESULTS AND DISCUSSION

- MVTR testing demonstrated that PU gel adhesive had the highest moisture vapour transfer rate, whilst silicone was proven to have a high level of occlusiveness.
- Peel adhesion testing highlighted that silicone gel adhesives had the lowest peel strength. However, the PU gel also showed low peel strength, particularly when compared to acrylic adhesives.
- Visual analysis of the stained porcine skin model indicated that the silicone and PU adhesive removed less stain when compared to an acrylic adhesive.
- Absorbance data verified this result with quantitative data and showed that silicone and PU removed the least dye from the surface and acrylic the most.

CONCLUSION

- The high MVTR level of PU gel adhesive proves that this adhesive is breathable and thus more comfortable when worn for extended periods of time.
- The acrylic adhesive had the greatest tack level however they also removed the highest amount of dye indicating that they caused the highest level of skin trauma on removal.
- Both the silicone and the PU gel adhesive indicated that they caused low trauma to skin on removal and were deemed to be more 'skin-friendly' than acrylic adhesive.

The role of adhesives in biofilm prevention

INTRODUCTION

Acrylics, polyurethanes and silicones are adhesives which are commonly used as biomaterials and used for adhering materials internally or externally on the human body. To date little work has been done to look at the affect these adhesives have on the prevention, formation and reattachment of biofilms. Biofilms are evident in all chronic wounds, with highly virulent biofilms relevant to the non-healing of chronic wounds. These wounds are frequently managed using wound dressings that use various adhesives to secure them to the skin. Adhesive wound contact layers ensure that dressing materials conform to the wound surface and thus may be in contact with wound biofilms. This study examined the influence of silicone, acrylic and polyurethane (PU) adhesives on the growth of *Staphylococcus aureus* and *Pseudomonas aeruginosa* biofilms using a novel poloxamer biofilm model.

EXPERIMENTAL METHODS

- 10⁸cfu/ml *S. aureus* and *P. aeruginosa* in Maximum Recovery Diluent (MRD) were inoculated into the poloxamer polymer.
- Samples (3 x 3cm) of silicone, acrylic and polyurethane adhesives were inoculated with 100µl of the Poloxamer bacterial suspension, and incubated at 35°C.
- At 24, 48 and 72 hours images of the bacteria, attached to the adhesives, growing in the poloxamer hydrogels were taken using a light and confocal laser microscope.
- Total viable counts were performed at 0, 4, 24, 48 and 72 hours. Samples of adhesives were placed in 10ml MRD and refrigerated to allow the poloxamer to liquify. When in solution, the MRD suspension was serially diluted, plated on to TSA plates and incubated 35°C. After 48 hours the colonies were counted. All adhesives were tested in triplicate.

RESULTS AND DISCUSSION

- Similar numbers of viable cells were isolated from *S. aureus* and *P.aeruginosa* poloxamer hydrogel biofilms grown in the presence silicone and acrylic adhesive.
- Visualisation of *S. aureus* and *P. aeruginosa* poloxamer biofilms demonstrated that biofilm development was similar in the silicone and acrylic exposed samples.
- Poloxamer biofilms of *S. aureus* demonstrated a fall in cell numbers after 24 hours when exposed to PU adhesive and images of these samples showed that biofilm formation was inhibited.

CONCLUSION

To date little work has been done to investigate the effects of adhesives on the formation of biofilms. The presence of biofilms in chronic wounds is generally clinically accepted, it is important to understand the effects that wound care adhesives may have on biofilms. Here we have used a simple and reproducible *in vitro* biofilm model to begin to understand these affects. We observed that the PU adhesive has an inhibitory effect on Gram positive *S. aureus* biofilms. *S. aureus* is often isolated from chronic and non-healing wounds and is known to form biofilms. PU gel adhesives have several characteristics that make them ideal for wound care applications including secure hold, breathability and low trauma upon removal. This study has indicated that the PU adhesive may have additional effects on biofilms, which could be beneficial if used as a wound contact layer. Further studies are required to fully understand the effects of adhesives on biofilm formation and maintenance, with particular focus on bacterial strains, which are isolated from chronic wounds.

Silicone adhesives and their use in skin and wound care

INTRODUCTION

Silicones have a number of qualities that make them ideal materials for use internally and externally as medical devices and biomaterials. They are inert, non-irritating, have low toxicity, low thermal conductivity and are water-repellent. A number of clinical studies have been performed which demonstrate how these properties confer specific advantages over other materials. Silicones are also used as a standard treatment for the prevention and treatment of hypertrophic and keloid scarring. Several studies have shown that long-term use of silicone gels and sheets can reduce itching and discomfort of scarred skin tissue, flatten and soften margins and reduce discolouration. Silicone can be made into adhesives and gels and are often described as a 'skin friendly adhesive' solution. Here we investigate the various characteristics of a new range of silicone materials designed specifically for use in skin and wound care.

EXPERIMENTAL METHODS

- Moisture vapour transfer rate (MVTR) testing was carried out on perforated and non-perforated silicone gel adhesives and measured at 37°C equivalent to 24 hours using upright Paddington cups (BSEN 13726-2:2002).
- Peel adhesion was measured at a constant peel angle using a 25mm width of adhesive material.
- Trauma on removal was investigated using porcine skin stained with methylene blue. Silicone gel and medical grade adhesive were applied to the skin surface with constant pressure and then removed following 2 hours to understand the degree of skin trauma caused on removal. Silicone gel adhesives were compared to medical grade acrylic adhesives.
- Effect of adhesive removal on the *in vitro* stratum corneum was visualised macroscopically and also quantified by measuring the absorbance of methylene blue dye released from tissue and adhesive samples in to 2mls of dimethyl sulfoxide (DMSO).

RESULTS AND DISCUSSION

- Both visualisation of the porcine skin and quantification of the methylene blue dye from the samples demonstrated that the silicone gel adhesive removed less of the stained skin surface cells than the medical grade acrylic adhesive.
- The silicone gel adhesive had a low MVTR value; however, perforation of the material permitted vapour transfer through the gel.
- Peel testing of the perforated and non-perforated material showed that the drop in adhesion was proportional to the amount of silicone adhesive removed and did not affect the overall adhesive performance of the material.

CONCLUSION

- As expected, the new silicone gel adhesive studied was shown to have a low MVTR level. This occlusive characteristic provides evidence that this material may help to reduce scarring on newly healed wounds.
- Perforation of the silicone gel adhesive allows for moisture permeability without significantly affecting the peel adhesion of the silicone gel, which allows this, adhesive to be used as a wound contact layer in combination with an absorbent layer such as a foam even in exuding wounds.
- Results of the *in vitro* skin trauma testing proved that the silicone gel had 'skin-friendly' characteristics since skin trauma was reduced significantly when compared to the acrylic adhesive.
- Skin-friendly silicone gel adhesives are ideal materials for use as skin and wound contact layers in applications ranging from advanced wound care to medical device fixation.

A Computer Model for Polymer Degradation in the Presence of Acidic Drug

K. Sevim and J. Pan

Department of Engineering, University of Leicester, Leicester, UK, ks377@le.ac.uk

INTRODUCTION

Poly(lactic acids) (PLAs), poly(glycolic acid) (PGA) and poly caprolactone (PCL)¹, are widely used to make bioresorbable devices such as drug delivery systems and tissue scaffolds². The basic degradation process for the polymers containing ester functional group in their main chain is hydrolysis. Water penetrates the polymers, breaking the long chains into oligomers. This process is known as chain scission. For PLA hydrolysis, acidity of the medium increases as more carboxylic acid dissociates that accelerates degradation of polymer. This process is known as autocatalysis³. The diffusion rate of drug in a polymer matrix is closely related to the level of polymer degradation. This paper presents a mathematical model for the interplay between an acidic drug (acetylsalicylic acid or aspirin) and polymer degradation.

MATHEMATICAL MODEL

The degradation behaviour of resorbable polymers is modelled considering three mechanisms: hydrolysis reaction between ester bonds and water molecules; acid disassociation of carboxylic ends and further catalytic effect arising from dissolution of acidic drug and its transport in the polymer matrix. Water concentration is not a limiting factor in the model and assumed to be abundant. The hydrolysis reaction takes place in the polymer matrix. As long ester bonds are broken into short chains, more and more carboxylic and alcoholic end groups are generated. Meanwhile, water dissolves the drug particles, leading to a further increase in acidity. The solubilised aspirin diffuses through the polymer matrix, further accelerates the degradation of polymer. In our model, the effect of aspirin diffusion on the degradation of polymer chains is considered. A numerical method is used to solve the differential equations.

RESULTS AND DISCUSSION

The model used here comprises a mathematical expression for polymer degradation by autocatalytic hydrolysis. Moreover, it considers drug particle dissolution, its diffusion through the polymer matrix and interaction with the hydrolysis of the polymer chains. Polymer degradation is modelled using a random chain scission model, while drug diffusion is governed by Fick's laws. The chain scission rate is given by a rate equation [1] developed by Pan and co-workers³:

$$\frac{dRs}{dt} = \left[Ce_0 \left(1 - \alpha \left(\frac{Rs}{Ce_0} \right)^\beta \right) \right] (k_1 + k_2' C_{H^+}) \quad [1]$$

in which dRs/dt is chain scission rate, Ce_0 is the initial concentration of ester bonds, C_{H^+} is the acid

concentration, and k_1 and k_2' are kinetic parameters of the ester bond. The effect of drug on degradation is reflected by C_{H^+} which is the sum of the acid disassociation of the carboxylic chain ends and the dissolved drugs in the polymer matrix.

Figure 1 shows the calculated distributions of drug concentration between two drug particles at different times. The left end of the curves is the interface between a drug particle and polymer matrix, while the right end is the mid-point between two drug particles. As time increases, drug concentration in the matrix changes from zero to a uniform distribution of its saturation value in the polymer. Because the drug concentration is not uniform in the polymer before the saturation, polymer degradation is also not uniform due to the different level of acidity, C_{H^+} , at different location. The differential degradation leads a huge difference in the diffusion coefficient of the drug at different locations because of its sensitivity to free volume. Consequently the model can handle a complex interaction between the polymer degradation and drug release.

Figure 1 Computer simulated distribution of drug concentration at different times

CONCLUSION

The preliminary results of transport-reaction model is presented that takes into consideration of the autocatalytic effect of polymer chain ends and the transport of the dissolved drug on the degradation of the polymer matrix. The model is able to deal with a complex interplay between drug diffusion and polymer degradation.

INTRODUCTION

Mesoporous magnesium silicate (m-MS) was firstly synthesized, and the in vitro degradability, bioactivity and primary cell responses to the m-MS were investigated. The results suggested that the m-MS with mesoporous channels of around 5 nm possessed the high specific surface area of 451.0 m²/g and pore volume of 0.41cm³/g as compared with magnesium silicate (MS) without mesopores of 75 m²/g and 0.21 cm³/g, respectively. The m-MS could absorb a large number of water with the water absorption of 74 % as compared with MS of 26 %. In addition, the m-MS could degrade in Tris-HCl solution with the weight loss ratio of 40 w% after immersion for 70 days. The m-MS had good in vitro bioactivity, which could induce apatite formation on its surfaces when soaked into

simulated body fluid (SBF), and the rate of apatite formation for m-MS was obviously faster than MS. The cell experiment results revealed that m-MS could obviously promote proliferation and differentiation of the MC3T3-E1 cells on its surfaces than MS with time, and exhibited normal cell morphology, indicating excellent cytocompatibility. This study suggested that the mesoporous magnesium silicate with high specific surface area and pore volume had suitable degradability, good bioactivity and biocompatibility, which might be an excellent candidate of a biomaterial for bone regeneration.

Macromolecular crowding maintains tenogenic phenotype *ex vivo*

Kyriakos Spanoudes, Abhigyan Satyam, Abhay Pandit, Dimitrios Zeugolis

¹Network of Excellence in Functional Biomaterials, National University of Ireland, Galway, Ireland.

kyriakos.spanoudes@nuigalway.ie

INTRODUCTION

Tendon tissue engineering is becoming increasingly important as the current surgical treatment modalities have numerous drawbacks. Cell-based therapies are aiming to create autologous treatments for patients. However, traditional culture conditions are associated with tenocyte phenotypic drift and incomplete tenogenic differentiation of stem cells. These difficulties have stemmed research towards creation of more functional *in vitro* micro-environments [1] that would resemble the native habitat of tenocytes *ex vivo*. Macromolecular crowding (MMC) has been postulated to imitate *in vitro* the *in vivo* dense extracellular milieu [2]. In this work, we hypothesise that MMC will maintain tenogenic phenotype *in vitro*.

EXPERIMENTAL METHODS

Human patellar tendon tenocytes were expanded up to passage 3 in DMEM media, supplemented with 10% foetal bovine serum and 1% penicillin / streptomycin. 50,000 / cm² tenocytes were subsequently cultured for a period up to 28 days, supplemented with ascorbic acid phosphate 100 µM/L and 75 mg/ml carrageenan (CR; MMC agent). The influence of CR on cell morphology, viability and metabolic activity was evaluated using phase-contrast microscopy, Live/Dead® and alamarBlue® assays respectively. Phenotype maintenance was verified using protein and gene assays based on the expression of positive markers (e.g. scleraxis, collagen I, tenascin C, tenomodulin) and trans-differentiation markers (e.g. osteopontin, osteocalcin, aggrecan).

RESULTS AND DISCUSSION

Preliminary results suggest that culture with CR does not compromise cell viability and metabolic activity, whilst maintains tenocyte phenotype. Further gene and protein analysis for longer time points are under way.

Fig. 1: Cell metabolic activity was maintained up to 6 days in culture.

Fig 2: Tenomodulin expression was maintained up to 4 days in culture.

Fig 3: Collagen type V expression was maintained up to 4 days in culture.

CONCLUSION

Macromolecular crowding, is a valuable biophysical tool for a tenogenic phenotype maintenance regimen in the quest for tendon regeneration strategies.

Effect of cooling rates after casting and subsequent Solution Treatment on Microstructure and Mechanical Strength of Dental Silver Alloys with different Cu contents

Tomoya Yasuda¹, Toshikazu Akahori², Yushi Hoshiya¹, Tomokazu Hattori², Hisao Fukui³

¹Graduate School of Science and Technology, Meijo University, Japan

³Dental School, Aichi-Gakuin University, Japan, 133434036@ccalummi.meijo-u.ac.jp

INTRODUCTION

The Ag–Pd–Cu–Au system was developed in Japan for applications in dentistry and is been widely used in inlays, crowns, etc. Recently, the mechanical strength of this alloy has been reported to be significantly enhanced when it is subjected to solution treatment (ST) at temperatures higher than 1073 K and subsequent water quenching without any aging⁽¹⁾. This unique hardening mechanism seems to be based on factors such as the ST temperature, cooling rate after ST, and initial microstructure before ST. Therefore, this study investigated the relationship between the mechanical strength and microstructure of samples with different constituent proportions of the Ag–Pd–Cu–Au alloy system. These were cast into plaster and Cu molds to control the various cooling rates followed by ST.

EXPERIMENTAL METHODS

Hot-rolled plates of Ag-20Pd-14Cu-12Au and Ag-20Pd-20Cu-12Au alloys were used and are designated as Ag-Cu_{low} and Ag-Cu_{high}, respectively. Samples were fabricated to have the same diameter and height, which is 2.0mm and 4.0mm, respectively, were fabricated by centrifugal casting. Plaster and Cu molds were used to control the cooling rate after casting. Some castings were subjected to ST at 1123 K for 3.6 ks in an argon gas atmosphere followed by water quenching. The castings and those subjected to ST were designated as As-cast and ST, respectively. Furthermore, they are distinguished by their diameters (e.g., As-cast/φ2.0 mm and ST/φ2.0 mm). A scanning electron microscope (SEM) equipped with a wavelength dispersive X-ray spectrometer (WDS) and X-ray diffraction (XRD) spectroscope were used to evaluate the microstructure of each specimen. The Vickers hardness (HV) test was performed to examine the mechanical strength.

RESULTS AND DISCUSSION

Figures 1 and 2 show BSE images of Ag-Cu_{low} and Ag-Cu_{high} cast in Cu and plaster molds and those after ST, respectively.

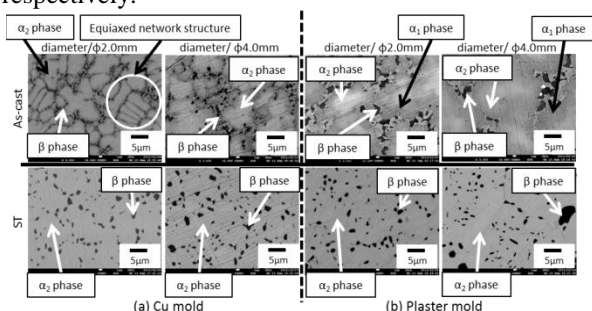

Fig.1 BSE images of Ag-Cu_{low} with Cu and plaster molds and those after ST.

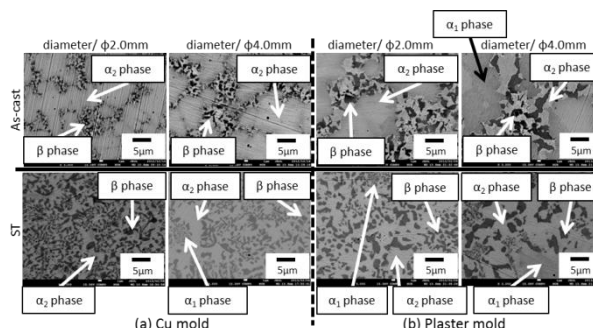

Fig.2 BSE images of Ag-Cu_{high} with Cu and plaster molds and those after ST.

The As-cast Ag-Cu_{low} samples demonstrated an equiaxed network structure, as shown in Fig. 1. The As-cast Ag-Cu_{low} sample with a φ2.0 mm diameter and cast into a Cu mold showed the smallest average diameter for the equiaxed network because it had the fastest cooling rate. Therefore, the average diameter tended to increase with the sample diameter and when the plaster mold was used. In contrast, the microstructure of The ST samples cast into Cu and plaster molds showed a large number of β-phases that precipitated at the boundaries of the equiaxed network structure. In this case, the coarsening of the β phase was significant for the sample with a diameter of φ4.0 mm and cast into a plaster mold as it had the slowest cooling rate.

The microstructure of the As-cast Ag-Cu_{high} sample cast into Cu and plaster molds also exhibited an equiaxed network structure similar to Ag-Cu_{low}, as shown in Fig. 2. However, the average diameter of the equiaxed β phase differed. The size and volume fraction of the β phase increased with the relatively high Cu/Ag ratio of 0.16. Furthermore, the microstructure after ST changed drastically: there was a large amount of β phase compound relative to As-cast.

CONCLUSIONS

- The diameters of the Ag-Cu_{low} and Ag-Cu_{high} equiaxed network structures decreased with increasing cooling rate after casting, which was controlled by the size of the casting and the material of the mold.
- The Ag-Cu_{low} and Ag-Cu_{high} microstructures after ST did not show an equiaxed network structure, but the sizes and volume fractions of the β phase were different from each other.

INTRODUCTION

In dentistry, Ag–20Pd–14Cu–12Au alloy (mass%) is widely used in inlays, crowns, etc. as a substitute material for precious metals. Recently, the mechanical strength of this alloy has been reported to be significantly enhanced when it is subjected to solution treatment at temperatures higher than 1073 K and subsequent water quenching without any aging. This unique hardening mechanism seems to influence the presence of the intermetallic compound (β phase) after solidification and the subsequent solution treatment. However, conditions that induce this unique hardening, such as the solidification temperature, have not yet been clarified. Therefore, this study investigated the relationship between the mechanical strength and microstructure of the Ag–20Pd–14Cu–12Au alloy after the solidification and subsequent solution treatment under various conditions.

EXPERIMENTAL METHODS

Hot-rolled plates of Ag–20Pd–14Cu–12Au alloy were used. Solidification was induced at temperatures of 1373, 1873, and 1973 K for 1.8 and 3.6 ks in an Ar gas atmosphere followed by water quenching (WQ). Some samples were fabricated with solution treatment (ST) at 1123 K for 3.6 ks in a vacuum followed by WQ. Hereafter, the samples with holding times of 1.8 and 3.6 ks for solidification were designated as As1.8ks and As3.6ks, respectively. The sample were further classified by the solidification temperature. As1.8ks and As3.6ks subjected to ST were designated as As1.8ks/ST and As3.6ks/ST, respectively.

Back-scattering electron (BSE) images from a scanning electron microscope (SEM) and elemental mapping by a wavelength dispersive X-rays spectrometer (WDS) were used to observe the microstructures and evaluate the phase constitutions. The Vickers hardness (HV) test was performed to evaluate the mechanical strength. The corrosion potential was measured in a 3 mass% NaCl solution to evaluate the corrosion resistance.

RESULTS AND DISCUSSION

Figure 1 shows the Vickers hardness of As1.8ks at solidification temperatures of 1373–1973 K and after ST.

Fig. 1 Vickers hardness of As_{1.8ks} at solidification temperatures at 1373 K–1973 K and those after ST.

The Vickers hardness (HV) of As_{1.8ks}/1373K and As_{1.8ks}/1873K were almost the same at around 300 HV. However, the HV of As_{1.8ks}/1973K decreased remarkably. This decrease may be caused by the dissolution of almost all β phases by solidification at the highest temperature (1973 K) or the formation of oxide, which can restrict the formation of the β phase. The HV of the samples subjected to ST decreased slightly, although As_{1.8ks/ST}/1873K showed the reverse trend. This change in hardness may reflect the influence of the decreased solution hardening on the α_1 phase because of the presence of a large α_2 phase. As noted above, the remarkable decrease in HV may be due to the volume fraction and restriction of the β phase. Precipitation of the β phase, which is an ordered or disordered intermetallic compound, increased the strain on the microstructure. Therefore, the presence of the β phase was attributed to the change in HV. As_{3.6ks} and As_{3.6ks/ST} showed almost the same tendency as As_{1.8ks} and As_{1.8ks/ST}.

The corrosion potential of As_{1.8ks} and As_{3.6ks} increased with the solidification temperature, although the potential increased more through ST. The potential may have been increased by the decrease in the volume fraction of the α_1 phase with relatively high Cu content.

CONCLUSIONS

- (1) It was difficult to observe the β phase in As_{1.8ks} and As_{3.6ks} subjected to solidification at 1973 K because of the dissolution or formation of oxide.
- (2) The corrosion potential of As_{1.8ks} and As_{3.6ks} increased with the solidification temperature and subsequent ST.

Morphological Control of Layered Double Hydroxide Crystals as Drug Carrier by Organic Molecules with Carboxyl Group

Taishi Yokoi*, Sota Terasaka and Masanobu Kamitakahara

Graduate School of Environmental Studies, Tohoku University, Japan, yokoi@mail.kankyo.tohoku.ac.jp

INTRODUCTION

Drug delivery is useful for enhancement of therapeutic effect by transporting pharmaceutical compounds to affected area. Layered double hydroxides (LDH) have been attracting interest as a drug carrier¹. LDHs are composed of positively charged metal hydroxide layers, which are composed of divalent and trivalent cations, and interlayer anions. Various anions can be incorporated into LDH crystal. The exchangeability of interlayer anions has been utilized to load, transport and deliver pharmaceutically active molecules.

LDH is synthesized through wet chemical processes, such as homogeneous precipitation². The obtained LDH crystals have generally hexagonal plate shape. LDH crystals grow the *a*- and *b*-axes directions and mainly expose the *c* face. If the crystal growth for the *a*- and *b*-axes directions is inhibited, unique and unusual-shaped LDH crystal will form. Morphological control of LDH crystals achieves development of novel drug carriers. However, the morphological control technique of LDH is still unclear. At the very beginning, to establish morphological control guideline of LDH crystals is important.

Isoelectric point of LDH containing Mg^{2+} and Al^{3+} as cationic components (MgAl-LDH) is around $pH=11^3$, hence MgAl-LDH has positively charge during the synthesis, namely homogeneous precipitation. Anionic molecules such as carboxylic acids should interact with LDH crystal and elicit morphological change. However, effects of carboxylic acids on morphology and crystal growth of LDH are not clarified. In the present study, we investigated effects of carboxylic acids addition for reaction systems on morphology of LDH crystals synthesized homogeneous precipitation method. We selected acetic acid and succinic acid as the additive, because these carboxylic acids do not make precipitates with Mg^{2+} and Al^{3+} .

EXPERIMENTAL METHODS

Solutions containing $100\text{ mol}\cdot\text{m}^{-3}$ magnesium nitrate, $50\text{ mol}\cdot\text{m}^{-3}$ aluminium nitrate, $300\text{ mol}\cdot\text{m}^{-3}$ urea and 0 or $100\text{ mol}\cdot\text{m}^{-3}$ morphological control agent, namely acetic acid or succinic acid, were prepared. The solution (50 cm^3) was maintained at 90°C for 5 days to form LDH. The precipitates formed were collected by vacuum filtration and dried at 90°C for over 24 hours.

Crystalline phases of the obtained samples were characterized by powder X-ray diffraction (XRD). Crystal morphology was observed under scanning electron microscopy (SEM) after thin Pt film coating.

RESULTS AND DISCUSSION

Crystalline phases of samples were characterized by XRD. Quintinite-3T ($Mg_4Al_2(OH)_{12}CO_3\cdot 3H_2O$), which is a kind of LDH, was detected in all the samples.

Figure 1 SEM images of samples: (a) LDH synthesized without morphological control agent, (b) LDH synthesized with acetic acid and (c) LDH synthesized with succinic acid.

Figure 1 shows SEM images of samples. Plate-shaped crystals were formed under the condition without morphological control agent. Stacked hexagonal plate-shaped crystals were formed in the condition with acetic acid. Aggregates constructing plate-shaped crystals were formed under the condition with succinic acid.

Spiral growth of LDH has been reported previously⁴. We considered that the adsorbed acetic acid molecules inhibited bonding between the substrate and newly formed LDH crystals thereby resulting in the formation of stacked disc-shaped LDH crystals. Assembled nuclei most likely grew to aggregates constructing plate-shaped crystals. Succinic acid should generate self-assembling of LDH nuclei.

CONCLUSION

We investigated effects of acetic acid and succinic acid addition on morphology of LDH synthesized by homogeneous precipitation. The morphology of LDH implied that acetic acid mainly affect crystal growth of LDH and succinic acid assist assembling of LDH nuclei. These findings can be applicable for development of novel drug carriers.

Properties of β -TCP based Calcium Phosphate Cement using mechano-chemical process

J. Y. Bae¹, Y. Ida¹, K. Sekine¹, F. Kawano² and K. Hamada¹

¹ Department of Biomaterials and Bioengineering, ² Department of Comprehensive Dentistry, Institute of Health Biosciences, University of Tokushima, Japan, c301151014@tokushima-u.ac.jp

INTRODUCTION

Calcium phosphate cement (CPC) is widely utilized today for various clinical applications. CPC shows many advantages as a bone-substitution material. The objective of this research is to develop a new CPC indicating fine injectability, short setting-time and high strength, simultaneously, and to expand the application of CPC.

EXPERIMENTAL METHODS

β -tricalcium phosphate (control TCP; β -TCP) powder was modified mechano-chemically using ball-milling. The phase constitutions of calcium phosphate were investigated using X-ray diffractometry (XRD). The powder after milling (modified TCP; m- β -TCP) was mixed with 2.5 mass% CaCl_2 solution, and then 2.5 mass% NaH_2PO_4 solution at a powder/liquid ratio of 4:1:1. The paste after mixing was filled in a syringe and the time performing injectability was measured. The load pressurize to syringe was applied using universal testing machine (Autograph AGS-500A, Shimadzu, Japan). Cross head speed was 20 mm/min and the maximum load was 300N. The injectability was calculated according to the equation shown as follows,

$$\text{Injectability}(\%) = \frac{W_{\text{exp}}}{W} \times 100$$

where W_{exp} is the weight of paste expelled from syringe, and W is the total weight of paste before injection.

To investigate the initial setting time of the cement, we measured the strength through the compressive strength (CS) and diametral tensile test (DTS) each time from 1 h to 5 hrs. The paste after initial setting was kept for 1 w for complete setting. Mechanical properties were evaluated by CS and DTS according to milling time. The porosity of the set cement specimen was measured using a gas pycnometer (AccuPyc1330, Micromeritics, USA).

RESULTS AND DISCUSSION

XRD profiles indicated that the peaks of TCP powder after milling became broader with increasing milling time from 0 h to 24 hrs, and then the powder became partially amorphous.

β -TCP cement paste was set quickly within 5 min after mixing, while m- β -TCP cement paste did not lose a flowability for 7 hrs. Calculated injectability of β -TCP 5 min after setting and m- β -TCP 1 h after setting were 2.98% and 23.8%, respectively.

β -TCP compacts 1 h after mixing collapsed during removal from silicone mold. Compacts 2 and 3 hrs after mixing showed near zero for CS and DTS. CS and DTS 4 and 5 hrs after mixing were 1.07 MPa and 0.13 MPa, and 1.09 MPa and 0.14 MPa, respectively. m- β -TCP

compacts more than 1 h after mixing were durable for CS and DTS. CS and DTS increased with increasing time after mixing; CS and DTS 1 h and 5 hrs after mixing were 0.53 MPa and 0.08 MPa, and 8.02 MPa and 2.62 MPa, respectively. Reduction of initial setting time and acceleration of CS and DTS increase was supposed to increase the high dissolution rate of m- β -TCP powder due to the fine powder size and instability of amorphous powder after milling.

The dependence of CS, DTS and porosity of the compacts on the milling time are shown in Fig. 1. The CS and DTS of compacts 0 h to 24h hrs after mixing were 0.68 ± 0.15 MPa and 0.24 ± 0.05 MPa, and 26.47 ± 4.82 MPa and 3.89 ± 0.49 MPa, respectively. Those of porosity from 0 h to 24hrs were 53.15 ± 1.7 % and 41.9 ± 1.97 %, respectively. All the CS data and DTS data of m- β -TCP were significantly higher than those of β -TCP ($t < 0.01$). The porosity showed a slight decline according to the milling time. The reduction of porosity is supposed to affect the increase of CS and DTS of compacts after milling.

Fig.1 Dependence of CS, DTS and porosity according to the milling time.

CONCLUSION

These results suggested that the mechanochemically-modified calcium phosphate powder dissolved rapidly and accelerated hydroxyapatite precipitation, which successfully shortened the cement setting time and enhanced strength. The m- β -TCP in this study can be a candidate for injectable CPC under higher stress.

INTRODUCTION

Induced membrane technique has been proposed by Masquelet *et al.*¹ for wide segmental diaphysis bone reconstruction with autologous cancellous bone graft. To reduce donor site morbidity following bone harvest, some authors proposed to add synthetic bone substitutes in combination or not with bone morphogenetic protein 2 (BMP-2) to the graft. To avoid the expenses of the growth factor, the use of the cholesterol lowering statins was investigated in numerous studies showing an enhanced expression of BMP-2 mRNA and osteoblastic differentiation *in vitro* and *in vivo*. Therefore, statins were proposed as BMP-2 substitutes.

The aim of this study was to evaluate the osteoinductive capacity of simvastatin in comparison to BMP-2 in subcutaneous induced membranes filled with the bone substitute MBCP+™ (Biomatlante) in association with total bone marrow allografts in rats.

EXPERIMENTAL METHODS

In vitro studies evaluated simvastatin toxicity at 10^{-6} M and 10^{-8} M and early osteoblastic differentiation on rat Bone Marrow Stromal Cells (rBMSC) cultures in comparison to cells cultured in basal medium or differentiation medium, analysed by Alkaline Phosphatase Assay and quantitative RT-PCR.

Subcutaneous membranes were induced by silicon spacers during 5 weeks. After spacer removal, the volumes were filled with 10 different conditions of MBCP+™, associated or not with total bone marrow (BMr), simvastatin (7µg absorbed/ mg MBCP+™), and rhBMP-2 (Inductos®; 0.025 µg/ mm³ MBCP+™). Four groups of animals were injected with simvastatin at 30mg/ kg/ week. Samples were analysed by microCT and decalcified histology. Osteoid formation was quantified from sections stained with Masson's Trichrome.

RESULTS AND DISCUSSION

Simvastatin caused no cytotoxicity at 10^{-6} M and demonstrated early osteoblastic differentiation of rBMSCs by ALP assays and qRT-PCR for Osteocalcin and BMP2.

MicroCT analysis did not reveal significant differences. Histology demonstrated higher scaffold cellularity for conditions with bone marrow cells.

Figure 1: **Representative histological sections** of 4/10 conditions and **MicroCT images** of 2/10 conditions. Sections were stained with Masson's Trichrome (A-D). MicroCT images showing mineralization of the material. MBCP+™ granules were conditioned with rhBMP2 (A,B), or animals received Simvastatin injections (C,D), rat bone marrow (BMr) was associated to conditions in the two right panels (B,B1,D, D1).

All conditions with BMP-2 induced osteoid formation (Figure 1), more prominent in association with bone marrow. Simvastatin absorbed to the MBCP+™ scaffold did not improve osteoinductive properties, while Simvastatin injections had an effect in some of the samples, as evaluated by histomorphometric measurements.

CONCLUSION

Simvastatin affected osteoblastic differentiation, but didn't improve osteoinductive properties of the biomaterial in induced membranes. According to our experience, BMP-2 stays the gold standard in osteoinductive studies in induced membranes.

Development and Characterization of Thermally Responsive PluronicF127-Chitosan-Kartogenin Conjugates Based Dual Drug Delivery System

Mi Lan Kang, Ji Yun Ko, Ji Eun Kim, Gun Il Im*

*Department of Orthopedics, Dongguk University Ilsan Hospital, Korea, gunil@duih.org

INTRODUCTION

PluronicF127 (F127) is a polymer possessing thermo-reversible and concentration-dependent gelation properties in aqueous solutions. Polymer-drug conjugates generally exhibit prolonged half-life, higher stability, water solubility, lower immunogenicity and antigenicity. The objective of this study was to develop and evaluate a novel drug delivery system which permits the thermally responsive drug release and dual drug delivery by polymer-drug conjugation and drug encapsulation.

Due to the localized nature of osteoarthritis (OA), a chronic joint disease, intraarticular (IA) drug injection is an attractive treatment approach. Recently, a study has been demonstrated that kartogenin (KGN) can induce chondrogenesis of mesenchymal stem cells (MSCs)¹. Therefore, KGN can be a useful regenerative medicine for OA treatment.

Here, we designed dual drug delivery system with thermo-responsiveness for OA treatment via IA injection which is composed of F127-chitosan oligosaccharide (COS)-KGN conjugated nanocapsules (NCs) encapsulating anti-inflammatory drug..

EXPERIMENTAL METHODS

Carboxylated F127 (F127COOH) can be obtained according to the reported work with maleic acid². ¹H-NMR spectrum confirmed the formation of chemical structure of F127COOH.

Bioconjugate of KGN and COS was synthesized by ethyl (dimethylaminopropyl) carbodiimide (EDC)/ N-Hydroxysuccinimide (NHS) catalysis. The F127-COS-KGN NCs were made by emulsification/solvent evaporation method. Conjugation of F127COOH and COS was carried out by adding EDC during the NCs synthesis process. The conjugation of COS with KGN or F127COOH was confirmed by FT-IR and ¹H-NMR. Diclofenac was encapsulated inside of the F127-COS-KGN NCs by change of wall-permeability according to temperature control. Size and morphology of the F127-COS-KGN NCs were characterized by DLS and FE-SEM, respectively. Especially, the size was investigated according to temperature control and molar ratio change of F127 and KGN.

Amounts of KGN and diclofenac released from NCs were determined by HPLC to confirm temperature controlled release. Toxicity of the NCs as a delivery vehicle was estimate by MTT assay.

RESULTS AND DISCUSSION

Pluronic F127 was activated by adding carboxyl groups from maleic acid to both ends of the polymer. The FT-IR spectrum of F127COOH showed a peak indicating the -COOH group. The ¹H-NMR spectrum of F127-COS-KGN NCs showed prominent resonance peaks corresponding to the methyl (-CH₃) and methylene proton at the C2 position of chitosan and benzene ring of KGN. Therefore, it can be supposed from these data that KGN and F127 was successfully conjugated with COS. Degree of KGN and F127 conjugated with COS estimated by ¹H-NMR was 3~5 and 40-50 mol%, respectively.

The F127-COS-KGN NCs are ~300 nm at 37 °C and expand to ~650 nm when cooled at 4 °C in aqueous solution. Temperature-controlled size variation was reduced according to increase of molar ratio of KGN. When the molar ratio of KGN was more than 0.5, size change of the NCs was not observed. Also, the more molar ratio of F127 was increased; the range of size change according to temperature control was grown. Therefore, the thermally responsive properties are dependent on the molar ratio of the F127COOH and KGN during synthesis.

While the encapsulated EB showed burst release for 6 hours, the conjugated KGN showed sustained release for 7 days. This is because higher structural stability of the conjugated system in the F127-COS-KGN NCs.

CONCLUSION

The F127-COS-KGN NCs were prepared dual drug delivery system having thermo-responsiveness for OA treatment via IA route. In conclusion, we can expect that rapid anti-inflammatory effect by burst released DCF and regeneration by sustained released KGN in OA joint. Further studies are ongoing in vitro and in vivo evaluation of anti-inflammatory activity and MSCs chondrogenesis.

Transduction of Tissue-specific Transcription Factor Protein as a Tool for Tissue Engineering

Masayasu Mie, Shinya Hashimoto, Mami Kaneko and Eiry Kobatake

Department of Environmental Chemistry and Engineering, Tokyo Institute of Technology
mie.m.aa@m.titech.ac.jp

INTRODUCTION

Regulation of cellular differentiation is one of the important subjects for tissue engineering.

During developmental processes in animal, transcription factors play important roles in the regulation of cellular differentiation. Based on these facts, forced expression of tissue-specific transcription factors have been studied for induction of cellular differentiation^{1,2}. We therefore focused on tissue-specific transcription factors as signaling molecules for tissue engineering.

To introduce exogenous transcription factors, gene transfection was used as a conventional method in many studies. However, gene transfection is associated with problems such as genome integration. To overcome such problems, we paid attention to protein transduction methods. Generally, to introduce protein into cells, protein of interests are required to fuse with a short peptide called protein transduction domain (PTD) or cell penetrating peptide (CPP)³. In our previous study, we showed that basic helix-loop-helix (bHLH) type tissue-specific transcription factor proteins, NeuroD2 and MyoD, could be introduced into cells without addition of PTDs⁴⁻⁵.

In this study, we tried to regulate motor neuron and oligodendrocyte differentiation by transduction of Oligodendrocyte transcription factor (Olig2) protein. We showed that Olig2 could be introduced into cells without addition of PTDs and induce cellular differentiation.

EXPERIMENTAL METHODS

Expression and purification of Olig2 proteins

The mouse *Olig2* gene was cloned from Mouse Fetal Normal Tissue embryo Total RNA by reverse transcription-PCR. The cloned fragment was introduced into pET vectors to express proteins fused to His-tag. Other variants of Olig2 were constructed from this plasmid. Proteins were expressed in *E.coli* BL21(DE3). After induction of protein expression, cells were broken by sonication and proteins of interest were purified with nickel-charged affinity resin.

Evaluation of the cellular membrane transduction ability of Olig2 protein

Purified Olig2 and its variant proteins were modified with Oregon Green 488 carboxylic acid succinimidyl ester. Fluorescently labeled proteins were added to mouse embryonic carcinoma cell line P19 cells and incubated for 12 h. Then cells were trypsinized and inoculated on glass base dishes followed by observation using laser scanning confocal microscopy.

Induction of cellular differentiation by addition of Olig2 proteins

For induction of cellular differentiation, Olig2 proteins were added to P19 cells. Cellular differentiation was confirmed by immunostaining or RT-PCR.

RESULTS AND DISCUSSION

Olig2 and its variant proteins were expressed in *E.coli* and purified. To assess their transduction abilities, proteins were labeled with fluorescent molecules. Olig2 is a member of bHLH type transcription factors therefore we have been expected a highly basic domain in Olig2 could work as PTDs as same as NeuroD2 and MyoD. After addition of labeled proteins, cells were observed using laser scanning confocal microscopy. As expected, Olig2 protein was introduced into cells without addition of external PTDs.

After confirming internalizations, Olig2 protein without modification was added to cells to induce cellular differentiation. By addition of transcription factor protein, cells changed their morphology (Fig.1). These results showed that Olig2 protein could induce cellular differentiation.

Fig. 1 Induction of neural differentiation by addition of Olig2 protein to P19 cells. Cells were cultured without Olig2 (A) and with Olig2 (B) protein. Scale bar represents 100 μ m.

CONCLUSION

Tissue-specific transcription factor protein, Olig2, has an ability to transduce into cells and induce cellular differentiation. These results suggested that tissue-specific transcription factor protein could be used as a signaling molecule for tissue engineering.

Construction of Multifunctional Proteins by Integration of Scaffolds and Growth Factors

Eiry Kobatake and Masayasu Mie

Department of Environmental Chemistry and Engineering, Interdisciplinary Graduate School of Science and Engineering, Tokyo Institute of Technology, Japan, kobatake.e.aa@m.titech.ac.jp

INTRODUCTION

For tissue engineering, scaffolds with signalling molecules where cells can adhere, migrate, proliferate and differentiate efficiently are required. As signalling molecules, growth factors play essential roles for controlling such cellular functions. However, when the soluble growth factors are applied to cells, it is difficult to control their local concentrations due to diffusion, cell uptake, and degradation. These problems may be overcome if growth factors are immobilized in a non-diffusible form on an insoluble scaffold, allowing cell surface events involving signal transduction to occur.

Fig.1 Schematic illustration for controlling cellular functions with multifunctional protein

Therefore we have constructed multifunctional proteins by integrating scaffolds and growth factors for tissue engineering. Here we present our strategy to construct multifunctional proteins. The method is based on formation of the complex between scaffold and growth factor by coiled-coil structure with hydrophobic and electrostatic interactions. Specifically, one peptide (Helix A; HA) capable of forming a coiled-coil structure was fused with a growth factor protein, and another peptide (Helix B; HB) with similar properties was fused with a scaffold protein. Growth factor fused with HA peptide was immobilized via coiled-coil helix formation on a cell-culture plate whose surface was coated with scaffold protein fused with HB peptide, and the cell behaviour on the surface was investigated.

EXPERIMENTAL METHODS

Promotion of cell growth: As the scaffold, we designed the protein (ERE-HB) which is consisting of elastin-derived structural unit, cell adhesive sequence (RGD), and HB. On the other hand, the fusion protein (HA-FGF) between basic fibroblast growth factor (bFGF) and HA was used as a signalling molecule. These proteins were expressed in *E. coli*, and purified. The surface of cell culture plate was coated with ERE-HB and modified with HA-FGF via coiled-coil structure. Cell adhesive activity and cell growth activity on the modified surface were investigated with human umbilical vein endothelial cells (HUVECs). Epidermal growth factor (EGF) with HA was also constructed and examined as another signalling molecule.

Induction of cell differentiation: For the induction of neural differentiation, the multifunctional scaffold protein (EAEC-HB) was constructed with elastin-derived structural unit, two functional peptide units that have the ability to enhance cell adhesive and neurite outgrowth, and HB unit for tethering growth factor. To induce more efficient neurite outgrowth, HA-FGF was utilized. Neurite outgrowth of PC12 cells was evaluated on the cell culture plate whose surface was modified with HA-FGF through coated EAEC-HB.

RESULTS AND DISCUSSION

Promotion of cell growth: On the ERE-HB-coated plate without HA-FGF as a negative control, clear cell growth was not observed. Contrary, significant cell growth was observed when HA-FGF was immobilized on the ERE-HB-coated surface. It is suggested that the bFGF moiety in the HA-FGF remained activity even after immobilization on the plate surface.

Induction of cell differentiation: PC 12 cells were well attached on the EAEC-coated plate. On the EAEC-coated plate without HA-FGF, little neurite outgrowth was observed. However, much higher rate of neurite outgrowth was observed in cells cultured on the bFGF-tethered scaffold protein.

CONCLUSION

A novel method for construction of biomaterials for tissue engineering was developed. One advantage of this technique is that the signalling molecule or a scaffold can be changed depending on the purpose. Such multifunctional proteins constructed by integration of growth factors and scaffold proteins could be a useful strategy for tissue engineering.

INTRODUCTION

Additive manufacturing, also referred to as rapid prototyping (RP), provides new opportunities in manufacturing custom medical devices by using 3D data. RP is also being exploited in tissue engineering where the advantages of additive manufacture are being utilized to build highly complex scaffolds that can support the growth of living cells. In spite of increasing interest in using RP in tissue engineering, there are significant processing difficulties for hydrophilic biopolymers¹. Therefore, we propose RP microstructuring by gel-in-gel method, in which cell loaded alginate is extruded into a supporting gel matrix. Consequently, extruded polysaccharide incorporating cell is immobilized and solidified by Ca²⁺ crosslinking.

EXPERIMENTAL METHODS

Gel-in-gel injection method: To prepare a supporting gel, various concentrations of agar and CaCl₂ were tested for immobilizing extruded threads. The best formulation was detected in the 0.3-0.5 % agar (w/v) concentrations range with 3.6 mM internal CaCl₂ concentration and was used in the rest of the experiments. Extruded alginate was solidified by soaking in CaCl₂ and washed twice with isotonic saline. Suspending gel, alginate, carried silk fibroin at various compositions. The filter sterilized solution was then ultrasonicated for two minutes to induce self-assembly on fibroin². Into the fibroin-alginate solution SaOs-2 cells were added and this was extruded into agar manually or by the RP equipment (Bioscaffolder®, Germany).

In vitro studies: The cell laden gels in culture plates were incubated in DMEM or in osteogenic DMEM medium at 37°C and 5 % CO₂. For live/dead cell assay gels taken at predetermined time points were washed and treated with calcein and propidium iodide (Cal/PI) solution for 20 min and studied under a fluorescence microscope. Confocal images were also obtained after staining the cells with Nile red and then RP. Viability in the gels was determined with Alamar Blue® assay where absorbances were determined at 570 and 595 nm with a microplate reader.

RESULTS AND DISCUSSION

We saw that microstructuring of alginate carrying cells by Gel-in-Gel approach was feasible and microstructures could be built additively in an agar matrix. Confocal (CLSM) microscopy was used to further characterize the RP formed extruded gel rods and cell distribution. The orthogonally placed rods are seen to be partially fused and cells distributed homogeneously within solid alginate as the CLSM images show in Fig.1.

Figure 1. CLSM images of RP produced alginate-cell microstructures in agar: (A) top, (B) 45° angle, and (C) cross sectional views of the same cell loaded area.

Cal/PI staining and quantitative Alamar Blue® showed that blends especially with high fibroin (0.5-1 % w/v) and 1% alginate (v/w) composition had higher viability of SaOs-2 cells for up to four weeks with respect to the lowest fibroin (0.15 %) blend or pure alginate gel.

Upon incubation in osteogenic medium SaOs-2 cells showed intensive Alizarin Red (AR) staining in the manually extruded microstructures. With the high fibroin containing compositions the intensity was higher than the low fibroin sample (0.15 %), indicating increase of mineralization with increased fibroin. The AR staining of RP processed alginate microstructures showed that encapsulated cells deposit mineral in their vicinity (Fig. 2.)

Figure 2. RP produced SaOs-2 microstructures in agar after 3 weeks of culture in the osteogenic medium (A). (B) Shows mineral deposition after AR staining.

CONCLUSION

Gel-in-Gel extrusion by manual and RP was applied successfully to hydrophilic biopolymer solutions. The cell viability in gel micropatterns was sustained for long periods in the presence of fibroin in the gel. SaOs-2 cells deposited the mineral in the microstructures depending on fibroin content.

Real-time monitoring of chondrocyte activity by electrical impedance measurement

R. Mizota¹, Y. Morita² and E. Nakamachi²

¹ Graduate School of Life and Medical Sciences, Doshisha University, Japan

² Faculty of Life and Medical Sciences, Doshisha University, Japan, ymorita@mail.doshisha.ac.jp

INTRODUCTION

In cartilage regeneration, it is important to evaluate effects of mechanical and electrical stimuli in terms of cell activity, gene expression and extracellular matrix (ECM) synthesis. Histological observation and biochemical analysis were carried to estimate synthesis of ECM, but these analyses have problems such as long processing times for sample preparation and disruption of ECM including chondrocytes because of enzyme treatment and homogenization. Therefore, it is difficult to evaluate continuously cell activity and cell response against the stimulation. There is a need to develop new method to achieve real-time monitoring of cell response without damaging cells to investigate optimal stimulation condition. It is expected that activity of chondrocytes is estimated by measuring change in microelectrodes impedance caused by synthesized ECM with an electrical impedance method. The purpose of this study was to develop real-time evaluation method for activity of chondrocytes using an electrical impedance method.

EXPERIMENTAL METHODS

Fabrication of culture device: The culture device was prepared to measure electrical impedance during cultivation as shown in fig. 1. It consisted of an array of interdigitated electrodes on a glass substrate and a polycarbonate chamber. The interdigitated electrodes were fabricated on glass surface using a photolithographic procedure. The interdigitated electrodes were patterned and deposited by sputtering of platinum and the array had a total of 40 pairs of finger electrodes. The width of the electrodes and the distance between the electrodes were both 100 μm .

Cell culture: Chondrocytes were isolated from the distal femur of 6-month-old pigs. Chondrocytes were seeded into the culture device at a cell density of 1.0×10^6 cells/cm², and chondrocytes were cultured in a humidified atmosphere of 95% air with 5% CO₂ at 37 °C for 7 days. Dulbecco's modified Eagle's medium supplemented with 10% bovine serum and ascorbic acid was prepared as culture medium. Electrical impedance measurement was carried out every 24 hours. Measurement of glycosaminoglycan (GAG) amount and microscopic observation with safranin-O staining were carried out after 3 and 7 days of cultivation.

Electrical impedance measurement: Electrical impedance of the array at a frequency of 100 kHz was measured under voltage of 10 mVrms using a potentiostat. The measurement was started 2 hours after the culture devices were put into the incubator. In this study, the electrical impedance at each cultivation day was normalized by the initial electrical impedance at 0h.

RESULTS AND DISCUSSION

Figure 2 shows transition of the normalized impedance with cultivation days. The normalized impedance without chondrocytes was constant through cultivation. On the other hand, the normalized impedance with chondrocytes decreased with cultivation days, and it decreased by 3% after 7 days of cultivation. Morphology of chondrocytes did not change and the number of chondrocytes did not increase after 7 days of cultivation. According to microscopic observation with safranin-O staining, synthesized ECM around chondrocytes was observed after 3 and 7 days of cultivation, and the amount of GAG increased with cultivation days. Therefore, the normalized impedance depended not on morphology and the number of chondrocytes but on the amount of ECM, and it decreased with increasing the amount of GAG. These results showed that activity of chondrocytes can be estimated by measuring change in the electrical impedance caused by synthesized ECM.

CONCLUSION

The normalized impedance with chondrocytes decreased with increasing synthesized ECM. Our results showed that the activity of chondrocytes can be estimated using the electrical impedance measurement with the interdigitated electrodes.

Dynamic Hardness Evaluation of Two Phases of Au-xPt-8Nb Alloys for MRI-artifact-free Biomedical Devices

S. Inui, E. Uyama, E. Honda and K. Hamada

Institute of Health Biosciences, University of Tokushima, Tokushima, Japan, c301251012@tokushima-u.ac.jp

INTRODUCTION

A metal artifact due to volume magnetic susceptibility (χ_v) mismatch between metal devices in the human body and the human tissue is a major magnetic resonance imaging (MRI) artifact. The authors have developed Au-Pt-Nb alloys as candidates for MRI-artifact-free alloys with χ_v similar to that of the human tissue (approximately -9×10^{-6}) and with excellent mechanical properties¹.

Nb content for artifact-free alloy is fixed to 8 %, since the χ_v of the alloy depends only on Nb content. Hence only Pt content can control the mechanical properties of the alloy. Although the Vickers hardness (Hv) of Au-Pt binary alloy increases with Pt content increase², the Hv of Au-xPt-8Nb alloy decreases with Pt content increase. This reverse dependency makes it impossible to increase the Hv of the alloy by means of Pt content control, and Au-5Pt-8Nb alloy is selected as the candidate alloy for artifact-free biomedical devices.

In this study, the effects of alloy microstructure on the mechanical properties of Au-xPt-8Nb alloy were investigated to clarify the mechanism of the reverse tendency. The microstructure of Au-xPt-8Nb alloy consists of two phases that originated in phase separation of Au-Pt binary alloy from α phase to α_1 phase (Au rich phase) + α_2 phase (Pt-rich phase). The dynamic hardness (Hd) of each phase was examined individually using nano-indentation technique, and the correlation between the Hd of each phase and the Hv of the whole alloy was analysed.

EXPERIMENTAL METHODS

Au-xPt-8Nb ($x = 5-40$) alloy ingots (approximately 4 g) were fabricated by argon-arc-melting. The ingots were hot-rolled to approximately 1 mm in thickness at 973 K. The total rolling reduction was 60–70%. The hot-rolled plate was homogenized at 1273 K for 15 min and then aged at 973 K for 30 min. After hot-rolling and heat-treatment, the specimens were polished finally by

diamond paste with a grain size of 1 μm .

Nano-indentation test was carried out using ENT-1100a (Elionix Inc. Tokyo, Japan). The maximum load and the loading rate were 2000 mgf and 0.2 gf·s⁻¹, respectively. Hd was calculated from the indentation profile. The measurement was performed nine times for each sample and the maximum and minimum values were removed from the mean value calculation. All data were statistically analyzed using Student's t test ($p < 0.05$).

The microstructure of the alloy was investigated by SEM and optical microscope (OM).

RESULTS AND DISCUSSION

Fig. 1 shows Pt content effect on Hd of α_1 phase and α_2 phase of Au-xPt-8Nb alloy. Hd of α_1 phase of alloys above 15Pt were significantly smaller than that of 5Pt alloy. The linear regression of Hd-x for α_1 phase was;

$$\text{Hd} = -3.0 \times x + 198 \quad (R^2 = 0.93)$$

In contrast, Hd of α_2 phase did not indicate clear dependence on Pt content. However, that of 20Pt, 30Pt and 35Pt alloys was significantly larger than that of 5Pt alloy. The linear regression of Hd-x for α_2 phase was;

$$\text{Hd} = 5.2 \times x + 188 \quad (R^2 = 0.44)$$

The OM observation showed the color change of α_1 phase from light yellow to light gold with Pt content increase. It suggested the change of phase composition and also mechanical properties of the phase.

The XRD profiles¹ and microstructure observations indicated that the volume fraction of α_2 phase increased with Pt content increase. However, they suggested that the primary phase of all Au-xPt-8Nb alloys in this study was α_1 phase, and α_2 phase was the dispersed phase. The volume fraction and hardness of dispersed phase should affect the alloy hardness. However, the hardness of the matrix phase might be a dominant factor for Au-xPt-8Nb alloys in this study.

CONCLUSION

The dynamic hardness of α_1 phase of Au-xPt-8Nb alloy decreased with Pt content, which corresponded to the dependence of Vickers hardness of Au-xPt-8Nb alloy on Pt content.

INTRODUCTION

An irreversible loss of subcutaneous adipose tissue in patients after tumor removal or deep dermal burns makes soft tissue engineering an important challenge in biomedical research. The development of a subcutaneous replacement (hypodermis) is still an unsolved problem. The ideal scaffold material should not only be stable for several weeks to serve as a framework for invading cells, but should also be fully biodegradable and hold a certain thickness and elasticity to provide plasticity as filler and shock protection. Certain characteristics such as tensibility or micro- and nano-structure are important to imitate the natural extracellular matrix.

We synthesized new polyurethane-based copolymers with different monomer ratios and different types of hydrolytically cleavable bonds to tune both the mechanical properties and the rate of biodegradation. The main goal of this study was to elucidate the adipose-derived stem cells (ASCs) viability, proliferation and differentiation on the two scaffolds evaluating their potential as a matrix in adipose tissue engineering

EXPERIMENTAL METHODS

A poly(ϵ -caprolactone-co-urethane-co-urea) (PEUU) and a poly[(L-lactide-co- ϵ -caprolactone)-co-(L-lysine ethyl ester)-block-oligo(ethylene glycol)-urethane] (PEU) have been synthesized as recently described.¹ Fleeces of this polymers have been prepared by solution electrospinning using a Spintronic apparatus (E. Huber, Gernlinden, Germany)¹. The material properties of the novel polymers were determined compared to a conventional poly(L-lactide-co-D,L-lactide (70/9, PL) using both polymer foils and fleeces. Polymer degradation was studied in Sörenson buffer at 37°C monitoring polymer weight loss and the released lactide amount over time.

Cell viability, adhesion, and morphology were examined cultivating ASCs on top of the polymers for 48 hours. Cell viability was analyzed by fluorescence staining (fluorescein diacetate/ethidium-homodimer-1), adhesion and morphology after staining the cytoskeleton with TRITC-phalloidin. Proliferation of ASCs grown on the materials was studied by MTT assay. The differentiation potential of ASCs grown on the polymers was determined after cell cultivation for 2 days followed by induction of adipogenesis for 3 days and further cultivation in nutrition medium. On day 21 lipids were stained with AdipoRed. Gene expression analysis of differentiating cells was performed as described.¹

RESULTS AND DISCUSSION

As hypothesized the new synthesized polymers strongly differ from the established biodegradable PL in their application relevant properties. Exemplarily, this is shown in Table 1 for the mechanical properties. Due to the presence of the ϵ -caprolactone soft segment, PEU and PEUU have much lower Young's modulus than PL and show a more elastic behaviour with a higher maximal elongation.

Polymer	Tens. strength [MPa]	Young's modulus [GPa]	max. elongation [%]
PEUU	37±5	0.18±0.01	1072±104
PEU	8 ± 1	0.13±0.08	15±0.7
PL	51 ± 4	1.4±0.3	6±0.6

Table 1: Mechanical properties of PEUU and PEU in comparison to PL.

The degradation of PEU was found to be only slightly diminished compared to PL (reference), whereas PEUU degrades much slower. Varying the type of linkage between the different polymer segments may therefore represent an effective tool to tune the degradation behaviour of scaffold materials.

ASCs were able to adhere, proliferate and differentiate on both PEU and PEUU fleeces. Morphology of the cells was slightly better on PEUU than on PEU showing a more physiological appearance. ASCs differentiated into the adipogenic lineage. Cells were forming lipid droplets showing a physiological phenotypical appearance after 21 days. Gene analysis of differentiated ASCs showed typical expression of adipogenic markers such as PPARgamma and FABP4.

CONCLUSION

Electrospun scaffold materials based on the newly synthesized polymers PEU and PEUU cover a broad range of properties due to their different chemical composition and structure. ASCs were able to adhere, proliferate and differentiate on both polymers. Overall, we can conclude that both PEU and PEUU fleeces are promising scaffold materials for adipose tissue engineering.

INTRODUCTION

Gene delivery requires multifunctional vectors that are site-specific, carry and protect genetic material, and are safe for use in human gene therapy^{1, 2}. Targeted nanoparticle systems are emerging as promising gene delivery vectors², due to their ability to bind, condense and package plasmids, as well as release cargo upon changes in environmental stimuli while protecting the payload against nucleases³. In this study, we aim to construct nanoassemblies of cyclodextrin-based polymer systems involving the functionalization of targeting peptides, incorporation of stimuli-responsive features and multivalent interactions between specific moieties. This can then be utilized to engineer “smart” supramolecular nano-carriers that can efficiently deliver plasmids to a specific location, providing an effective alternative to viral vectors.

EXPERIMENTAL METHODS

Three self-assembling polymer components based on CD were synthesized to form a cationic, DNA condensing polymer (CDP), a pH-sensitive, membrane destabilising CD-loaded polyrotaxane (CDT), and a peptide-conjugated polymer (CD-pep). The conjugation efficiency of these polymers was determined by FTIR and ¹H-NMR. They were then self-assembled to form supramolecular nanoparticles (SNPs) and were assessed by dynamic light scattering (DLS). Picogreen assay was used to investigate the binding capacity of the SNPs to the plasmids, which was further determined by DNA retardation assay. Cytotoxicity of polymer components was evaluated by CCK8 assay. Targeted transfection of cardiac fibroblasts with SNPs displaying RGD and DDR2 ligands were investigated using fluorescent microscopy and FACs. All biochemical assays and biological studies were performed in triplicate and reported as mean ± standard deviation.

RESULTS AND DISCUSSION

Polymer conjugations were validated by FTIR and ¹H-NMR.

Samples	Size (D _h , nm)	Zeta potential (mV)	PDI
pDNA	103.1 ± 21.1		0.69 ± 0.06
pDNA-CDP	72.6 ± 26.2	42.8 ± 0.78	0.49 ± 0.09
pDNA-CDP/CDT	137.9 ± 3.5	36.4 ± 3.3	0.29 ± 0.01
pDNA/SNP-RGD	263.3 ± 10.8	10.6 ± 0.45	0.19 ± 0.01

Table 1. The Characterisation of the Self-Assembled Polymer. Results are reported as mean ± standard deviation.

Figure 1. a) Gel electrophoresis of cationic polymer in different N:P ratios. b) Picogreen assay of binding capacity of particles to pDNA. Fluorescent images of transfected cardiac fibroblasts using c) RGD-targeted and d) DDR2-targeted nanoparticles. Scales bars represent 100µm.

These particles were shown to assemble in aqueous conditions as shown in Table 1, with a decreasing surface charge due to the addition of the polyrotaxane and targeting ligand. This indicates that the polymers interact to form a self-assembled structure. The CDP polyplexes were shown to fully bind to pDNA at N/P ratio of 2.5 as confirmed by gel electrophoresis and Picogreen assay (Fig. 1a, b). The polymer components were found to be non-toxic to cells. Figs. 1.c, d show that the particles can transfect primary cells in a targeted and specific manner with 5% efficiency. Future work is ongoing to enhance transfection outcomes.

CONCLUSION

In summary, we have developed a multifunctional, self-assembled supramolecular nanoparticle system which possesses pH-sensitive features and targeted specificity. This study has confirmed that this nanoparticle system can be loaded with plasmids, target and transfect specific cell types. This strategy has great potential for the design of future nanovectors for use in therapeutic treatments.

Biological Properties of an Acellular Xenogeneic Tendon Graft following Chemical and Irradiation Sterilisation

J H Edwards¹, J Fisher¹ and E Ingham¹

¹Institute of Medical and Biological Engineering, University of Leeds, Leeds, UK, j.h.edwards@leeds.ac.uk

INTRODUCTION

Damage to the anterior cruciate ligament (ACL) is increasingly common within a young and active population. In the case of ACL tears, replacement with autograft tendon is the gold standard treatment to maintain stability within the knee joint. Such grafting can cause donor site morbidity and associated problems for the patient¹ and a promising alternative is the use of acellular xenogeneic tissue. This study investigated the biological properties of an acellular porcine superflexor tendon (pSFT) graft following chemical and irradiation sterilisation methods.

EXPERIMENTAL METHODS

Acellular pSFT were produced following an established method involving peracetic acid (PAA) treatment for bioburden reduction and low concentration SDS for decellularisation. Grafts were packaged and stored at -80°C. Groups of tendons (n=6 in all cases) were sterilised using: PAA alone (standard method), 30 or 55 kGy gamma and 34 kGy electron beam (E-beam). Samples were analysed immediately after treatment and after 3 months storage at 4°C. The biological properties of the pSFTs were determined by histology (tissue structure), collagen (hydroxyproline assay) and denatured collagen (alpha chymotrypsin treatment) content, second harmonic generation (SHG) imaging (collagen structure) and *in vitro* biocompatibility assays. Biomechanical properties of grafts were assessed in a separate study. Two-way ANOVA was used to determine significance of differences between treatment groups (Tukey post-hoc analysis, p<0.05).

RESULTS AND DISCUSSION

Sterilisation using PAA or irradiation treatment did not cause any change in collagen content within the tendons immediately or three months after treatment. Denatured collagen content was increased significantly in irradiated samples at both timepoints (55 kGy > 30 kGy Gamma, 34 kGy E-beam > PAA only) (Figure 1).

Sterilisation and storage of grafts did not have any adverse effects on the *in vitro* biocompatibility of the tendon samples. Histological analysis showed some flattening of collagen crimp and separation of fibre bundles within the irradiated tissue samples (Figure 2). SHG imaging did not show any differences in collagen structure for any treatment group.

These results showed that irradiation sterilisation caused some disruption to the tendon structure, likely due to free radicals generated during the irradiation process. Although this had no effect on biocompatibility, it would be preferable to reduce these changes in order to ensure mechanical integrity of the grafts after implantation.

Figure 1: Denatured collagen content of pSFT samples following chemical and irradiation sterilisation. Results show mean ± 95% CI (n=6). * denotes significant differences compared to PAA only controls.

Figure 2: Sirius red staining in PAA (A,B) and 55 kGy Gamma (C,D) sterilised tendons after 3 months storage. Arrows indicate separation of bundles, scale bars show 200 µm.

CONCLUSION

Although irradiation sterilisation did not affect *in vitro* biocompatibility or collagen content of the tendon grafts, damage to the collagen structure was evident compared to PAA only controls. Fractionation or lower irradiation doses will be studied in the future in an attempt to reduce the adverse effects of the terminal sterilisation methods on this acellular pSFT graft. The effects of longer term storage of grafts will also be investigated to understand their suitability as an 'off the shelf' ACL repair solution.

Improved early cell adhesion on bioinert ceramics by alkaline phosphatase immobilization

Aliieh Aminian*, Bahareh Shirzadi, Laura Treccani and Kurosch Rezwani

Advanced Ceramics, University of Bremen, Germany

* aminian@uni-bremen.de

INTRODUCTION

Early, firm adhesion and spreading of bone cells on biomaterials is considered a prerequisite to achieve fast implant integration and tissue healing. As these processes are protein-mediated, surface functionalization and activation with immobilized biomacromolecules are considered a highly promising strategy for the biomaterial interface improvement. The enzyme alkaline phosphatase (ALP) is known to play a central role in bone formation, osteoblast cell differentiation and mineralization. Different studies demonstrated in the presence of organic phosphates, immobilized ALP can trigger the formation of calcium phosphate on metal surfaces¹ and enhances bone cell mineralization². In this work ALP was specifically employed to biofunctionalize and bioactivate the surface of two highly bioinert ceramics, alumina (Al_2O_3) and yttria-stabilized zirconia (Y-TZP), which due to their remarkable mechanical, chemical properties and biocompatibility are widely applied for dental and load bearing orthopaedic implants. ALP was covalently immobilized on them and its effect on early cell attachment and spreading of mesenchymal stem cells (MSC), human osteoblasts (HOB) and human osteoblast-like MG-63 cells was investigated under serum-free conditions to prevent the effect of other adsorbed proteins³.

EXPERIMENTAL METHODS

Prior immobilization Al_2O_3 and Y-TZP substrates were silanized with aminopropyltriethoxysilane (APTES) according to Meder et al.⁴. ALP was covalently immobilized via carbodiimide-mediated chemoligation assisted by active esters using via the biocompatible zero-cross linking system N-(3-Dimethylaminopropyl)-N'-ethylcarbodiimidehydrochloride/N-Hydroxysuccinimid (EDC/NHS).

The attachment of MSCs, HOBs and MG-63 cells on ALP functionalized alumina and zirconia was monitored after 30 min, 2 h, 4 h and 6 h under serum free conditions according to³. Cell morphology, spreading and focal adhesion point was evaluated by immunofluorescent microscopy. Cell nuclei, cytoskeleton and focal adhesion points were stained with 4',6'-diamidino-2-phenylindol (DAPI), Alexa Fluor® 488 Phalloidin and anti vinculin, respectively⁵. Adherent cell number was also quantified with total amount of DNA using Quant-iT™ PicoGreen® dsDNA assay Kit. Cell activity was measured by the WST-1⁶.

RESULTS AND DISCUSSION

ALP immobilized on alumina and zirconia substrates was found to enhance cell adhesion and spreading and more pronounced stress fibers, filopodia and surface-contact area were observed. In figure 1 a representative

image of sHOBs onto ALP-functionalized substrates and non functionalized surfaces is given.

For all type of cells, a higher number of adherent cells was found on ALP functionalized samples in comparison to non-functionalized surfaces. Percentage of adherent human osteoblast cells during the first 6 hours are shown in figure 2.

Fig 1. Immunofluorescence microscopy images of HOBs on non and ALP functionalized alumina and zirconia after 4 hours (Green: cytoskeleton, Blue: cell nucleus, Red: vinculin)

Fig 2. Percentage of adherent HOBs on non and ALP functionalized alumina and zirconia. Cell number was estimated by measuring total DNA amount.

CONCLUSION

Immobilization of ALP to the bioinert surfaces of alumina and zirconia was found to accelerate the initial adhesion of mesenchymal stem cells, human osteoblasts and human osteoblast-like MG-63 cells. These cells have more extended area on ALP functionalized samples than non-functionalized together with higher number of adherent cells. Our results demonstrate that biofunctionalization of inert ceramics with ALP can significantly improve initial steps of the cellular contact to the material surface and a considered highly feasible for designing bioactive materials for bone tissue engineering applications.

INTRODUCTION

In the fields of regenerative medicine, an effective cell separation method that can provide adequate purity, yield, and function after separation have been needed for fabricating transplantable tissues. In the present study, poly(*N*-isopropylacrylamide (IPAAm)-*co*-butylmethacrylate (BMA)), hydrophobized thermo-responsive copolymer, brush grafted surfaces with various BMA contents were prepared through surface-initiated atom transfer radical polymerization (ATRP). Temperature-dependent cells adhesion and detachment behaviour was observed for investigating the possibility of the surface as a cell separating materials.

EXPERIMENTAL METHODS

An ATRP initiator, 2-(*m/p*-chloromethylphenyl) ethyltrimethoxysilane, was modified on glass coverslips as shown in the first step in Fig. 1. Copolymerization of IPAAm and BMA was performed through surface initiated ATRP using CuCl/Me₆TREN as a catalyst and 2-propanol as reaction solvent. In the polymerization, α -chloro-*p*-xylene was added as free initiator and brush length was estimated using the prepared polymer in the reaction solution. BMA feed composition was varied from 0 to 5 mol%. Human umbilical vein endothelial cells (HUVEC), neonatal human dermal fibroblasts (NHDF), were used as model cells for observation of adhesion at 37 °C and detachment at 10 and 20 °C on the surfaces. GFP expressing HUVEC and NHDF were used for observation of cell separating behavior.

RESULTS AND DISCUSSION

Prepared P(IPAAm-*co*-BMA) brush grafted glass surfaces was characterized by ATR/FT-IR, ¹H NMR and GPC measurements. BMA composition increased with BMA feed molar ratio. Contact angle measurement and fibronectin adsorption measurement revealed that surface hydrophobicity increased with BMA composition of grafted copolymer. On observation of cells adhesion and detachment on the prepared copolymer brush, cells adhesion was enhanced with increasing BMA composition of copolymer, attributed to enhanced fibronectin adsorption. For investigating the effective temperature for cell recovery, cells detachment was observed at 10 and 20 °C (Fig. 2). HUVECs exhibited excellent cells detachment at 20 °C. On the contrary, NHDFs tend to detached at 10 °C. Using these cells' intrinsic thermo-sensitive properties for cell detachment, Mixture of HUVEC and NHDF was separated (Fig.3). A mixture of GFP-HUVEC and NHDF was seeded to thermoresponsive copolymer brush surface, and allowed to adhere on the surface at 37 °C. Subsequently, external temperature was reduced to 10 °C for recovering NHDFs. In this incubation

Fig.1 Scheme for preparation of hydrophobized thermo-responsive copolymer brush

Fig.2 Cells adhesion and detachment profiles

Fig.3 Cells separation using P(IPAAm-*co*-BMA) brush

period, NHDFs promptly detached while HUVECs adhered on copolymer brush surfaces. After 30 min incubation at 10 °C, the temperature was raised to 20 °C, and adhered HUVECs were recovered from the copolymer brush surface. The higher ratio of NHDFs and HUVECs was recovered in cell culture medium during the 10 °C and 20 °C incubation periods, respectively. Thus, hydrophobized thermoresponsive copolymer brush separated mixture of cells using cells' intrinsic detachment properties.

CONCLUSION

Hydrophobized thermoresponsive copolymer, P(IPAAm-*co*-BMA), brush can separate mixture of cells by using cells intrinsic thermo-sensitive properties for their detachment. Therefore, the prepared surfaces would be useful as cell separation materials without modification of cell surface.

A Novel Biological Polyester Based Wet Spun Scaffold for Bone Tissue Engineering

selcen.alagoz@metu.edu.tr

INTRODUCTION

In this study, poly(3-hydroxybutyrate-co-3-hydroxyvalerate), PHBV, a biodegradable, natural polymer, was used as an alternative for the petroleum based polyesters to fabricate a wet spun scaffold for bone tissue engineering. VEGF and an elastin like recombinamers (ELR) with REDV sequences specific for endothelial cells¹ were introduced to the scaffold to make it attractive for endothelial cells so that it can be vascularized as needed in a thick implant which otherwise cannot maintain the viability of the cells that have penetrated deep into the scaffold.

EXPERIMENTAL METHODS

PHBV scaffolds prepared by wet spinning were characterized under compression, and fiber morphology and porosity were determined by SEM and micro CT. Surface of the fibers was coated with ELR by exposing PHBV film with oxygen plasma (50 W, 5 min) and then immersing into ELR solution. Toluidine Blue staining and FTIR-ATR analysis were used to show of protein on the surface. AFM was used to study the influence of the treatments used in the binding process. PHBV nanocapsules loaded with BSA were produced by the double emulsion. BSA was used as a model protein instead of VEGF. Size distribution of PHBV nanocapsules was determined by using the Zeta Potential and Mobility Measurement System. These PHBV nanocapsules were incorporated to scaffold fibers by adsorption from a solution. Scaffold was examined with fluorescence microscope and SEM to study final form ready for in vitro studies.

RESULTS AND DISCUSSION

The ultimate compressive strength of dry scaffolds under compression (5 mm/min) was 4.65 ± 0.69 MPa, which showed compressive strength adequate for substituting human cancellous bone (~ 2 -12 MPa) not the native human cortical bone (~ 100 -230 MPa)². The average fiber diameter was about 90 μm and porosity of scaffolds was measured as 75% by using both SEM micrographs processed with NIH Image J program and micro CT data (Figure 1). Blue spots on the surface of ELR attached PHBV films were observed after Toluidine Blue staining. FTIR-ATR showed that upon treatment with O_2 plasma new peaks at around 1530 cm^{-1} and 1650 cm^{-1} was observed due to stretching of carbonyl groups. After ELR attachment, these peaks became more intense. This was probably due to the amide I and amide II groups of ELR attached onto the PHBV film³. AFM micrographs showed that surface roughness decreased upon oxygen plasma treatment

from 343.4 nm to 160.0 nm and increased to 280.3 nm after ELR attachment.

Figure 1: SEM image of the PHBV scaffold

PHBV capsules were found to have an average diameter of 340 nm, with particle size in the range 190-530 nm. SEM images showed that PHBV nanocapsules were attached on PHBV fibers (Figure 2).

Figure2: SEM image of PHBV fibers and VEGF loaded PHBV nanocapsules

CONCLUSION

In this study a biological polyester PHBV, which is an alternative to petroleum based polyesters was used to design a novel cell carrier. It was treated with an endothelial cell attractive ELR and VEGF loaded nanocapsules were attached. Thus, a novel multifunctional scaffold with appropriate mechanical and physical properties could be prepared.

Development of novel hydroxyapatite-chitosan porous 3D scaffolds for biomedical applications

Dimitris Tsiourvas¹ and Triantafillos Papadopoulos²

¹ National Centre for Scientific Research “Demokritos”, IAMPPNM, Dept. of Physical Chemistry, Greece

^{2*} Department of Biomaterials, School of Dentistry, University of Athens, Greece, trpapad@dent.uoa.gr

INTRODUCTION

It is nowadays widely recognized that implantable scaffolds for bone grafting applications should possess materials characteristics close to those of natural bone in order to be successful in their application, and a controlled pore structure that allows cells to migrate and prosper. Consequently, a lot of research efforts are now directed towards the development of porous 3D scaffolds of hybrid inorganic-organic nature based on natural materials possessing osteoconductive properties and excellent biocompatibility and hemocompatibility. Hydroxyapatite (HAp) has been extensively used in biomaterials research because it has the above mentioned properties¹. On the other hand, chitosan (CS) - based materials gained particular attention in the field of medical tissue engineering. Interesting characteristics are its antibacterial nature, the minimal foreign body reaction, and the ability to produce porous structures, suitable for cell ingrowth and osteo-conduction². In this study were prepared and physicochemically characterized 3D porous hybrid scaffolds based on HAp and CS or *N*-acetylated CS and especially scaffolds with high HAp content (75 % w/w) for attaining increased mechanical strength.

EXPERIMENTAL METHODS

HAp nanoparticles having an average radius of ~ 20 nm were synthesized in the presence of poly(ethyleneimine) (MW=5000) following a synthetic procedure analogous to our previous work³. For comparison, HAp powder (Aldrich) was also used. CS (high molecular weight, Aldrich) was dissolved in acetic acid solution (1.5%) and the appropriate amount of HAp was added to obtain a final HAp:CS weight ratio of 75:25. The resulting thick solution was moulded in 6mm diameter tubes and frozen at -25°C. After lyophilisation the resulting cylindrical scaffolds (6mm diameter, 40 mm length) were extensively washed and kept for further characterization. *N*-acetylation of the chitosan scaffolds was attained by immersing the dried scaffolds in a dry methanol solution of acetic anhydride (20%) for 24 hours at 37°C. ATR-FTIR spectroscopy, X-ray diffraction, optical microscopy, scanning electron microscopy with SEI and BEI images in 300x and 600x resolutions, 3-D optical profilometry and μ CT-scan analysis were employed for the characterization of the scaffolds.

RESULTS AND DISCUSSION

ATR-FTIR spectroscopy of the scaffolds confirmed the presence of HAp, and CS or *N*-acetylated CS. X-ray diffractograms also reveal the presence of well crystalized nanohydroxyapatite nanoparticles and the basically amorphous nature of CS. Optical microscopy and μ CT-scan images (Fig. 1A and B respectively)

clearly reveal the open porous structure of the scaffolds. Pores were having dimensions ranging from about 10 μ m to 300 μ m.

Fig 1. (A) Optical micrographs of scaffold sections (the bar represents 1mm); (B) μ CT-scan of a nanoHAp-CS scaffold.

Cross sections of μ CT-scan show a thick fiberlike structure of scaffold with dispersed HAp particles (black points) and irregular voids probably following randomly the setting after freezing of the fabricated liquid material. Vertical sections of μ CT-scan reveal an interlocking of the internal porosity throughout the mass of the scaffold. The optical microscopy and μ CT-scan results were in accordance with high resolution SEM images. The 3-D profilometry results show a bone like roughness of the experimental scaffolds presenting Sa values ranging between 10 and 30 μ m.

CONCLUSION

Based on the results of the present study promising porous scaffolds were developed covering the structural and biological demands for biomedical applications.

INTRODUCTION

Bone repair materials are widely applied in bone surgery, orthopaedics and dentistry¹. Polymeric materials based on polylactic acid (PLA), polyglycolic acid (PGA) and their copolymers are currently available for bone fracture repair applications with low load bearing². Given that bacterial-related complications can appear at early stages immediately after surgery, it is necessary to prevent/inhibit infections and inflammation processes. In this work, novel biodegradable multi-layered drug delivery coatings for polymeric implants are proposed as an strategy to reduce the risk of infections and inflammation simultaneously.

EXPERIMENTAL METHODS

Polymer implant processing: Polymer PLLDL (Purasorb PLLDL 7028, i.v. 2.91 dL/g, copolymer 70/30 L-lactide/DL-lactide, Purac) was used for discs preparation. Discs of 12 mm diameter and 4 mm height were prepared by compression moulding.

Polymer coating onto PLLDL implant: Medical grade poly(L-lactic acid,) PLLA (Purasorb PL 18, i.v.1.8dL/g, Purac) was used. A self-developed controller was used in the experiment for the dip coating process. Coated samples were prepared as follows:

Sample	Number of samples (n)	Coating polymer (Layer one)	Conc. Eugenol	Coating polymer (Layer two)	Conc. Dexamethasone
Control discs	3	8 % PLLA (w/v)	-	-	-
Bare discs	3	-	10% w/w	-	-
One layer discs	3	8 % PLLA (w/v)	10% w/w	-	-
Two layer discs (one drug)	3	8 % PLLA (w/v)	10% w/w	8 % PLLA (w/v)	-
Two layer discs (dual drug)	3	8 % PLLA (w/v)	10% w/w	8 % PLLA (w/v)	5% w/w

Characterization of the coating: Coating thickness (Profilometer), microstructure (SEM), and in vitro release kinetics of the drugs from the coated implants were studied. Eugenol and dexamethasone were quantified by RP-HPLC.

RESULTS AND DISCUSSION

Coatings thicknesses obtained after dip-coating of samples were evaluated by profilometer.

Table 1. Evaluation of obtained coating thickness [μm]:

Coating mode	Number of layers	Coating thickness [μm]
8 X PLLA	1	42.31 (± 2.21)
Eugenol (without polymer)	1	12.41 (± 0.10)
8 X PLLA with eugenol	1	36.36 (± 2.86)
8 X PLLA with eugenol / 8 X PLLA	2	78.85 (± 4.79)
8 X PLLA with eugenol / 8 X PLLA with dexamethasone	2	80.67 (± 2.20)

Table 1 shows that coating with 8% PLLA (w/v) resulted in approximately 10 mg/cm² and that two layer coating had an additive coating mass (20 mg/cm²).

These data were confirmed by the coating thicknesses with the same trend. Eugenol³, the main component of the essential oils of the clove with good local antiseptic and analgesic effect and dexamethasone a steroid used as anti-inflammatory drug and effects on cells⁴ were used. As shown in Figure 1A, polymeric coatings on implant discs have direct effect on the delivery profile of Eugenol. In Figure1B, the release kinetic of a two layer coating is shown in which the upper layer drug is released first and then the second layer drug in a sequential manner.

Figure 1. Evaluation of delivery rates of drugs: A) Eugenol delivery and B) Dual delivery of eugenol and dexamethasone.

This result implies that dip coating technique could be used for multi-layered coating of polymeric implants with sequential dual drug delivery.

CONCLUSION

It is possible to combine and control the sequential release of two different substances from a polymer coating of implants. Only one clinically approved polymer was used for the coating to entrap the substances. Dip-coating is an easy and simple technique for fast and sterile manufacturing process of polymeric bone implants.

INTRODUCTION

In order to quantitatively investigate the osteogenic effects on bone microstructure as well as to quantify the scaffold degradation within biopsy specimens sampled several months after implantation, histomorphometric quantification using synchrotron radiation (SR) X-ray imaging was performed. Compared with the conventional bone histological sections, 3D SR-micro-CT provides higher spatial resolution and contrast, and facilitates a more accurate distinction between newly formed bone and residual biomaterials. In the present study, we synthesized and characterized porous calcium silicate nanofiber / zein scaffolds, and investigated the bone regeneration in rabbit femur cavity defects by using SR-micro-CT.

EXPERIMENTAL METHODS

The calcium silicate nanofiber was synthesized by precipitation and hydrothermal treatment, and was uniformly dispersed into zein with different proportion to compose porous bioactive calcium silicate / zein (CSZ) scaffold for bone implant.

A long-term study in rabbit femur cavity defect model was carried out to investigate the efficacy of CSZ scaffolds in promoting bone repair and regeneration. 24 skeletal mature New Zealand white rabbits were used. Surgical intervention was performed under general anesthesia, afterwards lateral and medial approaches were performed in left shaved knees to exposure the distal femoral epiphysis and the cavitary defects were created with a medium speed burr (5 mm diameter and 5 mm depth). The CSZ scaffolds, as well as dense calcium phosphate cement (CPC) cylinders were implanted into the defects. The empty bony defects served as the control. Prophylactic antibiotic was given for 3 days. The animals were sacrificed for analysis at 4 and 12 weeks after surgery. In an attempt to explore the microstructure of scaffolds and to evaluate the repair process for the bone defects, SR-micro-CT measurements were performed at BL13W of SSRF (Shanghai, China). Bone radiomorphometric analysis was performed by using Image-Pro Plus and VGStudio 2.1. The amount of bone ingrowth into the scaffolds was quantified as the bone volume (BV) within the defined VOI (volume of interest) in each defect site. The bone mineral density (BMD) was also calculated for each region.

RESULTS AND DISCUSSION

The present study demonstrated that CSZ scaffolds exhibited noticeable weight loss in tris-HCl solution over time, indicating that CSZ scaffold was degradable. The in vitro cell culture results indicate that cells

adhered CSZ within the first 4 hours of culture. The superior ability of cells to attach to CSZ is probably associated with different surface features of biomaterials. The addition of silicate may give CSZ special surface properties – the silicon promoted cell attachment – and the hydrophilic surface of CSZ may be beneficial for cell adhesion.

The rabbits were scanned with SR X-ray imaging at 4 and 12 weeks to evaluate the in vivo osteoinductivity of CSZ scaffolds. At 4 weeks, the SR-micro-CT images revealed that obvious orthotopic bone formation in CSZ scaffold group occurred throughout the cross-section of the defect and the biodegradation of scaffolds was observed. Whereas, only a small amount of newly formed bone in dense CPC group appeared at the outer surface of cylinder.

At 12 weeks, the most extensive bone ingrowth was observed throughout the entire volume of the implants for CSZ scaffolds, and the formation of new bone cortex was observed as well. The dense CPC produced significantly less bone formation during the same period although the radiopaque areas enlarged with time. In control group, there was little radiopacity within the defects at both time points and an umbilicated cavity formed in the bone cortex at 12 weeks.

The regenerated bone volumes (BV) and bone mineral density (BMD) within the defect was also calculated to precisely evaluate the repair of bone defects. The results indicated that CSZ scaffold group contained higher bone volume than the dense CPC cylinder and control groups, respectively. A significant increase in BMD was observed for all groups from 4 to 12 weeks, which confirmed the results of the SR-micro-CT analysis. The CSZ scaffold group showed higher BMD values than dense CPC cylinder and control groups at 4 weeks, respectively. At 12 weeks, the BMD value of CZS scaffold was significantly higher than dense CPC cylinder and control groups, respectively.

CONCLUSION

By using SR X-ray imaging with high spatial resolution and density resolution, the cartilage, fibrous tissue and blood vessels around the defects could be clearly observed. Furthermore, three-dimensional and quantitative results of internal structure of the defect area provided a new analytical tools for investigating the mechanism of new bone formation and scaffold degradation.

INTRODUCTION

Peripheral artery disease and related revascularization procedures are increasing due to the aging population and growing incidence of diabetes mellitus. Up to now, autologous saphenous vein represents the conduit of choice for peripheral by-pass. Synthetic vascular graft in polyethylene terephthalate (Dacron®) and expanded polytetrafluoroethylene (ePTFE) are used when the vein is not available. However they have shown poor patency when used in small-diameter sizes (<6 mm) due to thrombosis and intimal hyperplasia. Attempts have been made to reduce the thrombogenicity of synthetic grafts by seeding the lumen with endothelial cells, therefore, the development of scaffolds that can support cell growth has become an important issue in the field of vascular tissue engineering.

The aim of this study was to prepare a composite vascular graft by spray, phase-inversion technique constituted by polyurethane and gelatin able to support cell growth.

EXPERIMENTAL METHODS

Gelatin-based polyurethane (PU-gel) grafts were fabricated co-spraying polyurethane (Estane®5714F1 2% in THF/DX) and gelatin aqueous solution (2%) to obtain a composite vascular graft. After materials deposition, grafts were placed in dH₂O at 4°C o.n. to allow solvents removal. Cross-linking of gelatin (PU-CLKgel) was obtained by exposition to glutaraldehyde vapour for 2 h at r. t. Then samples were immersed in 50 mmol/L glycine solution for 1 h to block residual aldehyde groups of glutaraldehyde. Polyurethane graft without gelatin (PU) was used as control. Graft microstructure was investigated by stereo-microscopical observation of Sudan Black stained samples and SEM. Uniaxial tensile tests were carried out to assess grafts mechanical properties. Static tests were performed until failure occurred on longitudinal and circumferential directions by a computer controlled tensile testing machine (100 N load cell) according to ASTM D412-06a protocol. Six test samples were evaluated for each graft materials and for both directions. For each samples stress-strain data, ultimate tensile strength (UTS), and ultimate elongation (UE) were calculated.

Human Mesenchymal Stem Cells (hMSCs) were obtained from bone marrow aspirate. Cells displaying a mesenchymal phenotype (CD34⁻, CD45⁻, CD44⁺, CD105⁺, CD90⁺ and CD73⁺) were used to evaluate the graft capability to support cell adhesion and growth.

PU-CLKgel and control grafts were punched to obtain round samples (2 cm² area). These samples were placed at the bottom of a 24-well plate and preconditioned in

culture medium for 30 min. hMSCs at passage 6 (six) were seeded onto the graft luminal surfaces (1.4x10⁴ cells/well). After 24, 48 and 72 h of incubation, cell viability was calculated by XTT assay and cells morphology was evaluated by Giemsa staining. Statistical analysis was performed using StatView™ by Student's t test.

RESULTS AND DISCUSSION

Microscopical observation of PU-CLKgel and control graft stained with Sudan Black did not show any difference at 40X magnification, however SEM analysis at higher magnification (500 and 2500X) evidenced differences between samples. The PU samples feature a microporous structure similar to that previously described relating to a polyurethane-polydimethylsiloxane graft obtained by spray, phase inversion technique [1]. The gelatin-based PU samples showed a fibrillar appearance typically to that owned by hydrogel. From the mechanical point of view, the presence of gelatin produced an increase of UTS (17.5% and 35.5%) and UE (9% and 20.6%) in both circumferential and longitudinal directions, respectively, compared to PU material. Similarly PU-CLKgel showed an increase of UTS and UE with respect to PU material.

Qualitative analysis of hMSC adhesion after 24, 48 and 72 h onto the grafts revealed remarkable differences between PU-CLKgel and control graft. hMSCs grown onto PU-CLKgel graft form a monolayer that reached confluence at 72 h and appeared to be similar to the physiological morphology of hMSCs grown on culture plastic. On the contrary cells seeded onto the control graft were not able to undergo appropriate spreading and proliferation, thus displaying a rounded morphology. hMSCs grown onto PU-CLKgel graft showed significantly higher O.D. value then cells seeded onto PU luminal surface at all time-points. Moreover hMSCs onto PU-CLKgel graft showed an increase of O.D. over the time indicating a proliferative activity.

CONCLUSION

A composite vascular graft was successfully produced by simultaneous spraying a synthetic polymer (Estane®5714F1) and a natural biopolymer (gelatin) in order to obtain a scaffold that combines the mechanical characteristics of polyurethanes with the favourable cell interaction features of the biopolymer fibers.

INTRODUCTION

Angiogenesis is the formation of new blood vessels from a pre-existing vascular network. It plays a vital role in the repair of tissues by establishing a blood supply, however, in the case of acute injury the rate of angiogenesis can be slow. It has become a major aim of tissue engineering to be able to restore the blood supply quickly to tissue after injury or in tissue transplantation. Angiogenesis is stimulated by proteins called growth factors. Growth factors have been used to treat ischemic tissue for some time. Application of a single growth factor has had limited success. Therefore, there has been a move towards releasing two or more pro-angiogenic growth factors to induce blood vessel formation.

Two sets of materials have been used to successfully release either vascular endothelial growth factor (VEGF₁₆₅) or platelet derived growth factor (PDGF-BB)^{1,2}. These systems mimic heparin through electrostatically binding to the growth factor peptide sequences containing arginine and lysine amino acids. However, the aim is to produce more control over the availability of these growth factors than is possible with heparin functional materials.

EXPERIMENTAL METHODS

OPHP was synthesized from oleyl alcohol (Sigma Aldrich UK) and phenyl phosphodichloridate (Sigma Aldrich UK). PS-co-DVB core OPHP-co-EGDMA shell latexes were produced in an emulsion reactor heated at 70°C with stirring at 400rpm. The latexes containing glycerol methacrylate acetone (GMAC) were produced in the same manner. PBMA latexes were made via surfactant free emulsion polymerization with PAMPS was added as a stabilizer. This produced latexes with PAMPS incorporated. Particle size, zeta potential measurements and TEM were done on all latex samples. To study protein release and binding 0.5ml 100ng/ml VEGF or PDGF (PeproTech UK) solution containing 1% bovine serum albumin was added to each latex sample. The protein was left to bind for 12 hours at 4°C. The protein solution was changed for PBS and samples placed in a 37°C oven for varying time points. Protein release was analyzed using sandwich ELISA kits purchased from R&D systems (Minneapolis, MN 55413). *In vivo* work was done using

several zebrafish transgenic lines. VEGF was released *in vitro* for 7 days then particles and supernatant injected and imaged after a further 3 days.

RESULTS AND DISCUSSION

OPHP and PAMPS based systems showed controlled release of pro-angiogenic growth factors over the period of 31 days. The ratio of OPHP to EGDMA can be altered to give varying release profiles of VEGF₁₆₅ and PDGF BB. The addition of GMAC to the OPHP system produces a slower release profile, without the plateau seen with OPHP-co-EGDMA. The inclusion of GMAC gives a larger outer shell, allowing proteins to bind deeper within the shell of the latex. This gives the steadier release profile seen with OPHP after the inclusion of GMAC.

PAMPS functionalized latexes show steady growth factor release over 31 days, with no burst release. The branched PAMPS have a slower release profile compared to linear PAMPS. This is due to branched PAMPS producing a larger network structure, allowing growth factors to bind deeper within the outer shell of the particle. In contrast, linear PAMPS produced a more open structure which allows for easier diffusion.

In vivo work indicates that the released VEGF is still functional and can elicit a response in endothelial cells.

CONCLUSION

Two novel systems have been developed that can successfully bind and release biologically functional VEGF₁₆₅ and PDGF-BB by electrostatic binding of the growth factors on to or within the outer layer of polymer particles. The shell architecture has a size exclusion effect upon the proteins.

INTRODUCTION

Various surface treatments have been examined to metals and alloys used as biomaterials in order to improve the biocompatibility. Recently, it has been reported that not just microscale but nanoscale environment has affects to cellular behaviour^{1,2}. Electrochemical approach to form highly defined porous alumina and TiO₂ nanotube layers has been reported^{3,4}. Under specific electrochemical conditions, self-organized nanohole arrays can be formed on stainless steel simply by anodization of stainless steel⁵. Cell behaviour of TiO₂ nanotube layers has been extensively examined⁶. But how cells behave on nanohole arrays on stainless steel surface is not clear yet. The present work reports how cells behave on nanohole arrays formed on type 316L stainless steel.

EXPERIMENTAL METHODS

Material examined was type 316L stainless steel, the composition is as follow: Cr: 17.35, Ni: 12.18, Mo: 2.07, Mn: 1.20, Si: 0.63, P: 0.030, C: 0.011, S: 0.001, Fe: Bal. (wt%). The material was cut into samples with a dimension of typically $\phi 15.5 \text{ mm}^2$ and 1 mm thickness. The samples were polished with SiC abrasive paper up to #2000 and finally mirror-finished with colloidal silica, then ultrasonically cleaned in acetone and ethanol, followed by rinsing with deionized water and dried at room temperature. Electrochemical treatments for the nanohole formation were carried out in ethylene glycol containing 2.01 M NaClO₄ using a two-electrode electrochemical cell with a platinum counter electrode. The electrochemical treatments consisted of sweeping the potential at 0.1 V/s from 0 V to a predetermined potential. Five types of specimens were prepared as follows; (a) nanohole anodized at 20 V, (b) nanohole anodized at 30 V, (c) nanohole anodized at 40 V, (d) polished with SiC #2000 and (e) mirror-finished. The diameter and depth of nanohole were measured by scanning electron microscopy (SEM) and atomic force microscopy (AFM). The specimens were sterilized in a steam using autoclave then provided for tests. Osteoblast-like cells (MC3T3-E1) were cultured on the specimens using cell culturing medium (α -MEM with 10 % FBS). The number of cell was counted during the cultivation. Cell activity was evaluated by measurement of ALP (alkaline phosphatase) activity.

RESULTS AND DISCUSSION

Figure 1 shows SEM images of highly ordered nanohole arrays on type 316L stainless steel. The diameter and depth increased in proportion to applied potential. Figure 2 shows the cell density on samples after cultivation of 3 days. The cell density on nanohole samples is significantly larger compared to that on mirror sample. Especially cell density on nanohole sample anodized at 20 V shows the highest. The ALP

Fig. 1 SEM images of type 316L stainless steel surfaces formed at (a) 20 V, (b) 30 V and (c) 40 V for 300 s in ethylene glycol containing sodium perchlorate.

Fig. 2 Cell density of MC3T3-E1 cultured on different surfaces of type 316L stainless steel at day 3. Each value and bar represent the mean and SD ($n=3$). #: $p < 0.05$ vs. mirror. *: $p < 0.05$.

activity on the sample anodized at 20 V is significantly higher than that on other samples. These results indicate that the optimal geometry of nanohole arrays on stainless steel exists for cell compatibility.

CONCLUSIONS

The proliferation and activity of osteoblast-like cell on nanohole array produced on Type 316L stainless steel were examined and the following conclusions are made:

- 1 The cell density on nanohole array is significantly larger compared to that on mirror finished sample. Especially cell density on nanohole sample formed at 20 V shows the highest.
- 2 The ALP activity on nanohole sample formed at 20 V is significantly higher than that on other samples.

INTRODUCTION

Calcium phosphate (CaP) bone cements are frequently used in the reconstruction of bone defects. They possess excellent biocompatibility, are known to be resorbed *in vivo* and could be used to locally deliver therapeutic substances into a defect area. The incorporation of Sr²⁺-ions into such cements and their release into a bone defect upon implantation gives rise to cements that are adapted to the specific needs of osteoporotic bone healing. This concept is based on the dual effect of Sr²⁺-ions on bone cells: while the osteoblast-related new bone formation is stimulated by strontium, the cellular bone resorption by osteoclasts is reduced¹. However, such cements must neither suffer from poor mechanical properties nor show an excess release of Sr²⁺-ions to avoid possible cytotoxic effects.

Here, we investigated an easy-to-prepare, strontium-releasing CaP bone cement (SrCPC) that could support osteoporotic bone defect healing through stimulating new bone formation and inhibiting the osteoclast-mediated bone resorption specifically in the defect area (Fig. 1).

Fig. 1: Concept of Sr²⁺-release from a SrCPC and its action on bone cells.

EXPERIMENTAL METHODS

Sr-substituted CaP cements were obtained by simple substitution of SrCO₃ for CaCO₃ in the precursor of an α -TCP based cement as recently described². Cement paste and set samples were thoroughly characterised with a variety of methods, including XRD, ToF-SIMS, SEM and He-pycnometry. Release of Sr²⁺-ions from set cements was studied in salt buffer solutions and cell culture media w/o serum addition and quantified by ICP-MS. *In vitro* characterisation included experiments focussing on osteogenesis (employing primary human mesenchymal stem cells w/o osteogenic stimulation) and osteoclastogenesis (using osteoclastogenically induced primary human monocytes). Cements were implanted in critical-size metaphyseal defects in female

Sprague-Dawley rats with osteopenic bone status after bilateral ovariectomy and calcium-, phosphate- and vitamin D-deficient diet. Histology, histomorphometry as well as ToF-SIMS were used to analyse the defect area after 6 weeks.

RESULTS AND DISCUSSION

SrCPC set into Sr-substituted hydroxyapatite as demonstrated by XRD and were characterised by a homogeneous strontium distribution within the cement matrix (ToF-SIMS analysis). Substitution resulted in cements with suitable handling properties and enhanced compressive (but not biaxial bending) strength. Sr²⁺-ion release depended on the immersion medium and was hampered by the presence of proteins due to their adsorption. However, SrCPC was shown to release Sr²⁺-concentrations between 0.025 and 0.1 mM (depending on the degree of substitution) under cell culture conditions. Enhanced proliferation and osteogenic differentiation were found *in vitro* using osteogenically induced hMSC cultured on SrCPC compared to pure CaP cement. This could be attributed to the release of Sr²⁺-ions as well as a reduced ionic interaction of the SrCPC with the cell culture medium. Furthermore, osteoclast formation and their resorptive activity (determined by resorption pit formation) were reduced on SrCPC. *In vivo*, enhanced bone remodelling activity as well as higher content of osteogenesis-associated markers (ALP and OCN) and osteoid formation were observed (analysed by histomorphometry and immunohistochemistry).

CONCLUSION

In this study a promising, easy-to-prepare strontium-containing bone cement was developed that could fulfil the specific needs of osteoporotic bone defect healing, namely to enhance osteogenesis and reduce osteoclast-mediated bone resorption.

Mesoporous bioactive glass/CaP bone cement composites as drug delivery system

Matthias Schumacher^{1*} and Michael Gelinsky¹

^{1*}Centre for Translational Bone, Joint and Soft Tissue Research, Technische Universität Dresden, Germany, matthias.schumacher@tu-dresden.de

INTRODUCTION

Calcium phosphate (CaP) bone cements have been used for bone regeneration applications since the early 1980s. Besides their excellent biocompatibility and high bonding strength to natural bone tissue they are known to be resorbed *in vivo*. Furthermore, the mild setting conditions of most CaP cements, in particular, allow the integration of therapeutic substances into the cement. Such therapeutics shall be released upon implantation into the respective bone defect. Besides blending the therapeutics into the cement precursor or adding it into the cements liquid, e.g. polymeric microspheres have been employed to tailor the release kinetics or to protect sensitive therapeutics such as protein-based therapeutics as bone morphogenic proteins (BMP). Furthermore, such adsorption of the drug onto a special carrier or into the pores of secondary particles embedded in the cement matrix, often referred to as “entrapment”¹, might allow the incorporation of different therapeutics with specific release kinetics.

In this study we used mesoporous bioactive glass (MBG) particles to adsorb and sustainably release a model drug from an apatitic CaP bone cement (Fig. 1).

Fig. 1: Principle of drug release via MBG particles embedded in a CPC matrix.

EXPERIMENTAL METHODS

Mesoporous bioactive glass was prepared using a self-assembling method as described by Zhu *et al.*³: during solvent evaporation from a Ca- and phosphate-enriched orthosilicate gel formation of pores (approx. 5 nm in diameter) occurs. MBG was ground and sieved to obtain particles < 20 µm, of which 5 and 10 wt-% were added to an α -TCP based CaP cement (CPC) known to set into carbonated hydroxyapatite⁴.

The obtained cement pastes were characterised regarding their setting kinetics. Set cements were analysed by scanning electron microscopy (SEM, Phillips XL30), XRD (Bruker D8) and mechanical strength was tested in compression mode (Zwick Z1010).

For drug release studies, dexamethasone (DEX, used as a model drug) was adsorbed into the pores of MBG. Cements containing 5 and 10 wt-% of the drug-loaded MBG were prepared. Release of DEX was studied during immersion in phosphate-buffered saline (PBS). Cytocompatibility of CPC/MBG composites was studied using SaOS-2 osteoblasts cultured in McCoy 5A

medium (Biochrom) employing the WST-1 assay (Roche).

RESULTS AND DISCUSSION

Setting of the cement paste was only slightly increased by the addition of MBG and was within the range recommended for CaP cements. XRD analysis confirmed the formation of hydroxyapatite despite of glass addition to the cement, indicating the excess Ca- and phosphate-ions delivered by the highly soluble MBG did not alter the cement setting. Surprisingly, compressive strength increased significantly for MBG/CPC composites (Fig. 2).

Fig. 2: Compressive strength evolution (left) and XRD-pattern (right) of CPC/MBG composites.

Metabolic cell activity on MBG/CPC composites well exceeded the level measured on CPC, which indicates an enhanced cell compatibility of the developed composites. Finally, release of the model drug dexamethasone was shown to be controlled by the presence of MBG particles.

CONCLUSION

We could demonstrate how mesoporous bioactive glass micro-particles can be used to adsorb and sustainably release drug molecules in CaP bone cements without chemical binding. Thus, MBG/CPC composites are a promising system to locally release delicate bone-specific drugs into a bone defect area.

INTRODUCTION

Regenerative medicine and tissue engineering take advantage of biomaterials based on polyurethanes (PU) which exhibit wide range of properties suitable for regeneration of heart muscle, skin, bone, cartilage and nerve tissue. This can be achieved through variable contents of polyol and isocyanate and different ratios. Previous study disclosed multiple influence of β -tricalcium phosphate (β -TCP) on properties of composite materials with PU matrix. Their properties and microstructure could be improved using calcium stearate (CS) and red turkey oil (SCO) [1]. Physical and chemical properties of polyol also influence characteristics of the PU materials. PUs synthesized from poly(ϵ -caprolactone) diol (PCL) promoted cell growth and tissue repair [2]. Previous study showed the possibility of tailoring the hydrophilic properties through varying PEG/PCL ratios in synthesized PUs [3]. PCL contributed to better mechanical properties. Consequently this changed mechanical, thermal properties and degradation kinetics of PU materials [4]. Polyethylene glycol (PEG)/PCL based polyurethanes also exhibited regular microstructure and pore interconnectivity. Moreover, PEG/PCL based hydrogels effectively supported *in vivo* cranial osteoregeneration [6]. The aim of this study is to investigate the influence of varying PEG/PCL ratios on properties of polyurethane foams. The effect of β -TCP on microstructure was also studied. The essence of the present study was to understand relationships between different chemical structure of PU and properties.

EXPERIMENTAL METHODS

PU samples were synthesized via one-step procedure with varying PEG/PCL ratios and addition of β -TCP microparticles. Main substrates used for the reaction include 4,4'-methylene diphenyl diisocyanate (MDI), PEG, PCL, 1,4-butanediol (BDO), CS, SCO and β -TCP. Characterization included FTIR, DSC, TGA, DSA, mechanical and porosity measurements and SEM observations in order to evaluate the *in vitro* bioactivity.

RESULTS AND DISCUSSION

FTIR and DSC/TG measurements showed the relationships between phase separation and content of PEG and PCL. Contact angle values and mechanical properties also changed with varying PEG/PCL ratios. β -TCP affected formation of hydrogen bonds. Figure 1 presents photos of cross section taken with optical microscope.

FIGURE 1 Cross section of PU samples synthesized from a) PEG b) PEG/PCL (50/50 wt/wt) c) PCL

CONCLUSION

Present study showed the possibility to modulate the properties of PU/ β -TCP foams via different PEG/PCL ratios. Exothermic effect of the polymerization also depended on the PEG/PCL ratios. The obtained polyurethane samples exhibited properties more suitable for bone tissue engineering.

Effect of fibre reinforcement on the crystallinity of PEEK for articular joint implants

Marco Regis^{1,2*}, Simonetta Fusi¹, Michele Pressacco¹, Marco Zanetti² and Pierangiola Bracco²

¹R&D Department, Limacorporate, Italy

^{2*}Chemistry Department, University of Torino, Italy, marco.regis@limacorporate.com

INTRODUCTION

In recent years, a lot of interest has grown on the use of PEEK and its composites in orthopaedic applications [1]. To date, the use of PEEK is limited to spine and trauma implants. In particular, concerns on wear resistance, as well as on body reaction to wear debris, and on material properties evolution during the in vivo use of PEEK were risen [2, 3], limiting its application in articular joints. As for every semi-crystalline polymer, PEEK properties largely depend upon its crystal structure. PEEK crystallinity has been extensively studied [4], but only little data is available on the effect of reinforcement addition on its crystallization behaviour, as well as on the resulting properties [5]. The aim of this study is therefore to investigate the effect of a carbon fibre reinforcement addition on PEEK crystallisation behaviour, to provide a material with controlled properties and enhanced mechanical performance to further extend the use of PEEK in orthopaedics.

EXPERIMENTAL METHODS

Non isothermal melt crystallization DSC studies were carried out to determine crystallization behaviour of unfilled PEEK (NI1) and two formulations of 30% wt. carbon fibre reinforced (CFR) PEEK, PAN and pitch based, named NI1CA30 and Motis, respectively (Invibio, UK). 6,5 to 8,5 mg samples were prepared from granules and tested in a TA Q20 DSC (TA inc, USA). Hermetic pans were chosen to encapsulate the samples. After a preliminary heating up stage at 400°C for 15 minutes, to eliminate the residual crystallinity and the small nuclei that might influence the crystal growth kinetics, samples were cooled down to 30°C at different cooling rates (2, 5, 10, 20 and 50°C/min). The tests have been repeated three times for each sample. DSC apparatus was calibrated with Indium samples for each of the cooling rates used in this test. n and Z_t were calculated from the Avrami equation derived from Arrhenius law:

$$\log[-\ln(1 - X_c(t))] = n \log t + \log Z_t$$

where $X_c(t)$ is the relative crystallinity degree at time t . n is the calculated slope of the linear portion of the $\log[-\ln(1-X_c(t))]$ vs. $\log t$ plot curve, and Z_t is the intercept of the same. Z_t has been then corrected taking into account the changes in crystal growth due to the different cooling rates [6]. The resulting samples crystallinity was evaluated as well, by heating up the samples to 400°C at 20°C/min in a subsequent DSC test.

RESULTS AND DISCUSSION

n and Z_c trends are reported in Figure 1. Despite some literature work indicates a decrease in n values with increased cooling rate [7], a clear opposite trend was observed for all materials.

Figure 1. calculated n and Z_c trends at different cooling rates for NI1, Motis and NICA30

Moreover, n values for Motis CFR PEEK were higher than for NI1 unfilled PEEK, while NI1CA30 had lower n values compared to NI1. The $n > 3$ values suggests the growth of spherulite-shaped nuclei, while for $n < 3$, as for NICA30 at 2°C/min, crystals may form in different shapes [8]. The resulting crystallinity of CFR PEEK samples is illustrated in Figure 2 DSC thermograms.

Figure 2. NI1CA30 (right) and Motis (left) crystallinity after the melt crystallisation study.

Peak appearance confirms the different crystal regions formed by varying cooling rates. At lower cooling rates, a second crystal order is formed, enhancing the overall crystallinity. The same trend was observed for each material tested.

CONCLUSION

The results suggest that different carbon fibres can play different roles in PEEK crystallization. Pitch fibres act as nucleation sites for a further crystal growth, while PAN fibres seem to be related to an entanglement obstacle for the chain organization. Also thermal history influences the resulting crystallinity, both in terms of overall amount and in terms of crystal type. This will have an impact on the final mechanical properties and on the in vivo behaviour of the material.

INTRODUCTION

The importance of the use of biocompatible materials for tissue regeneration and transplantation is increasing. The good mechanical and corrosion properties of $\text{Ti}_{40}\text{Zr}_{10}\text{Cu}_{38}\text{Pd}_{12}$ bulk metallic glass (BMG) and its *in vitro* biocompatibility makes it a potential candidate for orthopaedic implants¹. Surface roughness has been identified as a key aspect to regulate cell adhesion, proliferation and spreading. Some authors have described that materials with nano-rough surfaces have improved biocompatibility², although some other studies have shown that the improvement depends on the range of surface roughness³. Here, we report on the effect of nano-mesh surface of $\text{Ti}_{40}\text{Zr}_{10}\text{Cu}_{38}\text{Pd}_{12}$ BMG compared to mirror-like surface and to commercial Ti6Al4V material. We analyse toxicity, adhesion, morphology and differentiation on a human osteoblast-like cell line.

EXPERIMENTAL METHODS

$\text{Ti}_{40}\text{Zr}_{10}\text{Cu}_{38}\text{Pd}_{12}$ disk surfaces were polished to mirror-like roughness and some of them were anodized at 25°C in 5M NaOH to achieve a nano-mesh surface.

Saos-2 cells were cultured in presence and absence of the alloy. Alloy disks were glued onto glass coverslips using silicone, and sterilized by UV light for 2h. Cytotoxicity was evaluated by detecting the activity of intracellular esterases, using live/dead viability/cytotoxicity kit (Invitrogen) according to the manufacturer's protocol. Cell adhesion was analysed by immunodetection of stress fibres (actin) and focal contacts (vinculin) with a confocal laser scanning microscope (CLSM). Cells were processed for scanning electron microscopy (SEM) to analyse their morphology. Differentiation was evaluated by detecting the alkaline phosphatase (ALP) activity after 14 days.

RESULTS AND DISCUSSION

Results indicated that $\text{Ti}_{40}\text{Zr}_{10}\text{Cu}_{38}\text{Pd}_{12}$ BMG had no effect on cell viability, because no significant differences were observed among the two different surface topographies and the commercial Ti6Al4V. The number of live cells was higher than 97% in all cases. These results are in agreement with a previous study of biocompatibility of mouse preosteoblasts grown on this BMG¹. In all cases, Saos-2 cells were able to adhere to

the alloy, showing focal contacts and a flattened polygonal morphology (Fig.1).

Osteoblast differentiation was analysed after 14 days in culture using ALP activity, which increases with osteoblast differentiation. ALP activity was higher on $\text{Ti}_{40}\text{Zr}_{10}\text{Cu}_{38}\text{Pd}_{12}$ alloy than on Ti6Al4V, indicating that the BMG alloy allows a better osteoblast differentiation than the commercial one. Moreover, ALP activities in mirror-like and nano-mesh surfaces indicated that nano-roughness does not affect Saos-2 differentiation.

Fig. 1. SEM images of Saos-2 cells adhered to the nano-mesh surface (left) and to the mirror-like surface (right).

CONCLUSION

$\text{Ti}_{40}\text{Zr}_{10}\text{Cu}_{38}\text{Pd}_{12}$ BMG is biocompatible for human osteoblast-like cells in both surface structures, mirror-like and nano-mesh. Moreover this alloy seems to allow a better osteoblast differentiation than the commercial Ti6Al4V alloy.

INTRODUCTION

Poly-L-lactic acid (PLLA) is a biocompatible and biodegradable polymer; PLLA nanofibrous scaffolds are suitable for tissue engineering, since they mimic the fibrillar arrangement of the extracellular matrix. Indeed topographical, morphological, and mechanical properties of nanofibrous scaffolds are very similar to the properties of different tissues and organs. Continuous polymeric or inorganic fibers having dimensions ranging from tens of nanometers to a few microns can be produced with the electrospinning technique¹: PLLA can be successfully processed into nanofibers through electrospinning starting from a polymeric solution containing the polymer dissolved in organic solvents, such as dichloromethane (DCM) and dimethylformamide (DMF). The latter is usually added to DCM in order to increase the dielectric constant of the solution, thus ensuring electrospinnability. However, the boiling temperature of DMF is around 153°C (higher than that of DCM which is about 40°C), and it is therefore difficult to completely avoid traces of residual DMF in the produced nanofibers, with the risk of unacceptably affecting cell proliferation. In this work, atmospheric pressure non equilibrium plasma is introduced to favour the electrospinning process through the treatment of the polymeric solution; defect-free fibers were produced from a plasma treated solution of PLLA dissolved in 100% DCM, without the addition of DMF. The same solution lead to the production of strongly defected fibers when plasma treatment was not performed.

EXPERIMENTAL METHODS

PLLA (Lacea H.100-E, Mw = 8.4×10^4 g/mol, PDI = 1.7) was supplied by Mitsui Fine Chemicals. DCM was purchased from Sigma–Aldrich. PLLA was dissolved in 100% DCM at 8, 10, and 13% w/v concentrations. Different plasma sources operated at atmospheric pressure were used: a direct liquid phase discharge reactor, a gas phase discharge reactor with liquid electrode and a single electrode argon plasma jet². The plasma sources were driven by different high voltage generators, either producing pulses with a slew rate of few kV/ns or producing waveforms (sinusoidal, triangular and square) with a slew rate of few kV/us. Polymeric solutions were plasma treated and kept at room temperature (RT) before being electrospun. The treatment was performed by randomly moving the source at constant stand-off.

The electrospinning apparatus, made in house, was composed of a high voltage power supply, a syringe pump, a glass syringe, a stainless steel blunt-ended

needle connected with the power supply electrode and a grounded aluminium plate-type collector.

RESULTS AND DISCUSSION

SEM images of fibers electrospun starting from a solution of PLLA dissolved in 100% DCM are presented in Fig.1. While the electrospinning of the pristine solution resulted in no fiber formation (left), plasma treatment was found to enable the production of nanometric defect-free fibers (right)³. The effects of treatment time, electrical parameters sustaining the plasma discharge (voltage, frequency and waveform), delay time between plasma treatment and electrospinning, as well as the type of plasma source, have been investigated in order to optimize the process. Among the tested conditions, the best results have been obtained using the plasma jet driven by nanosecond pulses, which resulted in the production of defect-free nanofibers. Moreover, the improved electrospinnability of the solution after plasma treatment was found to last for more than three hours.

Fig.1 SEM images of PLLA fibers obtained from untreated solution (left) and solution treated with the plasma jet driven by nanosecond pulses (right).

CONCLUSION

The production of solvent- and defect-free PLLA nanofibrous scaffold suitable for tissue engineering and biomedical application was achieved through atmospheric pressure plasma treatment of the electrospinning polymeric solution.

INTRODUCTION

Enzymes are finely tuned biological catalysts that perform chemical reactions, with high specificity, however, loss of activity is observed if denaturation under non-optimal conditions. By using the self-assembled, peptide, VKVKVEVK¹ hydrogels we have investigated whether we can create an enzyme functionalised biomaterial that is capable of performing the enzymatic biotransformations and whether the enzymatic activity can be maintained and/or 'superactivity' observed. To develop this material we have chemically and/or genetically conjugated the self-assembling VKVKVEVK tag to the enzymes; pentaerythritol tetranitrate reductase (PETNR)^{2,3} and carveol dehydrogenase (CDH)⁴ so that they can be incorporated within the hydrogel *via* the interaction of the octapeptide tag with the octapeptide fibres.

Figure 1. Cartoon of tagging, and interaction with fibre.

We hypothesise that by tagging the enzymes a reduction in leeching from the hydrogel will be obtained, thus increasing the longevity of the hydrogel bioreactors.

EXPERIMENTAL METHODS

Gas chromatography (GC) has been applied to determine the extent of biotransformations in solution and hydrogel enzyme experiments.

UV-Vis spectrometry is applied to monitor the leeching of the enzyme out of the hydrogel. A UV-Vis spectrophotometric method has been developed to assay gel enzyme activity.

Rheology, micro differential scanning calorimetry (μ DSC), atomic force microscopy (AFM) and small angle neutron scattering (SANS) have also been employed to obtain structural and morphological information.

RESULTS AND DISCUSSION

We have successfully tagged two enzymes; PETNR and CDH with VKVKVEVK tag, and been able to incorporate them into hydrogels whilst retaining activity. The tagging of PETNR has reduced the leeching from ~98 % release to ~7 %. The tagging of CDH allows hydrogel incorporation without the enzyme precipitating unlike non-tagged CDH. This shows that

the longevity of the catalytic biomaterial has been increased. PETNR functionalised hydrogels have been shown to be able perform biotransformations whilst retaining native enantio and stereo specificity.

Figure 2. Transformation of ketoisophorone to levodione *via* PETNR.

The reusability of these hydrogels has been shown to be possible for up to 9 months, whereas PETNR in solution is inactive after 2 months. Thermal protection of the enzyme afforded by the hydrogel has been observed for elevated temperatures, and explained up by μ DSC data.

Activity studies have shown that by incorporating enzyme within VKVKVEVK hydrogels that denaturation through non-optimal conditions can be perturbed, thus maintaining activity.

CONCLUSION

The experiments undertaken show that incorporating enzymes within VKVKVEVK hydrogel biomaterial the reusability, longevity and operating conditions of PETNR can be expanded. This holds a lot of promise stabilising enzymes that are usually unstable, and may even up new reaction avenues. By bi-functionalising hydrogels enzymatic cascades are possible, thus allowing easy biphasic extraction, reducing time and solvent usage.

schlosshauer.burkhard@nmi.de

INTRODUCTION

Postsurgical adhesions often lead to a pathological fibrosis which can cause severe dysfunctions of affected organs including heart, spine or gut. Therapeutic approaches focus on keeping lesioned tissue surfaces apart to prevent their fibrotic adhesion. This can be achieved e.g. by the implantation of a resorbable spacer such as a biocompatible membrane. In contrast, we use a cell-neutral hydrogel, that has previously been applied to support autologous chondrocyte transplantation for cartilage repair (1-3) to develop a novel *adhesion barrier*. The hydrogel concept includes albumin crosslinked via a thiolated polyethylene glycol crosslinker as bulk matrix and hyaluronate for enhanced viscosity during gel formation. Desired features of the implant material are: polymerisation *in situ*/adaptation of any tissue topography, rapid gel formation, minimally invasive and injectable, adhesive to organ surfaces, biocompatible, non-inflammatory, resorbable and ultimately, prevention of postsurgical adhesions.

EXPERIMENTAL METHODS

The modified hydrogel (technically termed "InGel") was produced by rapidly mixing two solutions: (1) purified maleimide-functionalized albumin and (2) bis-thio-polyethylene glycol. Gelation kinetics and viscoelastic properties were determined by rheology. Fluorescently labelled albumin and dextran beads were added to gel solutions to improve detectability of the gel matrix for subsequent experimentation and to analyse states of intermixing.

Fibroblasts were cultured on InGel for different intervals to determine cell adhesion and viability *in vitro* (microscopy and resazurin assay). Cell migration was monitored by time-lapse video recording. Cell infiltration and gel disintegration was monitored by immunocytochemistry of cryosections. Protease induction *in vitro* was analysed by gel zymography of conditioned media from cells cultured on InGel. Adhesion barrier function was histologically characterized after application of InGel into rats after lesioning of the abdominal peritoneum and the opposing cecum. Positive controls did not receive any implants. The postoperative periods were 4 weeks.

RESULTS AND DISCUSSION

Albumin and PEG-crosslinker solutions formed hydrogels macroscopically within a minute after mixing. Rheological analysis revealed that the storage modulus G' of InGel was significantly higher than the viscous modulus G'' , indicative of the hydrogel being able to resist structural changes under strain. Though fibroblasts attached to hydrogels, the cell permissiveness of the gel surfaces was clearly restricted as evident from decreasing cell numbers with ongoing time *in vitro*. Furtheron, time lapse video recording suggested that cell migration was impaired. Importantly, no significant cytotoxicity was evident *in vitro*. Longterm exposure of cells to gels did not induce the expression of specific secreted matrix metalloproteinases as shown by gel enzymography which was consistent with prolonged gel integrity after implantation into rodents. Distinct MMPs are possibly not instrumental in gel degradation. Simultaneously, hardly any infiltrating cells were observed in the gel matrix after culturing.

Because of the principle biocompatibility, the promising restricted cell permissiveness and the suitable degradation profile, we initiated *in vivo* experiments in the rat abrasion/incision model. Pilot experiments demonstrated that InGel reduced the formation of postsurgical adhesions which otherwise were evident in all positive controls. Histological analysis supported the notion that also collagen deposition was reduced in the presence of InGel in comparison to positive control animals.

CONCLUSION

InGel displayed proper gelation, viscoelastic properties, restricted cell attachment, resorption kinetics and prevented largely the formation of postsurgical adhesions. Thus, restriction of pathological fibrosis fostered recovery of lesioned tissues. Therefore, InGel could possibly be used for adhesion prevention in general surgery.

INTRODUCTION

Electrospinning is a versatile method for production of matrices aimed at tissue engineering purposes including wound dressings, as these matrices are structurally similar to the extracellular matrix (ECM). Synthetic biodegradable polymers like Poly(L-lactide-co-D/L-lactide) (PLA) are suitable materials for these applications. However, one problem of PLA is its hydrophobicity which impairs initial protein adsorption and cell adhesion.

A plasma polymerized allylamine (PPAAm) film was shown to provide hydrophilic coverage with positive surface charge aimed at enhanced interactions with hyaluronan, a major component of the ECM. Furthermore, PPAAm-coatings have been demonstrated to promote adhesion of human osteoblasts (MG-63), gingiva epithelial cells (Ca9-22) and uroepithelial cells (SV40-HUC-1)^{1,2}. Furthermore, the *in vivo* inflammatory tissue response for PPAAm-coated titanium plates was comparable to uncoated plates shown in a previous study³. Therefore, the present study aimed at evaluating the influence of a PPAAm coating on the local inflammatory reactions against electrospun PLA fiber meshes.

EXPERIMENTAL METHODS

Implant samples. Pieces (5×5 mm) of electrospun PLA meshes were cleaned with O₂ plasma only (PLA), or cleaned and additionally coated with a PPAAm film (PLA-P).

***In vivo* study.** Each of 24 male Lewis rats received one PLA and one PLA-P sample simultaneously implanted into their neck musculature. After 7, 14 and 56 days, tissue samples containing the mesh matrices were retrieved from 8 animals per experimental day.

Histological examination. Cryosections (5µm) were prepared from explanted tissue samples and stained with primary antibodies for CD68-positive macrophages/monocytes (ED1), CD163-positive tissue macrophages (ED2), total T lymphocytes (R73), IL2R-positive cells (OX39), antigen-presenting cells (OX6), activated NK cells (ANK61) and the tissue regeneration marker nestin (rat-401) using the APAAP system. Additionally, mast cells were evaluated with toluidine blue staining. Morphometric evaluation of all histological images was performed by digital image analysis using the ImageJ software, and results were expressed as percentage of positively stained area.

Statistics. The non-parametric Mann-Whitney test was used for data analysis.

RESULTS AND DISCUSSION

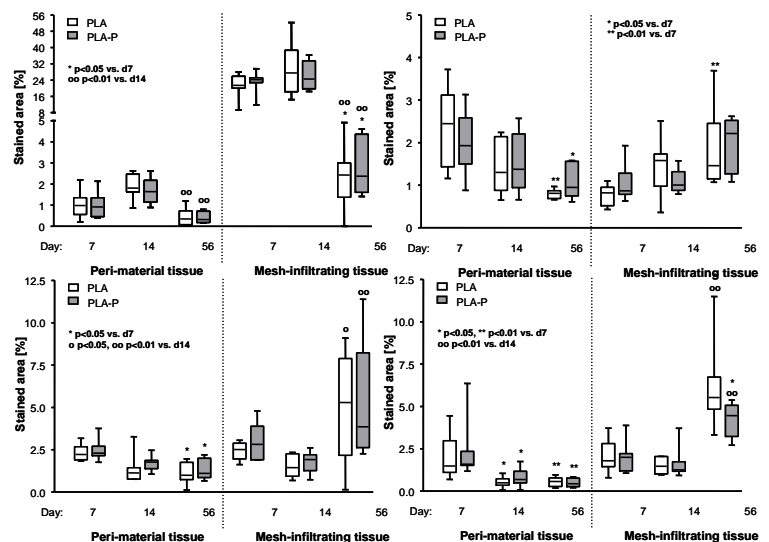

Figure 1: Response of CD68+ monocytes/macrophages (top left), CD163-positive tissue macrophages (top right), antigen-presenting cells (bottom left) and nestin expression (bottom right) in the peri-material and the mesh-infiltrating tissue. Boxes indicate median and interquartile range, whiskers highest and lowest individual value (n=8 animals/day).

CONCLUSION

All examined local inflammatory reactions were comparable for the PLA and PLA-P meshes, demonstrating that PPAAm did not negatively affect the tissue response. Compared to the peri-material tissue, the mesh-infiltrating tissue had a stronger response of pro-inflammatory CD68+ monocytes/macrophages, however declining until day 56. In contrast, anti-inflammatory CD163-positive tissue macrophages decreased in the peri-material tissue and increased in the mesh-infiltrating tissue, accompanied by increasing nestin expression indicating tissue regeneration. Additionally, no differences were found for all other cellular markers. Together with the cell-adhesive effects of PPAAm demonstrated earlier *in vitro*^{1,2} and recent data regarding PPAAm-coated titanium surfaces *in vivo*³, these results illustrate a general potential for PPAAm as a cell-adhesive biocompatible implant coating.

INTRODUCTION

Implantation of biomaterials causes local inflammatory responses in the surrounding tissue which are characterized by the presence of different cell types including macrophages, T lymphocytes, NK cells and mast cells. While inflammatory reactions on the one hand can cause adverse effects like complications and implant failure, on the other hand they play also an important role in beneficial processes such as wound healing and tissue regeneration. Within these processes, macrophages are of central importance due to their ability to degrade and ingest foreign materials and their interactions with other involved cell types.

Recent research indicates that macrophages can be classified into different subsets, with pro-inflammatory M1-type and anti-inflammatory M2-type macrophages being the main phenotypes. To better understand the role of macrophages in tissue regeneration following implantation of biomaterials, the present work aimed at examining the association of different macrophage subtypes with the tissue expression of nestin, a marker of cell proliferation and migration, both characteristic for regenerative processes. For this purpose, two experimental series covering different biodegradable matrices were included in the analysis.

EXPERIMENTAL METHODS

In vivo experiments. In a 1st experimental study, 5×5 mm pieces of electrospun meshes made from poly(L-lactide-co-D/L-lactide) (PLA) were implanted intramuscularly into 24 male Lewis rats. After 7, 14 and 56 days, samples of the peri-implant tissue were prepared from 8 animals per experimental day. In a 2nd study, 12 rats received 5×5 mm pieces of a cross-linked acellular porcine dermis collagen matrix (NRX). Peri-implant tissue samples from these animals were examined after 56 and 112 days, with 6 animals for each day.

Immunohistochemical analysis. Cryosections were prepared from the frozen tissue samples and stained with primary antibodies for CD68-positive macrophages and monocytes (ED1; M1-type), CD163-positive macrophages (ED2; M2-type) and nestin (rat-401). Bound primary antibodies were detected using the APAAP system. Quantification of cellular reactions as positively stained area was performed by digital image analysis using the ImageJ software system.

Statistical analysis. For both series, a correlation analysis (Pearson correlation coefficient; GraphPad Prism 4.03) was performed between the three examined markers from all animals over the respective whole study period.

RESULTS AND DISCUSSION

Figure 1: Scatter plots illustrating the relationship between reactions of CD68-positive macrophages/monocytes (ED1; M1-type) and nestin (left) as well as CD163-positive macrophages (ED2; M2-type) and nestin (right) over all experimental animals and days of the PLA series.

	PLA series		NRX series	
	r	p	r	p
ED1 vs. ED2	-0.4718	0.0016	-0.1810	0.5735
ED1 vs. Nestin	-0.6184	<0.0001	-0.3176	0.3412
ED2 vs. Nestin	0.4252	0.0050	0.2432	0.4711

Table 1: Correlation analysis between stained area of CD68-positive macrophages/monocytes (ED1; M1-type), CD163-positive macrophages (ED2; M2-type) and nestin. Data are given as Pearson's r and p values.

In the PLA series, a significant negative correlation between the amount of CD68-positive pro-inflammatory macrophages/monocytes (M1-type) and CD163-positive anti-inflammatory macrophages (M2-type) was found. Moreover, the CD68-positive macrophages demonstrated a significant negative correlation with nestin expression while the CD163-positive macrophages were significantly positive associated with this marker. Comparable trends without significance were found in the NRX series.

CONCLUSION

As demonstrated by the results obtained with two different implants, tissue regeneration of biodegradable matrices seems to be associated with anti-inflammatory M2-type macrophages. The fact that this correlation was stronger in the PLA series than the NRX series could be explained by the different time points and/or materials, possibly indicating a declining influence of M2 macrophages and/or finalized regeneration with longer implantation duration.

***In vitro* and *in vivo* osteoinductive potential of polycaprolactone-based bioactive composite scaffold fabricated via additive manufacturing technology**

INTRODUCTION

Generally, bone tissue engineering (TE) involves the use a resorbable polymer-based scaffold which lacks osteoinductivity. Therefore, to achieve osteoinductive polymeric-based scaffolds, one can incorporate bioactive materials such as bioactive glass (BG) into the polymeric-based scaffolds. These BGs are bioactive, that is they are able to promote formation of strong bond with bone when in close proximity ^[1, 2]. It has been shown that different composition of BG can provide different effect on cell behaviour ^[3], of which, the incorporation of Sr²⁺ into the BG network has been reported to have beneficial effect on cells by promoting osteoblast activity while inhibiting osteoclast activity ^[4]. Therefore, in this project, we aimed to develop a fully synthetic and resorbable scaffold made of PCL and BG (45S5 or SrBG) intended for the treatment of bone defects by utilising melt extrusion (ME) technique, a form of additive manufacturing technology. The resultant composite scaffold can potentially be highly osteoinductive, thereby circumventing the use of biological factors to induce scaffold osteoinductivity.

EXPERIMENTAL METHODS

Scaffold fabrication and characterisation: composite scaffold made of PCL and 50 wt% of 45S5 Bioglass® (45S5) or strontium-substituted bioactive glass (SrBG) were fabricated using ME technique. Scaffolds' overall morphology, porosity and BG particles distribution were assessed using micro-computed tomography (μ-CT). **Scaffold *in vitro* degradation:** scaffold (PCL, PCL/50.45S5 and PCL/50.SrBG) were immersed in 5M sodium hydroxide (NaOH), at 37°C ^[5]. Percentage of mass loss was presented at time-points. **Scaffold *in vitro* bioactivity:** Scaffolds were immersed in serum-free culture media at 37°C for up to 10 weeks. At time-points, scaffold were retrieved and examined under SEM for surface precipitations, while media were retrieved and analysed for it Sr²⁺ and Si⁴⁺ concentration using inductively coupled plasma-optimal emission spectroscopy (ICP-OES). **Scaffold *in vitro* osteoinductivity:** each scaffold was seeded with 100,000 ovine bone marrow stromal cells and cultured with non-osteogenic or osteogenic media for up to 21 days. The gene expression of osteopontin (OPN) and osteocalcin (OCN) were quantified through reverse transcription-polymerase chain reaction (RT-PCR). **Scaffold *in vivo* osteoinductivity:** scaffold was implanted subcutaneously into the back of nude rats. After 8 and 16 week, scaffold were explanted, histologically processed and assessed for mineralised tissue formation using MacNeal's tetrachrome with von Kossa stain. **Data analysis:** all data were represented as mean ± SD

and were subjected to one-way ANOVA and Tukey's post-hoc test. Significance levels were set at $p < 0.05$.

RESULTS AND DISCUSSION

Structurally, composite scaffold (PCL/50.45S5 and PCL/50.SrBG) highly resembles that of PCL scaffold. In term of scaffold *in vitro* degradation, it was shown that the degradation rate of scaffold was in the order of PCL/50.SrBG > PCL/50.45S5 > PCL, and was similar to our previous findings ^[6]. As compared to our previous study ^[6], increased BG loading into the PCL matrix greatly enhanced the composite scaffold's *in vitro* bioactivity; whereby, calcium-phosphate (CaP)-based surface precipitation was observed after just 1 week. Furthermore, the increased level of Sr²⁺ and Si⁴⁺ ions in the immersion media over time indicated sustained dissolution of BG for up to 10 weeks. *In vitro* cell studies showed that when cultured in non-osteogenic media, OPN and OCN gene expression were upregulated in PCL/50.45S5 and PCL/50.SrBG groups. This phenomenon was not observed for PCL group indicating that the dissolution ions from the BGs have the potential to induce cells to differentiate into osteoblasts. When implanted subcutaneously into the back of nude rats, although it was shown that all scaffolds can support host tissue infiltration, no mineralised tissue formation was observed in any samples after 8 and 16 weeks. This indicated that when implanted subcutaneously into small animal model, the composite scaffolds are not osteoinductive after 8 and 16 weeks. To further evaluate if these scaffolds possess species specific osteoinductivity ^[7, 8], further animal studies using different animal species of soft tissue model is required.

CONCLUSION

Both PCL/50.45S5 and PCL/50.SrBG composite scaffolds show potential *in vitro* osteoinductivity. However, *in vivo*, the osteoinductivity capability was not observed after 8 and 16 weeks,

INTRODUCTION

Poly(lactic acid) (PLA) polymers are eco-friendly, biocompatible and easily processed, which makes it highly attractive for biomedical applications [1, 2]. However, PLA is hydrophobic (results in low cells adhesion), presents an acidic medium when degrading, and lacks surface reactivity [2]. These limitations can be overcome by the incorporation of glass particles [3]. Glass particles can initiate the formation of apatite at the surface making its surface bioactive. This incorporation can be also used to control the degradation rate, and to improve cell adhesion. The basic environment generated by the leaching cations from the glass particles can contribute to a pH increase during PLA degradation, reducing the inflammatory response derived from the acidic pH.

The main objective of this work was to evaluate the suitability of silica-borate glass compositions as fillers of PLA-glass composite formulations targeting bone tissue-engineering applications.

EXPERIMENTAL METHODS

Glass compositions of general formula $0.20\text{B}_2\text{O}_3\cdot 0.40\text{SiO}_2\cdot x\text{MgO}\cdot y\text{CaO}\cdot (0.35-x-y)\text{SrO}\cdot 0.05\text{Na}_2\text{O}$ (molar ratio, where $x, y = 0.35$ or 0.00 , and $x \neq y$) were prepared ($<63\text{ }\mu\text{m}$), and composite fibres were formed by wet spinning of a PLA solution containing a suspension of the glass particles. Fibre meshes ($6\text{mm}\times 2\text{mm}$ discs) of the processed fibres were prepared and their cytotoxicity was evaluated by direct contact with human osteosarcoma cell line Saos-2, throughout 7 days of incubation ($37\text{ }^\circ\text{C}$ and $5\text{ }\%$ CO_2 atmosphere). Cell proliferation (DNA quantification) and metabolic activity (MTS) were monitored for 7 days. It was tested the water uptake and weight loss of the developed systems, as well as their capacity to form a calcium phosphate layer when immersed in simulated body fluid (SBF).

RESULTS AND DISCUSSION

PLA/Glass composite meshes were successfully obtained by Wet-Spinning and Fibre-bonding techniques.

Fig.1 - Cells proliferation profile during 7 days culture of Saos-2.

Three different composites were successfully obtained with 30% (w/w) of each synthesized glass. The cytotoxicity assessment indicates that the cells remain viable during the 7 days of culture (Fig.1) and no cytotoxicity was detected.

An increase in the composite weight loss ($\approx 20\%$ in some cases) was observed when the synthesised glasses were compounded with PLA. For the PLA_BS0.35MgO sample there is an increase of $\approx 5\%$ in the water uptake (when compared with PLA) indicating that the glass particles increase the hydrophilic character of the composite. In addition, the degradation medium increases its pH with time, being consistent with the release of cations from the glass particles.

Fig.2 - SEM images of samples (PLA_BS0.35CaO, PLA_BS0.35SrO, PLA_BS0.35MgO and PLA) after 28 days immersion in SBF at 37°C.

Preliminary bioactivity tests (Fig.2) by immersion of samples in SBF for 28 days showed crystallites with a cauliflower morphology on the top of glass particles, suggesting their ability to induce the formation of hydroxyapatite in the surface of the composites.

CONCLUSION

PLA/glass composites meshes were successfully obtained by Wet-Spinning and Fibre-bonding techniques. Direct contact assay (MTS & DNA) allow us to state that cells remain viable during the 7 days of culture. A preliminary bioactivity screening by immersion of samples in SBF for 28 days suggested their ability to form hydroxyapatite on the surface domains that are closer to the glass particles. Preliminary degradation study indicates a limited degradation and pH increase during this period.

INTRODUCTION

Three main components of tissue engineering are cells, matrix and signalling molecules. Currently, researchers use scaffolds as a temporary matrix that acts as a structural support for cells at the primitive stage of tissue development, both in terms of promoting desired phenotype and regeneration of tissues^{1,2}. Our main objective is to develop fully chemically and physically defined peptide-based hydrogels that can be used as three dimensional scaffolds for cell culture and tissue engineering applications. In this study, we will focus on how to control the stability of peptide hydrogels when used in cell culture conditions.

EXPERIMENTAL METHODS

Hydrogel preparation

Hydrogels were prepared using a series of β -sheet forming peptides (Figure 1) based on our previous work³⁻⁵. These peptides are based on the alternation of hydrophilic (lysine and glutamic acid) with hydrophobic amino acids (phenylalanine or valine).

Stability testing

Hydrogels stability was tested under cell culture conditions by investigating the physical degradation of the hydrogels at 37°C. Hydrogel weight loss, peptide dry content and the mechanical properties of the hydrogels were measured as a function of time.

Bovine chondrocytes were used as model cells to investigate the effect of the presence of cells on the stability of hydrogels. Viability tests and biochemical analysis to measure GAG and total collagen produced by the cells were carried out.

RESULTS AND DISCUSSION

Stability testing provides evidence on how the quality of hydrogels varies with time as a function of a variety of physiological factors. This work provides information on how to control the stability of these hydrogels. In future, this knowledge will allow development of new peptide formulations for increased cell culture duration.

Currently in cell culture application, the hydrogels persist for up to 21-30 days³. The study will also permit us to understand the relationship between peptide hydrogel formulation and stability, as well as the effect in the presence of cells.

CONCLUSION

We are one step forward in our objective to develop three dimensional scaffolds for *in vitro* and *in vivo* cell culture applications, with controlled physical properties and mechanical stability.

INTRODUCTION

Template-assisted electrohydrodynamic atomisation (TAEA), a recently developed surface patterning technique, is able to pattern bioactive nanosized calcium phosphate on titanium to guide osteoblasts [1]. Cell modulus (stiffness) affects many cell functions, for example, its able to correspond with stem cell lineage, and used as a biomarker to distinguish normal and cancerous cells [2]. Studies showed that silicate-substitute hydroxyapatite (SiHA) is a highly attractive alternative to conventional HA in bone replacement [3]. In this study, nanoSiHA was incorporated in TAEA surface patterning to mimic the size and chemical composition of bone mineral. Thus the cellular responses of osteoblasts and dental pulp stem cells to nanoSiHA patterns on titanium (Ti), from cell attachment to cell elasticity, were systematically investigated.

EXPERIMENTAL METHODS

The TAEA process setup is shown in Figure 1a. Freshly prepared nanoSiHA suspension was syringed to the needle at a flow rate of 4 µl/min, and present a cone-jet patterning mode (Figure 1b) with the applied voltage between the needle and the ground electrode set at 4.5-5.5kV. Copper templates with different shape and dimensions were placed on the surface of Ti.

Fig.1 (a) Schematic diagram illustrating the TAEA patterning and (b) A stable cone-jet mode was obtained for patterning

The structure and morphology of nanoSiHA patterns were characterized firstly. The biological responses of human osteoblast (HOB) cells to linear track and pillar patterns of nanoSiHA on Ti were investigated. The proliferation, differentiation and gene expression of HOB cells on nanoSiHA coated Ti was measured by AlamarBlue™ assay, Alkaline phosphatase assay, and Rt-PCR; and the attachment, orientation and elongation length of HOB cells were examined using scanning electron microscopy (SEM) and confocal microscopy. In order to understand the influence of pattern topography on the mechanics of the cell, shear force modulation force microscopy (SMFM) was used to determine the elasticity of osteoblasts (MC3T3-E1) cell and dental pulp stem cell (DPSC).

RESULTS AND DISCUSSION

Well defined nanoSiHA patterns, pillars and tracks of 1 to 5 µm height, were obtained using TAEA. Confocal imaging revealed osteoblast alignment within the patterning (Fig 2a). AlamarBlue™ tests showed the proliferation rates of HOB cells increased when cultured on patterned substrates than those on nanoSiHA coating. An increase of alkaline phosphatase production, an osteoblast differentiation marker, was found on the HOB cells cultured on patterned surfaces, as well as on the pillar and track patterns when the thickness increased from 1 to 5 µm. The expression of ALP was higher for the HOB cells cultured on pillar patterns. Runx-2 expression and collagen production of HOB cells was also increased on track patterns when compared to pillar patterned and nanoSiHA coated Ti.

DPSCs on pillar thickness 1 µm exhibited similar moduli to the cells on the coated surface. The elasticity of DPSC was found to vary greatly depending on the location of the cell, on both track and pillar patterns of thickness 5 µm. Higher moduli were found on MC3T3-E1 cells in comparison with those on DPSCs, regardless of location on the substrate or thickness of the pattern (Fig. 2b). These preliminary findings indicate that the cell lineage can be controlled by patterned topography on the surface of an implant.

Fig. 2 (a) Confocal of MC3T3-E1 cells on nanoSiHA tracks (b) Comparison of modulus of dental pulp stem cells and MC3T3-E1 cells on track pattern, thickness 5 µm

CONCLUSION

Well defined 3-D surface topographies of nanoSiHA on Ti by TAEA patterning have been able to guide and support the growth and proliferation of human osteoblast cells. Interestingly, dental pulp stem cells alter the modulus depending on the surface location.

The Potential Role of Statins in the Regeneration of Osteoporotic Tissue and the Use of Star Degradable Polymers for Controlled Local Delivery

Jason Burke^{2*}, Sarah Cartmell¹, Nicola Tirelli¹

¹School of Materials, University of Manchester, England

^{2*}Institute of Inflammation & Repair, School of Medicine, University of Manchester, England

jason.burke@postgrad.manchester.ac.uk

INTRODUCTION

Statins have been shown to have anabolic effects in osseous tissues via their inhibition of the mevalonate pathway. Changes in the expression of key associated factors such as bone morphogenetic proteins (BMPs), core binding factor alpha 1 (CBF α 1/RUNX2) and vascular endothelial growth factors (VEGFs) have all been shown in a dose dependent response to various statin analogues. Furthermore, statins have also been considered to inhibit the resorption activity of osteoclasts via the same metabolic influences and are again thought to act respective of local statin concentrations.^{1,2}

To fully harness the potential of statins for inducing bone growth in a clinical setting, we believe that optimum local concentrations must be provided in vivo and therefore have sought to provide a reliable, controlled delivery system by utilising the influences of polymer architecture on the degradation, and thereby drug release, of degradable polymers. Degradable star poly(D,L lactic acid) (PDLLA) polymers were synthesised, characterized and then tested for their effectiveness in delivering statins efficiently and uniformly in an in vitro test environment.

EXPERIMENTAL METHODS

PDLLA star polymers were synthesized to form 4-arm and 6-arm samples of varying degree of polymerisation using pentaerythritol and dipentaerythritol polyol initiators respectively. Samples were then characterized (GPC, NMR, FT-IR) alongside linear samples of comparable molecular weights and evaluated in respect of their: degradation kinetics (GPC), erosion kinetics (mass loss, imaging), drug release behaviour (HPLC) and cytotoxicity (MTS, Griess – Raw264.7 cells). Furthermore, samples were also used as substrates for primary human osteoblast (pHOb) cultures, to evaluate the effects of the statin-loaded polymer system on osteoblast activity (ALP assay, RT-PCR (BMP-2, RUNX2, OPN)).

RESULTS AND DISCUSSION

Characterisation showed that reliable synthesis of linear, 4-Arm and 6-Arm PDLLA polymers of various molecular weights was achieved. Cytotoxicity results from Raw264.7 cultures showed all polymers exhibited good biocompatibility. Degradation and drug release studies showed significant differences in the behaviours of the star polymers relative to linear comparisons of equal molecular weight. Degradation was slower and

more uniform in the star polymers while linear polymers followed apparent 1st order behaviour, as can be seen from Fig.1. Drug release behaviour and material erosion followed similar patterns. Finally, osteoblasts exhibited normal levels of activity when cultured on PDLLA substrates and gene expression of key markers was increased in statin loaded samples relative to controls.

Fig.1 – Graph showing the percentage loss in molecular weight of varying star and linear PDLLA polymers during hydrolytic degradation.

CONCLUSION

In this work to date, we have demonstrated the significance of polymer architecture in the degradation of degradable polyesters. The uniform degradation behaviour seen in star PDLLA samples has shown potential for providing controlled drug delivery of statins to local environments in vivo, in attempts to provide anabolic influences in osseous tissues. We are continuing to evaluate these systems and further characterise their behaviour while assessing the response of osteoclasts to the presence of statins in osteoclast-only and in osteoblast-osteoclast co-cultures.

Effective Cellular Uptake of Exosomes Using Cationic Lipids and pH-sensitive Fusogenic Peptide

Ikuhiko Nakase^{1*}

^{1*} Nanoscience and Nanotechnology Research Center, Research Organization for the 21st Century, Osaka Prefecture University, Japan, i-nakase@21c.osakafu-u.ac.jp

INTRODUCTION

Exosomes are ~100 nm cup-shaped vesicles secreted by cells, and substantial attention has been paid to cell-to-cell communications. Genes (including microRNA) and bioactive proteins are encapsulated in exosomes, and they can regulate cellular functions of other marginal cells by cellular uptake of exosomes^{1,2}. In addition, exosomes are expected to represent next-generation biological tools for delivery of therapeutic molecules as nanomaterials, because they have advantages including 1) infinite secretion, 2) additional encapsulation of biofunctional molecules, 3) expression of functional proteins in membranes, 4) no cytotoxicity, 5) no immunogenicity. However, low cellular uptake efficacy of exosomes and insufficient cytosolic release inside cells are problems. Therefore, improvements should be further needed to achieve successful delivery using exosomes. In this presentation, we report our developed technique to attain enhanced cellular uptake of exosomes and cytosolic release with simple method using cationic lipids and pH-sensitive fusogenic peptide.

EXPERIMENTAL METHODS

GALA (pH-sensitive fusogenic peptide, sequence: WEAALAEALAEALAEHLAEALAEALAEALAA) was chemically synthesized by Fmoc-solid-phase peptide synthesis on a Rink amide resin. The structure of the synthesized peptide was confirmed by matrix-assisted laser desorption ionization time-of-flight mass spectrometry. Exosomes derived from CD63-GFP-expressing HeLa cells were purified using Total exosome isolation reagent (Invitrogen), and average size of exosomes was 45 nm analysed using scanning electron microscope. Cells were treated with complex of CD63-GFP-exosomes, cationic lipids (Lipofectamine LTX, Invitrogen), and GALA peptide, prior to confocal microscopic observation and FACS analysis. Encapsulation of Texas red-dextran (70 kDa, Molecular Probes) in exosomes was conducted using electroporation system (NEPA21 Super Electroporator, Nepa Gene).

RESULTS AND DISCUSSION

For improvement of cytosolic release efficiency, we studied effects of pH-sensitive fusogenic peptide, GALA³, to enhance disruption of endosomal and exosomal membranes in the process of intracellular traffic of exosomes via endocytosis. We have already reported that cationic lipids/GALA complex system is useful for efficient cytosolic delivery of proteins^{4,5}. In this research, we challenged to further apply this system

to enhanced cellular uptake and cytosolic release of exosomes.

We firstly examined effects of commercially available cationic lipids, Lipofectamine LTX, on cellular uptake of exosomes for enhancement of binding of exosomes to cell membranes and internalization into cells. Results showed that simple complex of cationic lipids (2% (v/v)) with exosomes (membrane potential of exosomes was changed from -11.6 mV to -1.2 mV by complex with cationic lipids) significantly enhanced (~10-fold) cellular uptake of the exosomes (average size: 80 nm) (20 µg/ml, 24 hr in the presence of 10% FBS) without cytotoxicity.

A 30-residue amphipathic peptide GALA was designed to mimic viral fusion protein sequences that mediate escape of virus gene from acidic endosomes to cytosol³. Cationic lipids were also employed as an “adhesive” to paste the GALA peptide, which has negative charges from glutamic acids^{4,5}, onto surface of exosomes. As a model macromolecule, Texas red-labeled dextran (TR-dex, 70 kDa) was encapsulated into exosomes using electroporation, and internalization efficiency of TR-dex were evaluated. When HeLa cells were treated with TR-dex-encapsulated exosomes complexed with cationic lipids increased its cellular uptake. Furthermore, addition of GALA to the complex successfully enhanced cytosolic release of TR-dex from the exosomes inside cells, suggesting that GALA contributes to disruption of endosomal and exosomal membranes.

CONCLUSION

By effective usage of cationic lipids and pH-sensitive fusogenic peptide, we attained establishment of the simple technique to enhance cellular uptake and cytosolic release of exosomes. This technique will contribute to not only drug delivery using exosomes but also studies of biological activities of exosomal contents derived from various types of disease-related cells including bioactive proteins and genes.

Borates-loaded Biomaterials to trigger Cell Differentiation

P. Rico^{1,2}, A. Rodrigo-Navarro¹, M. Salmerón-Sánchez³

¹Center for Biomaterials and Tissue Engineering, Universitat Politècnica de València, Spain

²CIBER, Spain, parico@upvnet.upv.es

³Division of Biomedical Engineering, School of Engineering, University of Glasgow, United Kingdom

INTRODUCTION

Poly(L-lactic acid) (PLLA) is a widely used bioabsorbable material, approved by the FDA for several biomedical applications, with remarkable properties for tissue engineering and orthopaedic applications such as excellent biocompatibility and biodegradability¹. Boron, a trace element found in the human body, plays an important role in bone growth and development². The aim of the present study was to engineer boron-containing materials and to evaluate the effect of boron on cell behavior. In this work we evaluate the ability of this novel material system to promote differentiation of C2C12 and MC3T3 cell lines into myoblastic and osteoblastic lineages respectively. Overall, the potential of boron-loaded materials to release boron and enhance cell commitment toward musculo-skeletal lineages was evaluated.

EXPERIMENTAL METHODS

PLLA films with 2% or 5% boron were obtained by solvent casting, where boron was loaded as borax decahydrate in constant stirring. Water contact angle (WCA) was measured for the different substrates by the sessile drop method. Surface morphology of materials was evaluated by SEM. Cells were seeded on substrates (C2C12 and MC3T3-E1 lines) in order to evaluate myoblast and osteoblast differentiation respectively. Cell morphology and myogenic/osteogenic commitment were quantified by sarcomeric myosin detection and qPCR amplification of specific genes.

RESULTS AND DISCUSSION

WCA results showed similar wettability between PLLA and boron-loaded PLLA systems (2% and 5% respectively, WCA 78.4 ± 3.3 degrees) suggesting that low quantities of boron used do not alter the chemical properties of system. The analysis of surfaces by SEM did not reveal any new topographical feature associated with the presence of boron, that cellular results can be correlated with boron content and release. Culture of C2C12 cells showed an increase in differentiated myotubes as the content on boron in biomaterial does (figure 1). To ensure that boron was the only factor implicated in cell differentiation, another experiment was performed using PLLA as a substrate and including equivalent percentages of borax decahydrate at culture medium. The obtained results showed that boron induces myoblast formation, suggesting that those surfaces had the potential as a release system.

FIG 1: A) myotube formation detected by immunostaining of sarcomeric myosin protein. B) Quantification of C2C12 cells differentiation by image analysis.

Culture of MC3T3-E1 cells showed similar results after 15d of culture. We observed that differentiation markers increase with the content on boron does in the samples as obtained by the expression of specific osteoblastic proteins (Osteocalcin, Collagen I and Alkaline phosphatase). The gene expression of osteoblast markers (Runx2, IBSP) was also investigated obtaining major expression as a function of the boron content in substrates.

CONCLUSION

We observed that boron is able to direct cell differentiation in two different models: C2C12 cells to myotubes and MC3T3-E1 to osteoblasts.

Recent investigations have concluded that delivery of boron by degradation of borate glass is of special interest in biomedical applications but this is a toxic process due to the rapid release of boron. In this study, we found that the incorporation of boron into degradable materials produces a slow release of boron capable to promote cell differentiation. Furthermore, the study indicates that boron-loaded materials are excellent candidates to engineer cellular microenvironments aimed at the regeneration of musculo-skeletal systems.

INTRODUCTION

Because of the risk of galvanic corrosion, combined use of different metals such as SUS316L(SUS) and Ti-6Al-4V(Ti64) is supposed to be prohibited in in-vivo environment. However, there are unavoidable cases such as femoral shaft fracture after THA and internal fixation of complicated fracture. Although there are basic studies on the corrosion resistance with the standard electrode potential, there are few reports on in-vivo galvanic corrosion due to the combined use.

In this study, animal experiment was performed to investigate in-vivo galvanic corrosion in the combination use of SUS and Ti64. And tissue reaction and bone formation were investigated.

MATERIAL AND METHODS

Metal plates with 3 screw holes (15 x 5 x 1.2 mm) were made of SUS and Ti64 Mini DC plates. And cortex screws made of SUS and Ti64 (φ2.0 x 12 mm) were applied to fix the metal plates as the combined use and the control (Fig.1). These plates and screws were implanted into the medial aspect of proximal tibia in mature New Zealand white rabbits with 4 different combinations (Tab.1).

In order to investigate bone formation, X-ray pictures were taken at 0, 24 and 52 weeks after implantation. Then tibia bones were harvested with the implants. During harvesting, tissue reaction was carefully inspected every soft tissue layer.

The tibia bone was dehydrated and embedded in PMMA, and thin slices were made for Contact Micro Radiogram (CMR), cytological observation.

RESULTS AND DISCUSSION

(1).Successive X-ray observation

Bone formation around the implanted plates was observed. And cortical bone under the implanted plate became thin, and the plates were buried in cortical bone in all combinations at 52weeks. However osteolysis or abnormal bone formation was not observed (Fig.2).

(2).Visual observation of soft tissue and tibia bone

During harvesting, no discoloration and swelling were observed in soft tissue. The implants were mostly covered by newly formed bone tissue (Fig.3). It is considered that no influence of the galvanic corrosion was confirmed on surrounding soft tissue and tibia bone.

(3). CMR of cross section

The implanted plates were almost buried in cortical bone. And bone tissue became thin and porous under the implanted plates (Fig4). However, these changes were assumedly caused by the reduction of periosteal blood flow, and stress shielding due to the plate fixation.

Fig.5 Cytological observation (SUS-Ti64)

(4).Cytological observation

No inflammatory cells were observed, and quite normal findings were obtained in surrounding soft tissue and bone tissue (Fig.5).

CONCLUSIONS

At 52 weeks after implantation, no evidences of galvanic corrosion were observed in all investigation performed in this animal study. Further long term investigation is required to verify no galvanic corrosion.

The degradation relationship between mechanical and in vitro testing of a phosphate glass fibre composite

R. J. Colquhoun¹ and Prof K.E. Tanner¹

¹Department of Biomaterials, School of Engineering, University of Glasgow, Scotland
r.colquhoun.1@research.gla.ac.uk

INTRODUCTION

The degradation of phosphate glasses (PG) is regarded as being critical to the design of PG based biomaterials^[1]. Metaphosphate (50% mol P_2O_5) glasses represent a compositional group with structural networks highly suitable for fibrillation and have potential as reinforcing agents in degradable composites for tissue regenerative applications^[1,2]. However metaphosphate glass fibres (PGF) are susceptible to autocatalysis effects and accelerated dissolution rates (D_r) from their acidic degradation by-products^[1]. This effect can subsequently alter a PGF composite's mechanical property retention and cytotoxicity due to reductions in pH and the accelerated release of ions to cytotoxic levels.

With the D_r of PGF influenced by the ionic strength of experimental media^[1] it is important to consider how these degradation mechanisms translate across various testing techniques employing different ionic medias. The degradation properties of a PGF composite during mechanical testing and under conditions replicating those experienced *in vitro* were assessed.

EXPERIMENTAL METHODS

20mm, Ø20µm CorGlaes® Pure 107 metaphosphate glass fibres were degraded over 24 hours in distilled water (D.water), simulated body fluid (SBF), phosphate buffered saline (PBS) and Dulbecco's Modified Eagle Medium (DMEM) at 15 cm²/ml. Initial media ionic strength and mass loss recorded with D_r calculated.

CorGlaes® Pure 107/poly(lactic acid (PLA) composites were manufactured via a film stacking method at 0.2 fibre volume fraction (V_f). 60 x 15 x 2mm samples were degraded in D.water or DMEM at 37°C over 6 weeks (0.21 cm²/ml) with sample masses (wet and dry) and pH of the media and sample surface recorded periodically. Mechanical properties evaluated by three point bend technique following BS EN ISO 14125:1998+A1:2011.

RESULTS AND DISCUSSION

Table 1. Immersion media ionic strength/pH and D_r of CorGlaes® Pure 107 fibres

Media	Initial/ 24 hours pH	Ionic Conduc. (mS)	D_r (mg/cm ² /hour)
DMEM	7.40/6.56	11.47 ± 0.3	0.0072 ± 0.0004
SBF	7.40/2.01	19.53 ± 0.61	0.0139 ± 0.002
PBS	7.40/2.00	14.8 ± 1.14	0.0236 ± 0.002
D.Water	≈7.00/1.89	0.01 ± 0.0	0.028 ± 0.0003

Figure 1. Composite dry mass, D.Water Vs. DMEM

Figure 2.A) DMEM composite surface [1 week] B) FTIR of DMEM composite surface deposits vs CorGlaes Pure 107 C) Composite media pH

DISCUSSION

DMEM significantly retarded the PGF D_r and decrease in media pH compared to PBS and SBF (Table 1) but D_r failed to correlate with increasing ionic conductivity.

DMEM pH buffering was observed in bulk media during composite degradation (Fig 2C). However, comparable rates of mass loss (Fig 1) and mechanical properties attributed to fibre dissolution implied similar fibre D_r contrasting PGF dissolution data (Table 1). High surface area: volume ratio at fibre/matrix interface ($> 1 \times 10^4$ cm²/ml) was believed to counteract localised DMEM buffering. Precipitation of a surface layer during DMEM degradation appeared to be that of an amorphous calcium phosphate (ACP) incorporating elements of the PGF fibre composition (Fig 2A/B)^[3].

CONCLUSIONS

Degradation behaviour between D.water and DMEM media showed no alteration to the mass loss and mechanical retention mechanisms of the PGF composite despite the observed reduction in fibre D_r when assessed as a single element. This highlights the influence of the fibre/matrix interface on composite degradation and that mechanical degradation rates accurately represent those experienced during *in vitro* testing for a CorGlaes® Pure 107 fibre composite.

INTRODUCTION

According to the popularization of Ti-6Al-4V (Ti64) with good biocompatibility, the combination use with the conventional stainless steel of SUS316L (SUS) is increasing due to accidental misuse in emergency cases or necessary choice of stainless wire to tie up bone fragments in complicated fracture and femoral mid shaft fracture after Total Hip Arthroplasty.

Ideally, these high quality implant metals of SUS and Ti64 will avoid even galvanic corrosion due to the very stable oxide film. However, the combination use of different implant metal is prohibited by instruction manuals of the medical devices. And also there are few reports on in-vivo study of galvanic corrosion.

In this animal study, In-vivo galvanic corrosion of SUS and Ti64 was investigated by means of the surface observation and EPMA element mapping analysis.

EXPERIMENTAL METHODS

Mini DC plates (30 x 5 x 1.2 mm) and cortex screws (φ2 x 12 mm) made of SUS and Ti64 were subjected to this study, in which the plates were cut into the half length of 15mm with 3 screw holes. And Mature male New Zealand white rabbits were used as experimental animal. These specimens were implanted into the medial aspect of proximal tibia of the rabbits in 4 different combinations (Tab.1).

At 52 weeks after implantation, the tibia bones were harvested with the implants. Bone tissue formed on the implants was carefully detached, and the screws were removed. Then, the plates and the screws were observed by stereoscopic microscope. Furthermore, the tibia bones with the metal plates were cut into thick slice and dehydrated, then embedded in PMMA. And Element mapping analysis was performed, in which Chromium (Cr) was selected as a marker element of the anodic dissolution due to the galvanic corrosion because the standard electrode potential of SUS is lower than that of Ti64, SUS is accordingly supposed to be corroded.

Tab.1 Combinations of plate and screw

Specimen No.	Plate	screw
1	Ti-6Al-4V	Ti-6Al-4V
2	Ti-6Al-4V	SUS316L
3	SUS316L	Ti-6Al-4V
4	SUS316L	SUS316L

RESULTS AND DISCUSSION

In microscopic observation, the concentric friction imprints were observed in the screw hole of the plates and the back surface of the screw head, which were supposedly caused by tightening the screws (Fig.1, Fig.2). However, no evidences of galvanic corrosion were observed in all specimens at 52 weeks.

Regarding the mapping analysis, Cr element was almost evenly detected at bone tissue because small amount of Cr is physiologically contained in bone tissue. In detail, Cr element detected with the concentration gradient around the SUS plates, which is suggested Cr element elution from the SUS plates (Fig.3).

However, there is no difference between the combinations of SUS screw (identical metals) and Ti64 screw (different metals). Consequently, this Cr element elution is considered to be not due to the galvanic corrosion.

(a) Screw hole (b) Back of screw head
Fig.1 Combination of SUS plate - SUS screw

(a) Screw hole (b) Back of screw head
Fig.2 Combination of SUS plate - Ti64 screw

(a) with SUS screw (b) with Ti64 screw
Fig.3 Cr element mapping analysis on SUS plate.

CONCLUSIONS

In this animal study, it is demonstrated that galvanic corrosion was not generated in the combination of SUS and Ti64, or generated in very low level in 52 weeks after implantation.

Very small amount of Cr element elution is confirmed by EPMA element mapping analysis, which is considered as not due to the galvanic corrosion, but due to usual small electrolysis of SUS in the electrolyte solution of in-vivo environment.

Nanoscale Roughness Influences on Cell Proliferation

Prabhjeet Kaur Dhillon¹, Ajay Kumar², Shalmoli Bhattacharyya² and Subhendu Sarkar¹

¹ Department of Physics, Indian Institute of Technology Ropar, Nangal Road, Rupnagar, Punjab, 140001, India

INTRODUCTION

Studies of cell proliferation on topographically different substrates are currently being explored for their potential applications in biomedical sciences¹. However, the results obtained so far have been often conflicting^{2, 3}. All these studies characterize a surface using its average roughness and try to correlate cell proliferation characteristics with the overall roughness. Recent research revealed that typical length scales for cell protrusions important for sensing the substrate are of the order of a few nanometers⁴. Therefore, correlating cell proliferation characteristics with the average roughness is an oversimplification since a typical rough surface exhibits a range of roughnesses over different length scales. Our study investigates this problem using universal scaling theories to understand the behaviour of cells on surfaces.

EXPERIMENTAL METHODS

The surfaces were prepared by isotropically etching Si (100) (1x1cm²) surfaces with HNA (HF, HNO₃, CH₃COOH) for different times (30s, 60, 120s, 240s, 360s, 480s & 600s). The resulting morphologies were investigated using atomic force microscopy (AFM). Dynamic scaling parameters were also evaluated from the AFM data^{5, 6}. Cell proliferation studies using Dental Pulp Stem Cells (DPSCs) were carried out on these surfaces by fluorescence microscopy.

RESULTS AND DISCUSSION

Observed proliferation of DPSCs over etched surfaces (Fig.1) was compared with roughness parameters of the surfaces for different length scales.

FIGURE 1. Isotropically etched Si(100)surface (360s) (Left) and fluorescence microscopy image of DPSC proliferation on it (Right).

According to Dynamic Scaling Theory (DST), root-mean-square (RMS) roughness, a measure of lateral correlations at the interface follows a power law w.r.t. length scale: $w_{\text{sat}} \sim L^{\alpha}$, where w_{sat} is the saturation value of interface width and α is the roughness exponent⁵. When α lies between 0 and 1, a smaller value of α corresponds to a rougher local surface, i.e., it signifies a more rapid change in surface heights⁷. It was found that cell proliferation was

influenced by the short length scale properties of the surfaces i.e. the local roughness at smaller length scales (~50–150 nm) instead of average roughness. For shorter length scale, local roughness increases ($\sim 1/\alpha$) till 240s (cell proliferation decreases). Thereafter local roughness decreases till 360s-480s and cell proliferation increases, further local roughness increases and cell proliferation decreases (Table 1).

Etching time (s)	30	60	120	240	360	480	600
Nano-roughness	Increases				Minimum		Increases
Average no. of cells in a single field	8	7	3	3	23	20	3

TABLE 1. Comparison of nano-roughness and cell proliferation

AFM imaging of DPSC (Fig.2) showed that the features on the cell surface were of the order of 100-200 nm thus indicating a correlation of proliferation, cell topography and small scale roughness.

FIGURE 2. AFM image of single DPSC on cover plate.

CONCLUSION

DPSCs prefer to grow on locally smooth surfaces. Roughness at small length scales influences cell proliferation instead of average roughness of overall surface.

Role of Fibronectin assembly in Mesenchymal Stem Cell differentiation

P. Rico^{1,2}, H. Mnatsakanyan¹, M. Salmerón-Sánchez³

¹Center for Biomaterials and Tissue Engineering, Universitat Politècnica de València, Spain

²CIBER, Spain, parico@upvnet.upv.es

³Division of Biomedical Engineering, School of Engineering, University of Glasgow, United Kingdom

INTRODUCTION

Although significant progress in the last years has been made in the investigation of defined factors implicated in lineage commitment of stem cells, the effect of biomaterial properties on functional differentiation is poorly understood¹. Mesenchymal stem cell differentiation can be driven by the material/cell interface in absence of complex soluble chemistries or cellular reprogramming for example modifying the chemistry or topography². In this work we used materials with similar chemistry (PEA, poly(ethyl-acrylate) and PMA, poly(methyl-acrylate)) which results in different distribution and conformation of the protein at the cell-material interface. PEA induces FN fibrillogenesis network in the absence of cells while the protein conformation on PMA surface remain globular³. The aim of the present study is to evaluate the role of fibronectin distribution at the material interface – fibrillar vs globular – in promoting mesenchymal stem cell differentiation, by investigating cell commitment towards osteoblast and adipocyte lineages.

EXPERIMENTAL METHODS

Polymer sheets of PEA and PMA were obtained by radical polymerisation in UV. Thin films were prepared by spin-coating after dissolving the polymers in 2% toluene.

Protein adsorption was performed at a concentration of 20µg/ml and FN conformation was observed with AFM in tapping mode.

Mouse Mesenchymal Stem Cells (mMSC) were seeded on material surfaces in order to evaluate osteoblastic and adipogenic differentiation.

Cell adhesion was followed by immunofluorescence for focal adhesion proteins (vinculin, paxilin, talin). FAK and p-FAK expression were evaluated by western blot techniques. Cell contractility was evaluated by immunodetection of phosphorylated myosin light chain. For experiments including contractility inhibitors we used Y-27632 or blebbistatin.

Gene expression and adipogenic/osteogenic commitment were quantified by qPCR amplification and other immunostaining procedures of specific genes.

RESULTS AND DISCUSSION

Surface chemistries (PEA and PMA) showed similar wettability and total amount of adsorbed FN, but conformation and distribution of the protein were completely different. An interconnected FN network was found in PEA while on PMA FN conformation results in globular aggregates in AFM images.

Cell adhesion of mMSC, as followed by immunofluorescence, revealed the presence of well-

defined focal plaques formed on both, PEA and PMA substrates (Fig 1). Western blot analysis showed similar levels of FAK in both materials, while higher levels of pFAK were obtained on PMA substrates, which reveals higher signaling activity on globular FN.

Fig. 1: Focal adhesion plaques detected by immunostaining of vinculin on different substrates.

Mesenchymal stem cells showed differences on gene expression between materials after 15d of culture, which were correlated to the different conformation of FN on material surfaces. qPCR results suggested that cell commitment to adipogenic or osteoblastic lineages are favoured on PEA compared to PMA and glass control (Fig 2) -in absence of differentiation factors. This is also correlated with cell contractility on both surfaces.

Fig. 2: qPCR expression levels of osteoblastic (RunX2 and IBSP) and adipogenic markers (PPAR and LPL).

CONCLUSION

We have shown that the conformation and distribution of FN –fibrillar vs globular – on different material surfaces influence mesenchymal stem cell commitment towards osteogenic and adipogenic lineages.

Graphene oxide and 4-arm-PPO-PEO composite hydrogels for injectable biomedical applications

Yunki Lee, Jin Woo Bae, and Ki Dong Park*

Department of Molecular Science and Technology, Ajou University, Suwon, Republic of Korea, kdp@ajou.ac.kr

INTRODUCTION

Conventional polymeric hydrogels have been extensively used as a promising vehicle for tissue engineering and drug delivery applications. However, they appear to have some limitations for use as substitute materials of load-bearing tissues due to their insufficient mechanical properties. To improve mechanical properties of hydrogels, many strategies including double-network, topological cross-linking, and nanocomposite hydrogels, have been developed¹.

In this study, we report *in situ* forming graphene oxide (GO)-incorporated 4-arm-PPO-PEO-tyramine (Tet-TA) composite hydrogels with superior mechanical strength *via* chemical and physical cross-linking. Various properties of the composite hydrogels were characterized, and the effect of GO on mechanical strength of hydrogels was evaluated by varying the oxidation degree and feed amount of GO. Biocompatibility of Tet-GO hydrogels was investigated using MC3T3-E1 cells.

EXPERIMENTAL METHODS

4-arm-PPO-PEO block copolymer was modified by conjugating tyramine (TA) for horseradish peroxidase (HRP)-catalyzed cross-linking². Two kinds of GO varying in oxidation was prepared by a modified Hummers method and they were exfoliated using an ultrasonicator³. The chemical structures of GOs were characterized by X-ray photoelectron spectra (XPS) and fourier transform infrared spectroscopy (FT-IR). GO (0.1-0.4 wt%) was homogeneously suspended in Tet-TA (10 wt%) precursor solution prior to gel formation, and Tet-TA/GO hydrogels were subsequently formed in presence of HRP and H₂O₂ (Fig 1). The mechanical properties of hydrogels, including elastic, tensile, and compressive modulus, were evaluated by changing either oxidation level or feed concentration of GO. *In vitro* cyto-toxicity test was then investigated on the surface of hydrogels with MC3T3-E1 cells.

Fig 1. Schematic representation of injectable Tet-TA/GO composite hydrogels *via* enzymatic cross-linking.

RESULTS AND DISCUSSION

The various oxidation degree (O/C ratio; 0.09-0.59) of synthesized GO was identified by XPS and FT-IR

analysis. As additional cross-linkers, GO (0.1-0.4 wt%) was incorporated in Tet-TA hydrogels (10 wt%) formed *via in situ* oxidative cross-linking among the phenolic moieties catalyzed by HRP and H₂O₂. The gelation time of hydrogels was easily controlled by varying the HRP concentrations (8-58 sec) and oxidation level of GO affected cross-linking rate. Interestingly, the mechanical strength of Tet-TA hydrogels was effectively improved after incorporation of GO. Tet-TA/GO hydrogels exhibited 683 % increase in tensile strength and 983 % in compressive strength compared to pure Tet-TA hydrogels, indicating strong interaction between GO and Tet-TA polymer chain (Fig 2).

Fig 2. Compressive strength of Tet-TA/GO composite hydrogels with different oxidation degree (a) and feed amount of GO (b).

In vitro MC3T3-E1 cell culture for the evaluation of cyto-compatibility of hydrogels demonstrated that incorporation of GO within hydrogels had no effect on the toxicity of hydrogel matrix.

CONCLUSION

In situ Tet-TA/GO composite hydrogels have been developed as injectable replacements for load-bearing tissues. The obtained results demonstrated that physico-chemical properties of hydrogels could be controlled by adjusting oxidation degree and concentration of GO. Compared to pure Tet-TA hydrogels, optimized hydrogels showed 7.8 times and 10.8 times higher strength in tensile and compressive test. The incorporation of GO (0.4 wt%) into Tet-TA hydrogels did not affect the toxicity to MC3T3-E1 cells. As a result, *in situ* forming Tet-TA/GO composite hydrogels can be a promising candidate as an injectable scaffold for tissue replacement.

pH-Mediated Surfactant Release in the Development of Self-Sterilising Urinary Biomaterials

C. P. McCoy, J. L. Trotter, N. J. Irwin, L. Carson, D. S. Jones

School of Pharmacy, Queen's University Belfast, 97 Lisburn Road, Belfast BT9 7BL, Northern Ireland, UK
n.irwin@qub.ac.uk

INTRODUCTION

To combat medical device-associated infection, previous research has focused on two main strategies: (i) modification of the device surface to create an inherently anti-adherent exterior; or (ii) incorporation of antimicrobial agents that will subsequently be released to target microbial cells¹⁻². Limited efficacy in preventing bacterial colonisation, particularly *in vivo*, in addition to concerns over potential toxicity of antimicrobial agents and the emergence of bacterial resistance with antibiotics, however, ultimately restrict their clinical potential. The microbial anti-adherent properties of surfactant-modified surfaces have been widely reported³⁻⁴. We propose that controlled release of surfactant can reduce adhesion of bacteria and subsequent biofilm formation, without the toxicity and resistance issue associated with antibiotic systems.

The aim of this study was to determine rates of release of a non-ionic surfactant, Triton X-100, from poly(hydroxyethyl methacrylate) (p(HEMA)) hydrogels at pH 7, representing normal physiological urine pH, and pH 10, representing the elevated pH reported at the onset of urinary catheter infections. Bacterial adherence studies were also performed to investigate the resistance of Triton-loaded p(HEMA) to colonisation of the urinary pathogen *Proteus mirabilis*.

EXPERIMENTAL METHODS

Triton-loaded p(HEMA) films, containing Triton X-100, were synthesized from mixtures of Triton X-100, 2-hydroxyethyl methacrylate, 2,2'-azobisisobutyronitrile and ethyleneglycol-dimethacrylate. The solution was injected into moulds and polymerised for 18 h at 60°C. Release studies were performed at pH 7 and pH 10 in universal buffer solutions having a constant ionic strength, prepared using the formulation of Koller *et al.*⁵. Released Triton X-100 was quantified by UV-visible spectroscopy in conjunction with calibration curves prepared using universal buffer solutions of relevant pH. Five replicates were performed at each pH. Microbiological assessments were performed to assess adherence of *P. mirabilis* to the surface of Triton-loaded p(HEMA) relative to the control p(HEMA). The effect of pH on the cumulative amount of Triton released at designated intervals, and the bacterial adherence after 4 h and 24 h were statistically analysed by a one-way analysis of variance, followed by Tukey's honestly significant difference test for post-hoc comparisons between means of singular groups. Differences were considered significant if $p < 0.05$ ⁶.

RESULTS AND DISCUSSION

The effect of pH on the release of Triton X-100 from Triton-loaded p(HEMA) at 37°C with shaking is shown in Figure 1. Release profiles for Triton-loaded p(HEMA) in pH 7 and pH 10 were statistically similar. For example, after 24 h, 22.2% and 26.8% of the loaded

Triton X-100 was released from the hydrogels at pH 7 and pH 10, respectively.

Fig. 1: The effect of pH on the mean (\pm S.D.) release of Triton X-100 from Triton-loaded p(HEMA) at 37°C with shaking. Sink conditions were maintained throughout the study. Open and closed symbols refer to release at pH 10 and pH 7 respectively.

The insignificant effect of pH on rates of release is explained by the absence of ionisable moieties in both Triton X-100 and p(HEMA), and the consequential absence of pH-dependent ionic interactions to promote or delay release. The high molecular weight of Triton X-100 ($\sim 647 \text{ g mol}^{-1}$) and possible entanglements of the long polyethylene oxide chains were responsible, however, for the prolonged release of Triton X-100 from the hydrogel over periods of up to three weeks. Furthermore, greater resistance to adherence of *P. mirabilis* was displayed by the Triton X-100-loaded hydrogels than the control p(HEMA).

CONCLUSION

Release of Triton X-100 from surfactant-loaded polymers proceeded in a pH-independent fashion. The prolonged release of Triton X-100, in addition to the encouraging resistance of the surfactant-loaded p(HEMA) matrices to adherence of *P. mirabilis*, are, however, promising for the use of surfactants in the development of infection-resistant catheter coatings.

INTRODUCTION

Temperature-responsive chromatography using poly(*N*-isopropylacrylamide) (PIPAAm) grafted silica beads is highly useful to control function and properties of the stationary phase for high performance liquid chromatography (HPLC) by only change in column temperature.¹ Also, thermoresponsive cationic copolymer possessing tertiary amine group grafted silica beads was developed as thermoresponsive ion exchange chromatography matrices.² In the present study, we prepared silica beads grafted with thermoresponsive cationic copolymer brush possessing quaternary amine group as strong ion-exchange chromatography matrices. Characterization of the prepared beads was performed by observing elution profiles of adenosine nucleotides and acidic proteins.

EXPERIMENTAL METHODS

ATRP initiator, 2-(*m,p*-chloromethylphenyl)ethyl trimethoxysilane was immobilized onto silica beads (diameter of 5 μ m, pore diameter of 30 nm) (Fig.1). IPAAm, 3-acrylamidopropyl trimethylammonium chloride (APTAC), and *tert*-butylacrylamide (tBAAm) were copolymerized on silica beads surface using CuCl/Me₆TREN as ATRP catalyst and 2-propanol as ATRP reaction solvent. Prepared beads were packed into stainless steel column (50 \times 4.6 mm i.d.) and connected to HPLC system. Elution behaviour of adenosine nucleotide and acidic proteins was observed at various temperatures. For comparison, silica beads grafted with thermoresponsive copolymer possessing tertiary amine group (P(IPAAm-*co*-*N,N*-dimethyl aminopropylacrylamide)(DMAPAAm)-*co*-tBAAm) was also prepared for comparison of separation efficiency.

RESULTS AND DISCUSSION

Prepared beads were characterized by CHN elemental analysis and GPC measurements. Amount of grafted copolymer was 2.47-2.68 mg/m², and copolymer graft density was 0.11-0.15 chains/nm². The results indicated that dense cationic copolymer brush was successfully grafted on silica beads surface. The prepared beads packed column was connected to an HPLC system. Elution behaviours of adenosine nucleotides and human serum albumin (HSA) and fibrinogen were observed. Longer retention time of adenosine nucleotides was observed on quaternary amine column compared to that on tertiary amine column, attributed to strong cationic properties of quaternary amine group. Also, acidic protein HSA and fibrinogen was adsorbed high

Fig.1 Scheme for preparation of silica beads grafted with thermoresponsive cationic copolymer brush

Fig.2 Chromatogram of adenosine nucleotides at various column temperatures

Fig.3 Acidic proteins elution from quaternary amine column

temperature and successfully recovered by reducing column temperature. This is because acidic proteins adsorbed to cationic copolymer brush through both electrostatic and hydrophobic properties at high temperatures. These results indicated that the silica beads grafted with thermoresponsive cationic copolymer possessing quaternary are effective thermoresponsive chromatography matrices for separation of acidic biomolecules proteins.

CONCLUSION

Silica beads grafted with thermoresponsive cationic copolymer brush possessing quaternary amine group was prepared through surface-initiated ATRP. The prepared beads would be useful for thermoresponsive strong ion-exchange chromatography matrices.

INTRODUCTION

Poly(*N*-isopropylacrylamide) (PIPAAm)s exhibit temperature-dependent behaviors above/below their lower critical solution temperature (LCST) at approximately 32 °C in aqueous solutions. As one of the most famous applications, cell adhesion and detachment control on PIPAAm-grafted surface has been investigated intensively¹. Cultured cells at 37 °C on the surface are spontaneously recovered by lowering temperature below the LCST. This study developed a Langmuir-Schaefer method for fabricating PIPAAm-deposited surfaces. The PIPAAm deposited surfaces with various area per molecule and chemical compositions were characterized and cell adhesion and detachment characters on the surfaces were also discussed.

EXPERIMENTAL METHODS

Block copolymer of polystyrene-*block*-PIPAAm (St-IP) with specific molecular weights were synthesized via reversible addition-fragmentation chain transfer radical (RAFT) polymerization. St-IP chloroform solution was carefully spread at an air-water interface. After forming the film with various densities, the film was horizontally transferred on a hydrophobic substrate (Fig. 1)². The St-IP surfaces were analyzed by various methods of surface analyses, and cell adhesion and detachment in response to temperature on the surface was also evaluated. Bovine carotid artery endothelial cells (BAECs) were cultured on a St-IP surface at a concentration of 1.0×10^4 cells/cm² at 37 °C for 24 h. Then, for investigating a temperature effect on cell detachment on St-IP surfaces, the cells were incubated at 20 °C for 120 min, and the number of adhering cells was counted.

RESULTS AND DISCUSSION

The chemical composition of obtained block copolymer was characterized by ¹H NMR. The number of St moieties was defined at 130 in the synthetic block copolymers and the number of IP moieties was modulated by a reaction condition. For example, Synthesized block copolymers were abbreviated to be St-IP110 that has 130 St moieties and 110 IPAAm moieties. The effects of density of St-IP and PIPAAm molecular weight toward temperature-dependent cell adhesion and detachment were investigated (Fig. 2). On the St-IP surfaces at 3 nm²/molecule, the numbers of adhering cells were below 0.6 cells/cm², which was much lower density compared with the control surface. At 40 nm²/molecule, the number of adhering cells was 0.8-0.9 cells/cm², which was almost the same as the control surface. Fig. 2 also shows the cell detachment

Fig. 1. Preparation of thermo-responsive surface transferred from Langmuir film.

Fig. 2. Temperature-responsive cell adhesion and detachment on St-IP surfaces at 40 nm²/molecule.

on the St-IP surfaces after reducing temperature from 37 °C to 20 °C for 120 min. At 3 nm²/molecule, almost cells detached themselves from the LS surfaces by 30 min incubation. At 40 nm²/molecule, cells were gradually detached themselves from St-IP110, St-IP170 and St-IP240 surfaces, and perfectly detached from St-IP480 surfaces. These results indicated that (1) lower density was effective for increasing cell adhesion at 37 °C and (2) higher density and increasing PIPAAm molecular weight of St-IP molecule was dominant for acceleration cell detachment.

CONCLUSION

In this study, thermo-responsive block copolymer surface with various density was fabricated by a transference of Langmuir film and the cell adhesion and detachment properties were investigated. The precise control of density and composition of block copolymer was important factor for modulating cell attachment and detachment in response to temperature.

Reciprocating Sliding Friction of Polyvinyl Alcohol Hydrogels as Articular Cartilage Substitutes

Takashi Hayami¹, Koji Morimoto¹, Yoshihiro Kimura², Noriyasu Hirokawa¹ and Tadashi Shibue¹

¹Faculty of Biology-Oriented Science and Technology, Kinki University, Japan

INTRODUCTION

We studied the use of polyvinyl alcohol hydrogels (PVA-H) for the hemiarthroplasty of injured knee and hip joints¹. We prepared PVA-H in pure water (PVA-H/Water) and tested the basic tribological characteristics of PVA-H/Water artificial hemi-joints paired with hog articular cartilage in the end-face friction test². We compared the characteristics of reciprocating friction and end-face friction in PVA-H/Water paired with a hog articular cartilage joint.

EXPERIMENTAL METHODS

The PVA-H/Water solution prepared using 15 wt% PVA powder (DP: 1700) dissolved in pure water was stirred well and poured into a square mould and frozen at -20°C for 24 h. The resulting hydrogel was dried at room temperature, annealed for 5 h at 140°C in vacuum, and pressurized under 40 MPa at 140°C . The resulting specimen dimension and water content were $20\text{ mm} \times 50\text{ mm} \times 2.5\text{ mm}$ and $58 \pm 3\%$, respectively. Disciform articular cartilage specimens (7 mm in diameter) were harvested from the knee joints of hogs. The articular cartilages (thicknesses $1.5 - 2\text{ mm}$) were used in friction tests with intact synovial fluid and lamina splendens.

Fig.1 shows a schematic of the reciprocating friction test apparatus. The PVA-H/Water specimen was fixed to the bottom of the lubricant bath, and the cartilage specimen was fixed to a shaft with instant glue. The lubricant was a saline and bovine serum mixture. A normal contact pressure (P) of 1 MPa was assumed. The reciprocating frequency and stroke length were 0.4 Hz and 25 mm, respectively. The friction force (F) was detected using a strain gage load cell comprising two leaf springs. The friction coefficient (μ) was calculated from F and P . The friction distance (L) and root mean square speed was set to 144 m and 20 mm/s, respectively, under the same conditions as those employed in the previous end-face friction test. Further details about the synthesis of PVA-H/Water and the end-face friction test are provided elsewhere².

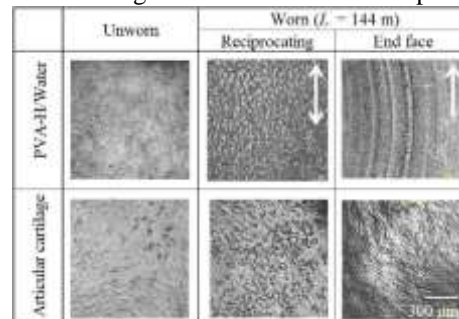

Fig.1 Reciprocating friction test apparatus.

RESULTS AND DISCUSSION

Fig.2 shows confocal laser microscopy (CLSM) images of the unworn and worn surfaces (at $L = 144\text{ m}$) of the PVA-H/Water and articular cartilage specimens for comparing the reciprocating and end-face friction modes. On the worn surface of PVA-H/Water, a linear

Fig.2 CLSM images of the surfaces of the specimens.

Arrows indicate friction direction.

Fig.3 Variation of Friction coefficient. $n=3, \pm\text{SD}$

abrasion mark with a surface roughness of $1.3\text{ }\mu\text{m Ra}$ was observed in the end-face mode, whereas a digging-up pattern with a number of irregularities ($3.8\text{ }\mu\text{m Ra}$) was observed in the reciprocating mode. On the cartilage surface, the fine bumpy pattern prior to friction remained on the worn surfaces of the end-face mode. In the reciprocating mode, however, the pattern was worn off, and larger irregularities formed along the friction direction. The roughness of the worn cartilage in both friction modes was $2.6 - 2.8\text{ }\mu\text{m Ra}$. As shown in Fig.3, in the end-face mode, μ increased from 0.025 to 0.14 as L was increased. However, in the reciprocating mode, μ rapidly increased from 0.06 to 0.12 at the start of friction. Even if L was increased to 144 m, μ remained nearly constant at 0.12 without obvious change.

The wear resistance of PVA-H/Water in the reciprocating mode was clearly lesser than that in the end-face mode. We concluded that the tribological characteristics of PVA-H/Water paired with the cartilage are altered by the friction modes. The loading of the alternate friction force enhances microvoids. A repeated loading can convert these voids into micro-cracks. Therefore, these results suggest the necessity for improving the fatigue and settling resistance of PVA-H/Water, particularly for decreased wear damage in reciprocating friction.

INTRODUCTION

Silk fibroin scaffolds for bone tissue engineering can be produced by porogen-leaching, lyophilisation or gas foaming^{1,2,3}. For the first approach, individually tunable pore and interconnection size can be achieved for scaffolds templated by porogens produced by microfluidics, known as inverse opals⁴. The homogeneous architecture of inverse opals has been shown to impact not only cell distribution and diffusion of macromolecules throughout the construct but also differentiation of preosteoblastic cells⁵. In this work, silk fibroin scaffolds exhibiting an inverse-opal structure were developed and compared to others fabricated by the conventional salt-leaching method in terms of performance in bone tissue engineering.

EXPERIMENTAL METHODS

Monodisperse polycaprolactone particles were produced in a microfluidic device by creating droplets of a polycaprolactone solution in water and subsequently slowly evaporating the solvent. After washing and assembling them into a close-packed lattice, a heat treatment was conducted to induce necking between the particles. The particle pack was then infiltrated with an aqueous silk fibroin solution. Upon complete evaporation of the water, the porogen particles were dissolved.

Salt-leached scaffolds were produced using table salt particles as porogens, as reported elsewhere¹.

The scaffolds were seeded with human mesenchymal stem cells and cultured in osteogenic and control medium as described elsewhere¹. Control groups of scaffolds cultured without cells were also investigated.

Scaffolds were characterized after 2, 4 and 6 weeks in culture. The amount of DNA was measured using a PicoGreen DNA assay (n=4). Alkaline phosphatase activity was quantified by measuring the conversion of p-nitrophenolphosphate to p-nitrophenol (n=4) and the degree of mineralization was measured using a calcium assay based on o-cresolphthalein (n=4). Statistical analysis was done by ANOVA, pairwise student's t-test, where applicable, with a posthoc Bonferroni correction.

RESULTS AND DISCUSSION

Increased calcium deposition per scaffold (1761 ± 390 vs. $3275 \pm 662 \mu\text{g}$; $p < 0.01$) was observed for the inverse-opal scaffolds (Figure 2), even though no statistical difference in cell number was observed (Figure 1). This increase might have arisen from differences in pore monodispersity, pore interconnectivity and/or pore wall stiffness.

Figure 1: Calcium content measured per scaffold after 6 weeks in culture for salt-leached and inverse-opal scaffolds cultured in osteogenic or control medium.

Figure 2: (a) DNA content measured on scaffolds after 2 weeks in culture in osteogenic and control medium. (b) Conversion of p-nitrophenolphosphate to p-nitrophenol by ALP after 6 weeks in culture in osteogenic or control medium for both scaffold types.

CONCLUSION

Similar cell number as well as ALP activity indicating osteogenic differentiation was measured on both scaffold types. Inverse opal scaffolds mineralize significantly more than salt-leached scaffolds.

INTRODUCTION

One major problem with medical devices is the fact that surrounding tissue is not able to recognize the artificial surface as tissue like material. In case of blood oxygenators, this can induce blood coagulation which leads to blocking of the surface and inhibition of gas exchange.^[1] For metal implants such as pacemakers, incomplete tissue integration frequently promotes infection and additionally leads to implant migration.^[2]

RESULTS AND DISCUSSION

To prevent these problems, we are going to modify and humanize the surface. One approach is to covalently attach RGD-peptides to the implant surface promoting cellular adhesion and allowing the integration of the device in the tissue. The RGD-modified blood oxygenator can be seeded with lung endothelia cells which stealth the surface from the blood stream.

In a first step the activation of surfaces is performed with open-air plasma. This technology enables the chemical derivatization of surfaces in increasing wettability or introducing reactive groups.^[3] Linked to a PEG spacer it is possible to bind an oxanorbornadiene to the surface. With this system the ligation of azide-labelled RGD-peptides or other azide containing active component is performed in a copper-free "Click"-reaction.^[4]

Figure 1: Attachment of RGD to polymer and metal surface

An alternative approach to bind specific proteins to the surface is followed using the high affinity of biotin to streptavidin. A biotinylated surface will allow the immobilization a variety of Strep-tagged proteins.^[5]

CONCLUSION

In order to prepare new materials for medical devices the plasma technology enables chemical reactions on biomedical surfaces, like polymers or metals. Functionalization with adhesion factors based on RGD it will be possible to seed cells on surfaces. Avoiding of a copper-mediated click reaction reduces the hazard of remaining toxic compounds on the surface.

The biological evaluation showed that this approach leads to a dense cell layer. New approaches are tested to varify the applications of this method.

Evaluation of network and pore morphology of self-assembling peptides for biomimetic therapy

Franziska Koch¹ and Uwe Piesles¹

¹ICB/Nanotechnology, University of Applied Sciences, Muttensz (CH), franziska.koch@fhnw.ch

INTRODUCTION

Beside caries, periodontitis is nowadays a very common degenerative disease that affect adolescents and young adults. It is characterized by a microbial alteration which leads to a painful inflammation resulting in the degradation of alveolar bone, root cementum and periodontal ligament. If the progressive destruction of these three different tissues, named above, left untreated, it could lead to tooth lost.

Figure 1: The development process of periodontitis.

Currently, there are a lot of different treatment options like conventional invasive open flap debridement, mechanical anti-infective therapies and bone replacement grafts¹. In the last years the idea came up to use self-repair mechanism in the patient and stimulate host's innate capacity². This treatment strategy uses different kinds of material which were placed in a periodontal defect where progenitor/stem cells from neighbouring tissues can be recruited for in situ regeneration. In the present study newly synthesized peptides were produced to form hydrogels which could be applied through an injection in a periodontal defect without a surgery. The peptides, called P11-4 and P11-8, consist of 11 amino acids which could be triggered via pH and salt concentration to form beta-sheet structures³. Furthermore these beta sheet structures could form higher ordered structures like fibrils and fibres leading to a 3D network that serve as extracellular matrix (ECM).

Figure 2: Model of hierarchical self-assembly of chiral rod-like units⁴

EXPERIMENTAL METHODS

The purpose of the present study was to investigate the morphology of different 3D networks and its pore sizes and distribution under physiological conditions. Therefore TEM, SEM and tensiometry was used to estimate the potential of the nematic gels to recruit neighbouring cells in a periodontal defect.

RESULTS AND DISCUSSION

The results showed first that P11-4 and P11-8 were able to form higher ordered structures like fibrils under physiological conditions which could be seen in Figure 3a and 3b. In general it was demonstrated that the pore size ranged from 95 μm to 400 μm and their distribution of the 3D networks in an aqueous environment varied depending on used peptide concentration.

Figure 3: TEM image of a) P11-4 (20mg/ml) and b) P11-8 (20 mg/ml) Magnification 7000 x

It is known from Murphy & O'Brien 2010 that ultimately scaffolds should have a balanced distribution of pore sizes between 95 μm and 325 μm . The pore size is deciding if improved cell attachment is occurring, (optimal pore size range 95 μm to 150 μm), or cell migration (optimal pore size range 300 μm to 800 μm) or also to improve diffusion of nutrients in and waste products out of the scaffold⁴. Therefore the porous structure of self-assembled P11-4/8 peptides are beneficial candidates for tissue engineering as they show an optimal pore size distribution at concentration of 20 mg/ml for in vitro experiments.

CONCLUSION

The full potential of the peptides to act as a self-repair scaffold in the containment of periodontitis is still under investigation.

Morphological Gradients for Protein-Adsorption and Blood-Interaction Studies

Rebecca P. Huber^{1,2}, Katharina Maniura-Weber², Nicholas D. Spencer¹

¹Laboratory for Surface Science and Technology, Department of Materials, ETH Zurich, Switzerland

²Laboratory for Materials-Biology Interactions, Empa, St. Gallen, Switzerland, rebecca.huber@mat.ethz.ch

INTRODUCTION

To investigate the influence of a surface parameter on a given process, working with individual samples requires many repetitions with the challenge of maintaining the experimental conditions constant. This approach is laborious and cost-ineffective. Roughness gradients are a very promising tool to investigate the effect of surface topography on a biological system, as a wide range of parameters can be explored in a single experiment. Additionally, homogenous conditions are ensured during all measurements^{5,6}.

The success of a surgical implant is dependent on an appropriate biological response to the implant surface¹. Wound healing around implants is a complex process in which water molecules from the surrounding blood first come in contact with the surface. In the next step, ions and blood proteins adsorb and a fibrin network is formed, before osteoblastic cells respond to the protein-covered surface².

Blood protein adsorption and blood coagulation are greatly influenced by the topography of titanium surfaces^{3,4}, which may further impact the eventual adhesion, migration and differentiation of primary human osteogenic cells on a titanium implant. It is therefore of major importance for implantology to understand the early interaction between blood and the implant and how this further steers osseointegration.

EXPERIMENTAL METHODS

To study the effect of nano-roughness on protein adsorption and blood coagulation, nanoparticle density gradients were fabricated (see Fig. 1a)). A flat silicon wafer was first rendered positively charged with a coating of poly(ethylene imine), and then slowly immersed into a highly diluted silica-particle suspension, to generate a linear particle-density gradient on the surface. The gradient was subsequently heat-treated at 1050 °C to sinter the particles to the surface. In order to mimic the surface of implants, the samples were sputter coated with titanium. Finally, the gradients were exposed to fluorescently labelled albumin, fibrinogen or fibronectin. To achieve an easy and rapid data read-out, a fluorescence micro-array scanner was used to map all adsorbed proteins.

In a second step, the same gradients were used to study blood coagulation by incubation of the gradients for 2 to 10 min with partially heparinized (0.5 IU/ml) whole human blood from healthy volunteers. The formation of the blood clot was investigated by scanning electron microscopy and fluorescence microscopy.

RESULTS AND DISCUSSION

Particles of different sizes were tested, with diameters of 12, 39 and 72 nm. The protein-adsorption experiments showed no significant influence of nano-features on protein adsorption for all sizes of nanoparticle investigated.

In Figure 1 b) SEM images along a 39 nm nanoparticle density gradient following a 5 min blood-incubation experiment are presented. It is clearly visible that the appearance of the blood clot changes along the particle-density gradient. While coagulation was observed everywhere on the sample, a denser fibrin network could be detected towards the high-density end of the gradient. Such a fibrin network is of importance for further healing of the wound, as well as for cell adhesion and differentiation.

Fig. 1: SEM images taken every mm along the 39 nm nanoparticle density gradient. a) Gradient before blood incubation. b) Gradient after incubation for 5 min in whole human blood.

CONCLUSION

Nanostructures were shown to enhance blood coagulation, but appear to have no significant influence on protein adsorption from solutions.

This study suggests that implant surfaces with a high-density nanostructure show improved blood clot formation and should therefore enhance osseointegration.

pokerface1031@gmail.com

INTRODUCTION

Posterior capsular opacification (PCO) is the fibrous capsule developed onto the implanted intraocular lens (IOL) by the transformed lens epithelial cells (LEC). Literature has shown that the incidence of PCO in hydrophilic acrylic IOL is much higher than hydrophobic IOL¹. Our previous study shows the adhesion of LEC is more favoured onto the hydrophobic than the hydrophilic materials². By combining these two facts, we propose a strategy of surface functionalization to promote LEC adhesion to control PCO.

EXPERIMENTAL METHODS

The RGD (Arg-Gly-Asp) peptide is grafted onto the conventional hydrophilic acrylic polymer, mainly composed by pHEMA (Poly(2-hydroxyethyl methacrylate)), using oxygen plasma followed by crosslinker coupling. After a cleaning procedure to remove the physical adsorbed peptides, the polymer samples were examined for the cytotoxicity, optical and mechanical properties as well as the ability to attract porcine LEC attachment.

RESULTS AND DISCUSSION

The surface functionalized surface exhibits enhanced biological properties in cell adhesion and cell morphology maintenance, which are similar to the hydrophobic material control (Fig. 1). In addition, there is no adverse feature observed in cytotoxicity (Fig. 2), optical (Fig. 3) and mechanical properties (Table 1).

Figure 1 shows that LEC attachment enhanced by RGD peptide grafting to the level of hydrophobic material control. In addition, the spatial distribution and cell morphology are similar.

Figure 2 (next column, left) shows that the cell viabilities in the extracted medium from the surface functionalized materials are all above the 70%, the non-cytotoxicity definition by ISO 10993-5 (2009).

Figure 3 (upper right) shows that the light transmittances of the surface functionalized materials are unaltered. All the materials appear clear yellow for the “blue filtering” design from the manufacturer.

Sample	Diopter	Injector	Optic damage	Haptic damage	Injection force (N)
Virgin IOL	19.0-22.0	Accuject 2.2 – 1P	N	N	13,87
RGD Adorbed	19.0-22.0	Accuject 2.2 – 1P	N	N	14,41
RGD Grafted	19.0-22.0	Accuject 2.2 – 1P	N	N	13,64

Table 1 shows that the intraocular lens injection forces remain similar after the RGD peptide surface functionalization. No optic and haptic damage was observed.

CONCLUSION

With the enhanced attachment to the surface functionalized IOL material, the LEC could form a thin layer to reconstitute the physiological condition as it in nature lens. This is corresponding to the proposal of PCO development control³. In addition, the cells share similar spatial distribution and cell morphology to the hydrophobic material control, implying less chance to be transformed. On the other land, the surface functionalization keeps the original material properties for the ophthalmological implantation. Therefore, we conclude the surface functionalized IOL has the potential to control PCO.

INTRODUCTION

Optical Projection Tomography (OPT), is a non-destructive 3D imaging technique, where a suspended specimen, immersed in an index-matching liquid, is rotated and an image is taken at each orientation. The 3D volume of the samples can be reconstructed using back projection algorithm [1].

Hydrogels are transparent biomaterials with a refractive index close to the refractive index of water. This reduces light reflection and scattering in hydrogels in a water solution, enabling OPT imaging without using optical clearing treatments. These optical characteristics enables the use of OPT to image the 3D microstructures of hydrogels and for *in vivo* OPT imaging of tissue engineered (TE) samples based on hydrogels. Here we present preliminary results of OPT imaging of different Gellan Gum (GG) hydrogels. Projections and 3D hydrogels reconstructions are shown and the statistical properties of the images are analysed.

EXPERIMENTAL METHODS

Four different hydrogels with physical crosslinking [*e.g.* monovalent cations or spermine (SPM)], different crosslinker quantities and chemical modifications with methacrylate (MA), and one hydrogel with combination of chemical and physical crosslinking, were imaged: (1) GG-MA 2% UV photocrosslinker, (2) GG-MA 2% ionic crosslinker, (3) GG 2% ionic crosslinker [2], (4) GG 1.1% ionic crosslinker (SPM) and (5) GG 0.6% ionic crosslinker (SPM). The hydrogels were inserted into fluorinated ethylene propylene tubes and submerged in water. Images were taken with a 5X objective, providing resolution of 3µm, around 360° at steps of 0.9 degree. 3D reconstructions were computed with back projection algorithm. Statistical information, as kurtosis (a measure of the shape of the probability distribution of the image histogram) and entropy (a measure of the randomness of the pixels intensities), were calculated from the projections and reconstructed slices in four samples of each hydrogel type.

RESULTS AND DISCUSSION

The projections and 3D reconstruction of hydrogels (1) and (5) are presented in Fig. 1 and 2. The microstructures of the hydrogels are visually different. These may be related with the properties of the hydrogels as density, viscosity and homogeneity.

Table 1 shows the mean values of the kurtosis and entropy, in the projections and 3D reconstructions, from each type of hydrogel. The hydrogels that present higher visual density of microstructures (hydrogels (1) and (2)) have lower values of kurtosis and higher values

Figure 1: OPT projections of (a) GG-MA 2% UV photocrosslinker and (b) GG 0.6 % ionic crosslinker (SPM) hydrogels.

Figure 2: OPT 3D reconstructions of (a) GG-MA 2% UV photocrosslinker and (b) GG 0.6 % ionic crosslinker (SPM) hydrogels.

of entropy while the opposite happens for the transparent hydrogels (hydrogels (3), (4) and (5)). High kurtosis values are related with a more homogeneous pixels intensities distribution in transparent hydrogels while high entropy is related with a more random intensity distribution in high density hydrogels.

Table 1. Kurtosis and entropy values for the projections and reconstructions of (1) GG-MA 2% UV photocrosslinker, (2) GG-MA 2% ionic crosslinker, (3) GG 2% ionic crosslinker, (4) GG 1.1% ionic crosslinker (SPM), (5) GG 0.6 % ionic crosslinker (SPM) hydrogels. Mean Value \pm Standard Deviation

	Projections		Reconstruction	
	Kurtosis	Entropy	Kurtosis	Entropy
1	4.9 \pm 0.20	5.8 \pm 0.04	3.7 \pm 0.08	5.48 \pm 0.1
2	5.3 \pm 0.2	5.7 \pm 0.05	3.6 \pm 0.07	5.75 \pm 0.0
3	7.3 \pm 1.2	5.0 \pm 0.33	114.7 \pm 99.2	2.94 \pm 0.5
4	8.7 \pm 3.2	4.7 \pm 0.27	43.1 \pm 7.9	2.52 \pm 0.4
5	35.4 \pm 11.8	3.7 \pm 0.09	202.2 \pm 65.5	1.24 \pm 0.3

CONCLUSION

We have shown that OPT is a suitable tool for imaging hydrogel microstructure and that statistical data, such as kurtosis and entropy, could be used to characterize hydrogels according to their optical properties.

INTRODUCTION

Kidney diseases affect millions of people worldwide. The incidence of kidney diseases is rising by almost 8% every year interdependently to its main causes: diabetes and high blood pressure. The chronic condition of the kidney illness eventually leads to the end stage renal disease (ESRD). The best treatment option in such a case is renal replacement. However, due to the high cost of the procedure the majority of the world population cannot afford it. Therefore, dialysis is considered as a cheaper alternative treatment. Dialysis is a life sustaining therapy for patients who progress to ESRD and do not receive a transplant. Despite the relatively high cost of dialysis patient survival remains poor. Current dialysis systems remove small, water soluble metabolites but fail to remove significant amounts of higher molecular weight and protein bound uraemic toxins whose retention is the most damaging. To address this problem, we are developing an alternative extracorporeal treatment using adsorption principle by activated carbon as the main clearing process.

EXPERIMENTAL METHODS

Activated carbon (AC) materials both beads and monolithic columns were assessed for their ability to adsorb inflammatory molecules from blood in a circulating system. The materials studied included AC granules from Norit (Netherlands) and MAST Carbon (UK) monoliths prepared from phenyl-formaldehyde resin precursors. These materials were assessed for their adsorptive capacity for a range of biological toxins in a recirculation system using fresh frozen human plasma to mimic the process of haemoperfusion in the clinic. An enzyme linked immunoadsorbent assay (ELISA) was used to determine the concentration of the proinflammatory cytokines, tumor necrosis factor (TNF), interleukin-6 (IL-6) and IL-8 (BD Biosciences) in the plasma samples.

RESULTS AND DISCUSSION

TNF, IL-6 and IL-8 cytokines were chosen because of a size range of molecules over which adsorption by the carbons can be assessed. All three cytokines were effectively removed from the solution and blood plasma. Figure 1 demonstrates results of adsorption of cytokine IL-8 over time. It is clearly seen that activated carbon particles from Norit with pore sizes between 4-100 μm effectively remove cytokines from the solution within 24 hours. Adsorption of cytokines was directly proportional to the time of incubation, where adsorption increases with increased time of incubation. IL-8 cytokine adsorption increases to 30 minutes of incubation and continues to fall after this time. In comparison to TNF, adsorption of IL-8 cytokines was

higher. This may be due to the difference in the molecular weight of cytokines, TNF is a larger molecule and thus may have a slower rate of adsorption and also may require larger pores within the carbon particle for its adsorption.

Monolith filtration/adsorption experiments to determine the adsorption capacity of the MAST carbon monoliths revealed the increasing adsorption of the cytokines TNF, IL-6 and IL-8 from blood over time up to 60 minutes of circulation. The greatest removal was measured for the smallest cytokine IL-8 with ~70% removal achieved at the 60 minute time point with ~65% removal of IL-6, whereas removal of the larger TNF molecule was less successful, reaching a maximum of 40% removal. These results followed the pattern of the adsorption by the Norit carbon particles, whereby the adsorption capacity for larger TNF molecule was lower than for the other two smaller cytokines.

Figure 1. Levels of cytokine IL-8 remaining in the solution after incubation with activated carbon beads over time compared to the positive control (no adsorbent), (mean n=3, +/- sem).

CONCLUSION

The adsorption profile for the cytokines TNF, IL-6 and IL-8 revealed that the monoliths were able to remove clinically relevant levels from blood, although the removal of TNF was more challenging. These results suggest that using carbon monoliths as a haemoadsorption device could provide a potential therapy to treat patients with high levels of inflammatory cytokines in their systemic blood in conditions such as systemic inflammatory response syndrome and sepsis that possibly can lead to kidney dysfunction and renal failure.

Evaluation of short-term degradation of bicomponent electrospun fibres via AFM analysis

Marica Marrese, Vincenzo Guarino*, Valentina Cirillo, Luigi Ambrosio

Institute for Polymers, Composites and Biomaterials, National Research Council of Italy, Mostra D'Oltremare, Pad.20,
V.le J.F. Kennedy 54, 80125, Naples, Italy, vguarino@unina.it

INTRODUCTION

The use of atomic force microscopy (AFM) in biomaterials science and tissue engineering applications has increased quickly over the last few years. Beyond being a merely tool for characterising surface topography, AFM has made significant contributions in the understanding of the structure and properties of biomaterials surface and interfaces. Tip-sample interactions in AFM measurements provide complementary information about topography, chemical and elastic properties of any condensed matter. The aim of this study is to investigate on the chemical and morphological changes of Gelatin-rich Polycaprolactone (PCL) fibres during the degradation process in simulated culture medium by the use of Atomic Force Microscopy (AFM) in order to collect more information to better explain in vitro mechanisms of cell/fibre interaction.

EXPERIMENTAL METHODS

PCL/Gelatin fibres were successfully fabricated by using an automatic equipment (Nanon01, MECC, Japan) and then conditioned in simulated culture medium (SCM, i.e., Eagle's alpha minimum essential medium without protein serum) until 6 days. At the first stage, morphology of fibres was qualitatively investigated by Field Emission Scanning Electron Microscopy (FESEM) in low vacuum (LV). Then, morphological and structural properties were quantitatively estimated via Atomic Force Microscopy (AFM) as a function of process conditions and post-treatments in order to evaluate the effect of Gelatin degradation on the fibre architecture at different times. Tapping Mode (TM) was employed to scan electrospun fibres surface whereas AFM imaging was performed at room temperature by using a silicon cantilever probe, a resonant frequency of 320 kHz and a scan rate of 0.2 Hz. Mean fibre diameter was calculated averaging 10 measurements at different incubation times. The images of interest were first captured by AFM raster scanning and then processed using the NanoScope Analysis data processing software 1.40 (Bruker Corporation, USA).

RESULTS AND DISCUSSION

TM-AFM measurements reveal a random network of beadless fibres of untreated PCL/Gelatin electrospun membranes. Just after 1 day in SCM, changing in

topographical features can be detected onto the fibre surface due to the beginning of Gelatin loss along the fibre surface. As a consequence, a larger reduction of PCL/Gelatin fibres diameter respect to untreated ones is detected. Gelatin depletion directly affected the surface roughness (R_q), showing an increase of R_q value from (46.2 ± 5.3) nm up to (78.91 ± 15.94) nm, as the SCM treatment goes on. Recording AFM interactions between the tip and the surface, adhesion force and chemical surface changes during the treatment were detected. Since the scanned PCL/Gelatin fibres are a bicomponent polymer blend system, it has been possible to identify differences in material properties at different locations on the sample surface by AFM phase image. Phase contrast between PCL and Gelatin domains are ascribable to different sample characteristics such as sample hardness, adhesion and elasticity, with drastic changes at different times in SCM solution. Hence, these data suggest that Gelatin probably plays a complex role on the interaction with cells by modifying bioactivity and stiffness of fibres during in vitro culture.

CONCLUSION

In this study, AFM analysis has been properly set to estimate the Gelatin loss from fibre surface during SCM treatment. Results showed a progressive slowing of the hydrolytic degradation of protein which does not significantly alter fibrous structure. An increase of surface roughness as well as a decrease of fibre diameter have been detected. In this context, Gelatin release coupled with improved roughness of fibres surface should similarly occur in cell culture, positively influencing the basic mechanisms of cell adhesion and spreading, this better mimicking the real microenvironment of natural tissues.

INTRODUCTION

Porous titanium had been proposed as implant materials in bone tissue engineering due to their low young modulus, their high biocompatibility and osteointegration properties. The study of the impact of different porous materials permits designing optimal porous implants due to the higher specific surface in contact with bone when compared with smooth surfaces.

Several methods had been proposed to ensure the formation of apatite in the titanium surface promoting an effective bone adhesion of an implanted titanium surface to living bone. Kokubo et al. (1) proposed a thermo-chemical method, which consist in a chemical and thermal treatment, to form a bone-like apatite layer on its surface in a simulated body fluid (SBF). For this, it is also important to evaluate how the surface composition and the porosity will influence in the cell-material interactions because of potential consequences for bone regeneration and vascularization.

The aim of this study was to investigate the effect of the bioactive treatment in novel sintered porous titanium materials for vertebrae stabilization implant. In this study, the surface of porous titanium scaffolds was compared with same material with different optimizations of typical bioactive treatments.

EXPERIMENTAL METHODS

A standard bioactive treatment consist in a chemical step of immersion of the porous samples in an aqueous NaOH solution at 60°C for 24 h, subsequent drying process at 60°C and in a thermal step by heating to 600°C for 1 h.(1).

The effect of the surface treatment was analyzed using scanning electron microscopy (SEM), TF-XRD, Optical Surface Profilometry (MI) and Raman dispersive spectrometer analysis. The apatite-forming ability of the samples was examined by soaking titanium samples in SBF and examining the homogeneity of the bioactive surface by SEM, focused ion beam (FIB) and TF-XRD.

RESULTS AND DISCUSSION

The bioactivity treatment was confirmed by the presence of titanates, over the surface and inside the pores, which will favour the apatite *in vivo* formation

(Fig.1) Different bioactive treatments were studied by TF-XRD and RAMAN techniques. Raman results suggested that the identified titanate structures will facilitate the *in vivo* apatite formation by promoting the ion interchange process for the apatite formation process, while other titanate structures are not able to induce ion interchange. The morphology and crystallinity of the obtained apatite may depend on this titanate structures.

Figure. 1. SEM micrographs of the surfaces of some of the studied bioactive porous materials after immersion in SBF for 12 days. These samples were treated with different bioactive treatment conditions, A) NaOH 5M 1:1; B) NaOH 1:2.

CONCLUSION

The presented bioactive scaffolds show the beneficial effects for tissue ingrown for their use clinical use.

⁴ ATMT Research Institute, Department of Textile Engineering, Amirkabir University of Technology, Tehran, Iran.

INTRODUCTION

Poly (ϵ -caprolactone), (PCL) has recently attracted considerable research attention notably in biomedical areas. It can be spun to fibers for subsequent fabrication of desirable textile structures. Due to excellent characteristics, such as biodegradability, biocompatibility and three-dimensional structures, PCL fibers whose diameter range from nanometer to millimeter, are broadly studied for biomedical applications such as bioresorbable constructs, drug delivery systems and tissue engineering scaffolds. Extrusion of the PCL into monofilament and multifilament may be achieved by melt spinning, solution spinning, and electrospinning. There are distinct features of each of these processes that are subsequently reflected in fiber properties. Many factors and variables can affect the ultimate properties of fibers obtained via solution spinning. In recent years, the mechanism of fiber formation and the influence of wet spinning parameters on PCL fiber properties have been studied through experimental observations [1, 2]. However knowledge on the influence of the dry - spinning parameters on the properties of PCL fibers through theoretical simulations is lacking. In this study, the effect of dry-spinning parameters including solution concentration, spinning speed and draw ratio on mechanical and morphological properties of fibers were systematically investigated using the response surface methodology (RSM).

EXPERIMENTAL METHODS

The effects of dry-spinning parameters on fiber properties were investigated applying a full-factorial Face Centered Central Composite Design (CCD) by using RSM (Design Expert 8.0.7.0, Stat-Ease, Inc., USA). The experimental range and coded levels of independent variables are presented in Table 1.

Table 1. Coded and actual levels of the design factors.

Variable	Code	Real values of the coded levels		
		-1	0	1
Concentration (wt %)	A	20	25	30
Spinning speed (cm/s)	B	3	5	7
Draw ratio	C	5	6	7

A three-factor CCD design with a total of 20 runs, including 8 factorial points, 6 axial points and 6 replicates at the center points, was used to fit a second-order response surface. Statistical significance of the model and the regression coefficients were estimated by analysis of variance (ANOVA) combined with the

application of Fisher's F-test as well as Student's T-test. The probability values (p-value) are utilized to consider the statistical significance of the determined model, with a threshold value of $p < 0.05$. The accuracy of the model was also checked by the coefficient of determination R-squared (R^2).

RESULTS AND DISCUSSION

The effect of dry-spinning parameters on mechanical and morphological properties of PCL fibers were systematically investigated using RSM. The ANOVA results indicated that the linear mass density ($\bar{\lambda}_m$) of fibers was most suitably described with a two factor interaction (2FI) model (Eq. 1).

$$\bar{\lambda}_m = +18.55 + 1.36A + 1.26B - 4.04C - 0.085AB \quad (1)$$

Statistical analysis shows that solution concentration (A) is the major factor affecting the linear density followed by draw ratio and spinning speed, respectively. Quadratic and linear models were fitted to the results of tensile strength (TS) and Young modulus (Y) respectively as following equations:

$$TS = -167.75 + 2.78A + 33.79B + 10.68C - 2.83B^2 \quad (2)$$

$$Y = -20.811 + 5.27A + 13.96B \quad (3)$$

The size and cross-sectional shape of fibers have direct effect on the surface properties of fibers. The size or diameter of fiber determines its total surface-to-volume ratio (L/A). In this study, the cross section of fibers were not completely circular therefore L/A ratio and the circularity (C) of fibers was calculated using image analysis of fiber cross section SEM images in Photoshop CS -5 software. The quadratic models were suggested to the results of L/A ratio and circularity of fibers respectively (Eq. 4, 5).

$$L/A = +0.128 - 8.23 \times 10^{-3}A + 3.35 \times 10^{-3}C + 1.37 \times 10^{-4}A^2 \quad (4)$$

$$C = -1.90 + 0.192A - 3.4 \times 10^{-3}A^2 \quad (5)$$

Statistical results show that the solution concentration (A) is the major factor affecting the L/A ratio and circularity of PCL fibers.

CONCLUSION

Response Surface Methodology (RSM) was performed to optimize the dry- spinning parameters for PCL fiber production. Different significant models obtained by Central Composite Design (CCD) are very useful for determining the optimal process parameter values for production of fibers with desirable properties.

Gentamicin-Loaded Microparticles Immobilized on Porous Scaffolds for Prevention of Biomaterials-Related Bone Infections

Urszula Posadowska*, Malgorzata Krok-Borkowicz, Lucja Rumian, Elzbieta Pamula

*Faculty of Materials Science and Ceramics, AGH – University of Science and Technology, Krakow, Poland
uposadow@agh.edu.pl

INTRODUCTION

Surgical procedures performed on bone tissues are often accompanied by the risk of microbial infections¹. These infections frequently result in bone tissue damage, formation of treatment-resistant biofilm, or expansion of microbes to soft tissues². Microbes elimination requires application of antibiotics in high doses³. To avoid adverse effects recent studies have explored the usage of antibiotic-loaded implants⁴. Therefore, in our study we intended to produce poly(l-lactide-co-glycolide) (PLGA) micro-particles (MPs) containing gentamicin sulphate (GS) and immobilize them on PLGA scaffolds in order to produce a new type of local drug delivery system for prevention of biomaterials-related bone infections.

EXPERIMENTAL METHODS

Gentamicin sulphate (Galfarm) was encapsulated in PLGA (PLGA, 85:15, Mn=80 kDa) microspheres via double-emulsification technique. To optimize the size and solubilization properties of MPs emulsion formation in different conditions was tested. Parameters such as surfactant concentration (1%, 4% polyvinyl alcohol - PVA), amount of loaded gentamicin (2, 10, 20 mg/ 100 mg PLGA) as well as form of antibiotic (solid or dissolved) were adjusted. Solubilization properties (encapsulation efficiency and loading efficiency) and drug release from MPs were evaluated by derivatization with OPA reagent (UV-vis spectroscopy, $\lambda=332$ nm). PLGA porous scaffolds produced by solvent casting-particle leaching⁵ were pre-wetted either by UHQ-water or ethanol. MPs suspended in hydrogels (collagen type I or sodium alginate) were immobilized on the scaffolds. The effectiveness of MPs immobilization was analyzed by scanning electron microscopy (SEM).

RESULTS AND DISCUSSION

Physicochemical parameters of drug-loaded carriers highly affect drug release rate. For microparticles drug release and their presence in the extracellular space are advantageously longer than for nanoparticles⁶. Thus, our first aim was to produce micro-sized, homogenous particles characterised by good solubilization parameters. Performed studies showed that size of the MPs decreased with GS content - from 16 μ m to 3 μ m. The size did not depend on the form of drug, but loading and encapsulation efficiencies were significantly higher when GS was applied in a solid form (Fig 1, $p < 0.05$). Increase in PVA concentration resulted in improvement of MPs homogeneity. Drug release studies of MPs showed short burst release followed by prolonged release phase.

Fig 1. Encapsulation efficiency (%EE) and loading efficiency (%LE) of the microspheres with solid and liquid form of GS vs. initial drug amount (2, 10 or 20 mg / 100 mg PLGA).

Fig 2. PLGA scaffolds microstructure (SEM) without modification (A) and with immobilized MPs in collagen type I hydrogel (B).

We detected positive effects of MPs immobilization when the scaffold were pre-wetted with ethanol, which improved PLGA hydrophilicity. Beneficial for immobilization effectiveness was when MPs were suspended in hydrogels – especially collagen (Fig 2). It can be attributed to collagen affinity to PLGA surface as already reported for PLGA scaffolds in our previous studies⁷.

CONCLUSION

We detected that immobilization of gentamicin-loaded MPs within the scaffolds was effective. Hence we may conclude that our biomaterials constitute a prospective solution in prevention of biomaterials-related bone infections.

l.lee.1@research.gla.ac.uk; Lesley-Anne.Turner@glasgow.ac.uk

INTRODUCTION

Mesenchymal stem cells (MSCs) hold great potential in regenerative therapies, though low cell numbers in the body currently limits their use in clinical applications. We wish to greater understand stem cell renewal in order to promote expansion of MSCs and obtain an autologous population, which could be further differentiated into desired cell lineages. Previous work with nanoscale topographies demonstrated stimulated osteogenic differentiation of MSCs¹ or retention of multipotency² on two different nanopatterned surfaces, which provides a method to study MSC self-renewal and differentiation. We hope to determine the best conditions to promote MSC growth on nanotopography whilst retaining their multi-potentiality.

EXPERIMENTAL METHODS

MSCs were enriched from human bone marrow (adherent) mononuclear cells by magnetic activated cell sorting. MSCs were seeded onto flat (planar), a surface comprising a square lattice arrangement of pits (SQ) or a near-square arrangement incorporating an element of random distribution; $\pm 50\text{nm}$ (NSQ). Nanopits were 120nm diameter, with 300nm centre-centre spacing and 100nm depth. MSC responses to nanotopography were characterised using immunocytochemistry in conjunction with image analysis (CellProfiler) or coupled with in-cell western detection, Coomassie blue staining, scanning electron microscopy (SEM) and metabolomics. Statistical significance was assessed using paired students t-tests between two variables, with p values below 0.05 deemed significant.

RESULTS AND DISCUSSION

Optimisation of cell density was found to be important for effective use of these patterns with polycarbonate as a base material. Our optimised cell number allows for good coverage of the surface, retention of stem cell marker expression on SQ, whilst promoting a degree of clonal growth which may be important for promotion of self-renewal. Further investigation into the mechanism of self-renewal revealed changes in levels of cell cycle-related proteins between MSCs cultured on SQ and NSQ. SEM imaging showed that filopodial contact guidance was apparent on SQ in comparison to NSQ and flat (figure 1). Metabolomics identified a number of small molecules used and produced by MSCs in response to nanotopographies.

Figure 1. SEM imaging of the SQ and NSQ surfaces with representations of MSC filopodia distribution on SQ and NSQ after short-term culture (1hr). Scale bars: 750μm and 1μm as marked.

These results suggest that there is an association between physical interactions of MSCs with particular nanotopographies which parallel with differences in growth and eventual phenotype on the two surfaces.

CONCLUSION

Cell density was identified as being of key importance for effective retention of stem cell marker expression on SQ. We propose that morphological differences of MSCs on SQ in comparison to NSQ are linked to biochemical changes involved in cell cycle, and highlight a number of key metabolomic targets for maintenance of multipotency.

Elastomeric Polycaprolatone scaffold for cardiovascular tissue engineering

Shraddha Thakkar¹, Anita Mol Driessen and Frank Baaijens

Soft Tissue Biomechanics & Tissue Engineering, Eindhoven University of Technology, the Netherlands
s.h.thakkar@tue.nl

INTRODUCTION

In situ tissue engineering of cardiovascular tissues is emerging as a promising approach to create living replacement by direct implantation of the scaffold *in vivo*. In this approach, the scaffolds must be able to withstand hemodynamic loads while enabling cell infiltration and tissue formation [1]. Scaffolds composed of synthetic materials have gained great attention due to ease in processing and characterization [2]. Polycaprolatone (PCL) is known for its biocompatibility, slow degradation rate and the ability to accommodate a wide variety of cells [3]. However, PCL has limited fatigue resistance and is relatively stiff, while fatigue resistance and flexibility are essential properties for cardiovascular scaffolds. We have developed multimaterial scaffolds using dual electrospinning. In this approach, a backbone polymer (BP) and fast degrading polymer (FDP) are spun simultaneously to form a multifiber scaffold. By elimination of the FDP, the void space in the scaffold is enhanced, facilitating cell infiltration [4]. Two biodegradable polymers have been investigated as BP: an elastomeric polycaprolatone (ePCL) and PCL, with polyethylene-oxide (PEO) as FDP. Scaffolds were subjected to biaxial tensile tests. Scaffold architecture (fiber diameter, porosity) before and after removal of PEO was analyzed using scanning electron microscope (SEM). ePCL results in higher porosity and fatigue resistance and less stiffness than PCL scaffolds. Further experiments to investigate cell recruitment, adhesion and differentiation should indicate which of these materials is best suitable for cardiovascular in situ tissue engineering.

EXPERIMENTAL METHODS

Scaffolds were produced by dual-electrospinning (Figure1). 14% w/w solution of PEO (Mw100,000) was prepared in chloroform was spun as FDP. 12.5% w/w ePCL or 20% w/w PCL was spun along with PEO. Biaxial tensile testing performed using 1.5N load cell. The scaffold morphology with and without PEO was analyzed using scanning electron microscope (SEM).

Figure 1: Dual electrospinning setup consisting of rotating target and two syringes attached to positive voltage

RESULTS AND DISCUSSION

Scaffolds were fabricated using the same spinning conditions. PCL scaffolds were thicker and stiffer in nature with fiber diameter of around 7-8.5 μm , while ePCL fiber diameter was 4-5 μm . Overnight degradation in water showed a significant decrease in weight of ePCL scaffold. Elimination of PEO enhances the void spaces, which in turn will improve cell infiltration. SEM images (Figure 2) after removal of PEO showed higher porosity in case of ePCL scaffolds compared to PCL scaffolds. Increase in porosity of the scaffold may lead to decrease in mechanical properties [5].

Figure 2: SEM images (1000X) of electrospun scaffolds without PEO A) PCL B) ePCL

PCL/PEO scaffolds were stiffer than ePCL/PEO scaffolds. After removal of PEO, PCL scaffolds showed a large decrease in mechanical properties, whereas ePCL scaffolds showed a minor decrease in mechanical properties and better fatigue resistance.

CONCLUSION

Scaffolds fabricated with ePCL are fatigue resistant and flexible, which are vital properties for the development of cardiovascular substitutes. Dissolution of PEO increases the porosity of the scaffold, while maintaining the overall scaffold morphology.

INTRODUCTION

Polypropylene (PP) meshes are used since the 1970s, when Lichtenstein for the first time described utilizing polypropylene mesh for tension-free hernia repair [1]. Nonetheless, numerous experimental and clinical studies have revealed different problems: a typical foreign-body reaction at the interface of mesh devices, including inflammation, fibrosis, calcification, thrombosis or infection [2,3]. Recognizing the importance of the problem, we fabricated for the first time injectable polymers capable to turn into flexible materials in defected tissue cavity. These new materials are applicable in endoscopic procedures.

The present work will present the biological response *in vitro* and *in vivo* of flexible materials formed upon UV-curing of telechelic (meth)acrylic macromers comprising fatty acids [4]. In addition, we examined the potential of the injectable material for herniated tissue reinforcement and reconstruction in animal model.

EXPERIMENTAL METHODS

The basis for new injectable elastomeric materials for hernia repair were telechelic macromers end-capped with methacrylic functionalities which were synthesized according procedure described in [4] to provide UV curable systems (black light, $\lambda_{\text{peak}}=365$ nm, 2-5 min in air, 1-2% of photoinitiator IrgacureTM 819). Materials biocompatibility was assessed in *in vitro* and *in vivo* (rabbits) studies. Hydrolytic and enzymatic degradation was determined *in vitro*. Artificial hernia was created in rabbits by excision of 1 to 2 cm of muscular-fascia lobe and revealing the peritoneum. Viscous telechelic macromer was injected into hernia opening and irradiated with UV light for 5 min to create flexible film *in situ in vivo*.

RESULTS AND DISCUSSION

As we already demonstrated in earlier studies, new flexible networks fabricated from telechelic monomers are matching well the mechanical properties of the abdominal wall. The *in vitro* cytotoxicity test showed that polymer extracts caused a concentration-dependent decrease in viability of fibroblasts. The materials showed slow hydrolytic and enzymatic degradation with a mass loss of 8% after 49 days *in vitro*. The results of biocompatibility tests *in vivo* (28 days implantation) showed low level of inflammation with mostly fibroblasts, lymphocytes, and macrophages. Giant cells were not observed. Finally, hernia repair was performed by injecting the viscous macromer into

the area of the opening. After short UV-curing, the defect was closed with *in situ* polymerizing material. The visual inspection of healed tissue showed healthy tissue perfectly closing herniated tissue in a similar way as polypropylene mesh did (Fig. 1).

Fig. 1. Gross inspection of healed tissue after 28 days with a) injected new material, b) with PP mesh.

CONCLUSION

New injectable viscous biomaterials were fabricated. The results demonstrated that new injectable and photocurable systems can be used for minimally invasive surgical protocols in repair of small hernia defects.

Corrosion resistance assessment of NiTi alloys in 0.9% NaCl solution

Camila Dias dos Reis Barros (Camila Barros)¹ and José Antônio da Cunha Ponciano Gomes (Ponciano Gomes)¹

¹Department of Metallurgy and Materials Engineering, Federal University of Rio de Janeiro, Brazil,
creis@metalmat.ufrj.br

INTRODUCTION

NiTi shape memory alloys are used as biomaterials because of their proprieties such as biocompatibility, good corrosion resistance and pseudoelasticity^{1,2}. The additions of ternary elements can improve the mechanical proprieties, however, changes in alloy composition can affect the corrosion resistance of these materials^{3,4,5,6,7}. This study aims to evaluate the corrosion resistance of NiTi, NiTiCo and NiTiCr alloys in 0.9% NaCl solution, and compare the results obtained.

EXPERIMENTAL METHODS

Electrochemical tests were performed such as impedance spectroscopy and anodic polarization. The corrosion potential were measured after 1h of immersion. The electrochemical impedance were performed in a frequency range within 10 kHz and 10 mHz. with 10 mV of amplitude. The anodic polarization were taken from the corrosion potential to 800mV above this in a range of 20 mv/min.

RESULTS AND DISCUSSION

The behavior of the alloys corrosion resistance were evaluated through the Nyquist diagram shown in Figure 1 and the anodic polarization curves shown in Figure 2. The results obtained though these electrochemical tests showed the good interconnection between the values of R_p (polarization resistance) and ΔE (passive range) through these curves.

Figure 1: Impedance spectroscopy of NiTi alloys in 0.9%NaCl solution.

Figure 2: Anodic polarization of NiTi alloys in 0.9%NaCl solution.

The binary alloy presented the highest values of polarization resistance ternary alloys evaluated in impedance spectroscopy, while the ternary alloys showed low values of polarization resistance.

The binary alloy presented the highest values of corrosion resistance with greater passive range and without the presence of pitting, while the NiTiCo and NiTiCr alloys showed low values of pitting potential with a short passive range.

CONCLUSION

With the results obtained so far it was observed that the addition of ternary elements could implicate the corrosion resistance of the alloy, which were evidenced by the reduction of the passive range for ternary alloys compared to binary alloy that remained to be passive. Among the alloys studied, the corrosion resistance were observed in the following order: NiTi > NiTiCr > NiTiCo.

Supermacroporous Cryogels for Bioligand Binding

Ganesh Ingavle, Yishan Zheng, Carol Howell, Irina Savina and Susan Sandeman

Biomaterials and Medical Devices Research Group, School of Pharmacy and Biomolecular Sciences,
University of Brighton, United Kingdom, g.c.ingavle@brighton.ac.uk

INTRODUCTION

Polymeric cryogels are efficient carriers for the immobilisation of biomolecules because of their unique macroporous structure, mechanical stability and different surface chemical functionalities. Cryogels have been investigated for a number of bio-related applications, including bio-separations, bio-catalysis, chromatography, monolayer cell separation, and recently regenerative medicines [1-3]. Recently, a growing interest has been shown in using cryogels as adsorbents for diverse applications including protein purification and biomedical therapy [4-6]. The aim of the study was to demonstrate macroporous monolithic cryogel column potential in the field of biotoxin removal using covalent immobilisation of monoclonal antibodies.

EXPERIMENTAL METHODS

Cryogels with commonly used surface functional groups suitable for biomolecules immobilization such as hydroxyl and epoxy functionalities were synthesized using cryogelation technique (Fig. 1). The adsorptions of monoclonal IgG antibodies were evaluated on poly (vinyl alcohol), poly-hydroxyethyl methacrylate (HEMA-MBA), poly-hydroxyethyl methacrylate (HEMA-PEGDA) having hydroxyl functionalities and poly(acrylamide/allyl glycidyl/MBA) having epoxy functionality with immobilized protein A. The affinity ligand (protein A) was chemically coupled to the reactive hydroxyl and epoxy-derivatized monolithic cryogels and the binding efficiency of the IgG antibodies to the cryogel column were determined.

Fig. 1. Schematic showing the different steps involved in cryogel formation.

RESULTS AND DISCUSSION

The MTS and LDH assay results showed that the viability and membrane integrity of V79 cells after 24 hours of 100% and 50% cryogel extract treatments were very close to the control treatments, indicating that the cryogel extracts did not cause cytotoxic effect during

the 24 hours exposure time. Optimum binding capacities, 92.7 and 122.4 mg/g of adsorbent (cryogel), for protein A and IgG, respectively were observed in AAm/AGE/MBA cryogel as shown in Table 1. Our results show differences in the binding capacity of protein A as well as IgG to the cryogel adsorbents caused by ligand concentration, flow characteristics, physical properties and morphology of surface matrices (Table 1).

Table 1. Binding capacities of cryogel towards protein-A and IgG antibodies

	Protein-A mg/g of adsorbent	IgG mg/g of adsorbent
AAM-AGE	92.7	122.4
HEMA-MBA	40.5	60.5
HEMA-PEGDA	41.9	51.2
PVA-GA	86.8	97.4

CONCLUSION

This work demonstrated that it is possible to bind specific IgG monoclonal antibodies to the supermacroporous cryogels with different functionalities. The high binding capacity towards IgG antibodies, mechanical strength, biocompatibility, flow characteristics of the cryogel adsorbents indicated potential application of these materials for bio-toxins removals.

INTRODUCTION

Nanofibres are currently one of the most intensively studied materials for applications in biomedical areas [1]. In order to apply nanofibres for biomedical use, it is convenient to modify their surface chemically and physically with bioactive molecules [2]. Therefore, potential toxic effects of modified biomaterials is necessary to determine as well. Developing new biomaterials based on nanofibres, any degree of toxicity are not suitable for further study.

EXPERIMENTAL METHODS

In this study the scaffold composed of nanofiber web – polyurethane (PUs) deposited on polypropylene textile substrate by electrospinning process was used.

In the first step, low-temperature plasma treatment in the atmosphere of air was applied to modify the surface of polyurethane nanofiber web. The scaffolds were subsequently modified with solution of berberine chloride (BRB) and solution of 0.5% chitosane containing β -cyclodextrine (CH/ β -CD). The modified scaffolds were prepared by dipping scaffolds, immediately after plasma treatment, to the solutions, drying them at room temperature and afterwards rinsing in distilled water.

Both human dermal fibroblasts and mouse fibroblasts (3T3 NIH) were used for “in vitro” biocompatibility tests - assay contact toxicity and MTT assay.

RESULTS AND DISCUSSION

The initial results indicated that after the process of modification the weight of scaffold increases to approx. 20%, although after rinsing in distilled water this increase was reduced to approx. 5%.

Results of ATR-IR spectroscopic determination of the modified scaffolds confirmed the presence of absorption bands related to the presence of modified ingredients (BRB, CH/ β -CD).

Toxic effect was evaluated visually by using microscopic observation and by counting the number of 3T3 and DF cells in corresponding parallel experiments.

Fig. 1: Evaluation of toxic effects of scaffolds on DF cells by microscopic observation: **a**, DF cell control **b**, PUs-BRB **c**, PUs-CH/ β -CD

Fig. 2: Evaluation of toxic effects of scaffolds on 3T3 cells by microscopic observation: **d**, 3T3 cell control **e**, PUs-BRB **f**, PUs-CH/ β -CD

The microscopic observation did not show the toxicity of modified scaffolds. Cells in the contact with scaffolds PUs - BRB and PUs-CH/ β -CD (Fig. 1b-c, Fig. 2 e-f) were grown without visible changes comparable with the cell DF and 3T3 control (Fig. 1 a, Fig. 2 d).

Eluates of tested nanofiber webs were used for MTT test. Using MTT assay, we found that several day eluates prepared from modified scaffolds did not show toxic effects.

CONCLUSION

Experiments performed on both cell systems show that the modified scaffolds are not toxic. In the future it will be necessary to perform further analyses which clearly will demonstrate that the modified scaffolds are suitable for further use in the biomedical field.

Pre-clinical Evaluation of Additive Manufactured Surfaces for Orthopaedic Applications

Grace Stevenson¹, John Haycock², Sarrawat Rehman¹, James Hunt³ and Edward Draper¹

¹JRI Orthopaedics Ltd, Sheffield, UK

²Centre for Biomaterials & Tissue Engineering, University of Sheffield, UK

³Mercury Centre, University of Sheffield, UK
grace.stevenson@jri-ltd.co.uk

INTRODUCTION

Cementless fixation of orthopaedic implants was introduced in the 1970s, and is the favoured method of fixation for younger, active patients¹. Cementless fixation can be achieved by bone ingrowth into porous metallic coatings prepared from sintered beads, bonded fibre metal mesh or plasma sprayed titanium². However, such surfaces are only available as coatings which can be prone to delamination and cracking which can lead to implant loosening¹. Additive manufacturing technologies, e.g. electron beam melting (EBM), are of great interest for orthopaedic applications, as they enable the manufacture of surfaces which mimic trabecular bone structure³. Such surfaces are impossible to produce via traditional manufacturing routes. Using EBM, parts are built up layer by layer from a CAD design, and solid implants with a porous surface can be created in one manufacturing step, therefore reducing the delamination issues associated with coatings³. Biological evaluation is a key step in assessing the suitability of surfaces prepared by new technologies for orthopaedic applications. The aim of this work was to carry out pre-clinical assessment of surfaces produced by EBM technology using primary human osteoblast culture, and cutting edge 3D confocal imaging to capture the shape and adhesion of the cells to the surfaces throughout the lattice structures.

EXPERIMENTAL METHODS

Titanium alloy (Ti6Al4V-ELI) discs (12 mm diameter x 9 mm depth) with a solid base and upper porous lattice structure were prepared by EBM (ARCAM S12 EBM machine). Lattices were prepared with two truss lengths (1.5 mm and 2.5 mm) to evaluate the effect of pore size. Scanning electron microscopy (SEM) and 3D profilometry were used to assess the morphology of the surfaces. *In vitro* bone cell response to the surfaces was investigated using commercially sourced primary human osteoblast (HOB) cells. Cell viability was examined using MTT absorbance, and cell shape, adhesion and calcium deposition on test surfaces were examined using 3D confocal microscopy and immunolabelling.

RESULTS AND DISCUSSION

SEM imaging showed clear differences in overall morphology between lattices with 1.5 mm and 2.5 mm truss lengths (Figure 1). Biological testing showed a significant difference (* $P < 0.05$ by Student's t-test) in cell viability between the 1.5 mm and 2.5 mm lattice structures, indicating that the lattice parameters had an effect on cell activity. 3D confocal microscopy enabled imaging of cells throughout the lattice structures, with

cells clearly observed along lattice trusses (Figure 2). Mineralised nodule formation was observed indicating that cells may subsequently lay down bone on these surfaces.

Figure 1 SEM micrographs of EBM lattice structures with truss length of a) 1.5 mm and b) 2.5 mm

Figure 2 a) 2D and b) 3D confocal images of primary human osteoblast cells immunolabelled with phalloidin-TRITC to show actin filament distribution across an EBM lattice structure.

CONCLUSION

Additive manufacture technologies offer unique opportunities to create new surfaces for orthopaedic applications. This work demonstrates that human bone cells respond favourably to surfaces manufactured by EBM technology; however the lattice parameters used, e.g. truss length, can significantly affect cell response. It is essential that cells are able to penetrate through the lattice structures and adhere to the surfaces to enable bone ingrowth.

⁴Clinical Sciences, UoB, UK, ⁵iNANO, Aarhus University, Denmark, ⁶Aerospace Engineering, UoB, UK

INTRODUCTION

Central Venous Catheters (CVCs) are essential in the treatment of critically ill and immunocompromised patients. However, they are associated with high rates of nosocomial bloodstream infection, with significantly higher incident rates among patients requiring long-term venous access.¹ Due to increasing concern regarding antibiotic resistance, there is a considerable drive to design and fabricate new antimicrobial CVC surfaces, to reduce initial colonisation by microorganisms and eventual biofilm formation without the need for conventional antibiotics.

Chlorhexidine (CHX) is well known for its broad-spectrum antimicrobial efficacy. Due to its mechanism of action, based on bacterial cell membrane disruption and subsequent intracellular leakage, CHX is thought less likely than antibiotics to promote the development of bacterial resistance. The purpose of this study is to investigate the antimicrobial efficacy of recently reported CHX-hexametaphosphate nanoparticles (CHX-NPs)² against methicillin-resistant *Staphylococcus aureus* (MRSA), *Pseudomonas aeruginosa* and *Escherichia coli*, for the development of an antimicrobial polyurethane (PU) CVC with long-lasting anti-biofilm efficacy.

EXPERIMENTAL METHODS

Nanoparticle synthesis: 5 and 50 mM CHX-NP suspensions were prepared by mixing a 1:1 ratio of aqueous CHX: aqueous HMP, at room temperature and pressure.²

Antimicrobial efficacy of CHX-NPs: Antimicrobial efficacy was investigated using total viable counts (TVC), time-kill kinetics, bacterial viability assays combined with Confocal Scanning Laser Microscopy (CSLM) and Scanning Electron Microscopy (SEM). For TVC and bacterial viability assays, CHX-NP functionalised specimens were inoculated with 1/100 dilution of a pre-culture of bacteria. CHX-NP solutions were inoculated with each microorganism for time-kill kinetic studies and subsequent TVCs were performed at 0, 30, 60, 90 and 120 min time points. MRSA, *P. aeruginosa* and *E. coli* were treated with 5 and 50 mM CHX-NPs for 0, 15 and 30 min for SEM.

RESULTS AND DISCUSSION

Live/Dead bacterial viability assays (Figure 1) indicated that 5 and 50 mM CHX-NPs prevented biofilm formation of MRSA, *P. aeruginosa* and *E. coli*. 5 mM CHX-NP time-kill kinetics demonstrated a pattern of bacteriostatic activity against MRSA and *P. aeruginosa*. *E. coli* showed a decrease in viable counts consistent

with bactericidal activity, defined as a reduction of $\geq 3 \log_{10}$ (99.9% killing) of the total count of CFU/ml.³

Figure 1. Maximum intensity projections of CSLM Live/Dead image stacks of untreated (A) and treated (B) *P. aeruginosa* with 5 mM CHX-NPs. Scale bars 20 µm ($Z = 7.815 \mu\text{m}$ (A) and $4.926 \mu\text{m}$ (B)).

After 15 min exposure to CHX-NPs, significant biofilm disruption was observed and cells showed surface irregularities, suggesting cell membrane disruption. After 30 min exposure, damaged bacterial cells were observed with cellular debris, thus suggesting cell lysis (Figure 2).

Figure 2. *P. aeruginosa* (A) untreated after 15 min and (B) treated with 50 mM CHX-NPs after 30 min. Scale bars 10 µm.

CONCLUSION

5 and 50 mM CHX-NPs prevented biofilm formation of MRSA, *P. aeruginosa* and *E. coli*. The bactericidal and bacteriostatic effects of CHX-NPs are thought to be mediated by cell membrane disruption. These findings suggest that the incorporation of novel antimicrobial CHX-NPs into a PU CVC may provide a promising new approach to the prevention of catheter-related infections.

INTRODUCTION

As new three-dimensional materials for hard tissue replacement are needed in a variety of biomedical treatment approaches, artificial scaffolds are promising mainly due to their ability to support cell attachment, proliferation and differentiation¹. These 3D structures should exhibit biocompatibility, a high level of interconnected porous structure and pore size along with the necessary mechanical strength.

Several inorganic materials have been used for this purpose such as silicate bioactive glasses². Their ionic dissolution products can stimulate expression of several genes of osteoblastic cells³, stimulate angiogenesis⁴ and present antibacterial^{5, 6} effects, while ion release from Mg or Zn containing bioactive glasses can stimulate tissue formation⁷ and significantly enhance the proliferation and differentiation of mesenchymal cells. Therefore, tailoring bioactive glasses to meet the needs of dental tissue morphogenesis and regeneration could provide scaffolds containing elements like Mg and Zn.

EXPERIMENTAL METHODS

Two sol-gel derived glass-ceramic compositions were synthesized as shown in table 1, while a Zn-free Mg-based sol-gel bioactive glass was used as control⁸.

a/a	SiO ₂ (% wt)	CaO (% wt)	MgO (% wt)	ZnO (% wt)
60S10M	60	30	10	---
60S7M2Z	60	30	7.5	2.5
60S10M2Z	60	27.5	30	2.5

Sol-gel derived bioactive glasses were produced as described in literature⁹ and then the glasses were pulverized in a hydraulic press and sieved to particle size under 40µm. The sieved powders of the bioactive glasses were then soaked in SBF solution for various immersion times. The characterization of the samples before and after immersion in SBF was conducted using Fourier Transform Infrared (FTIR) Spectroscopy using a Perkin-Elmer Spectrometer Spectrum 1000 in MIR region, Scanning Electron microscopy with associated energy dispersive spectroscopic analysis (SEM-EDS) and X-Ray Diffractometry (XRD) using a Philips (PW1710) diffractometer with Ni-filtered CuKα wave radiation. Inductively Coupled Plasma Atomic Emission Spectroscopy (ICP-AES) was used for the measurement of the ionic concentration of the SBF solution before and after the soaking time.

RESULTS AND DISCUSSION

The synthesized bioactive glasses revealed the characteristic FTIR bands of silicate glasses¹⁰. The main characteristics of both spectrums are the broad band at ~1100 cm⁻¹ assigned to the Si-O stretching mode and a band at 490 cm⁻¹ assigned to the Si-O-Si bending one. The XRD patterns of all compositions reveal high amount of an amorphous glassy phase prior to SBF immersion.

After immersion, the identification of an amorphous Ca/P phase was revealed on the surface of the samples, by both FTIR spectra and XRD patterns after 3-10 days, depending on the composition. Zn-based bioactive glasses exhibited identical behavior. EDS analysis confirms this finding, whereas ICP-AES reveals the ionic variations during immersion time.

CONCLUSION

Sol-gel derived silicate glasses containing Mg and Zn were synthesized. Bioactivity evaluation revealed the formation of a Ca/P phase on the surface of the samples. Further work is needed to investigate their potential application in scaffolds synthesis for dental tissue regeneration.

INTRODUCTION

It has been recently shown that fibronectin (FN) is able to self-assemble into physiological-like (nano)networks in poly(ethyl acrylate) (PEA) in the absence of cells; i.e. as a consequence of the protein-material interaction, leading to the so-called material-driven FN fibrillogenesis¹. Interactions between chemical groups of PEA surface and FN molecules during the adsorption process might induce exposure of self-assembly sites of FN to drive fibril assembly. However, this phenomenon does not occur on poly(methyl acrylate) (PMA), on which FN is adsorbed keeping the globular conformation, even if the side chain differs only one in one single carbon².

A series of samples with different EA/MA ratio were synthesised seeking to modulate the degree of FN fibrillogenesis. We have studied FN adsorption and conformation of the protein at the material surface using AFM. Then, murine C2C12 myoblast adhesion and myogenic differentiation was investigated to address the relationship with the fibrillogenesis degree at the material interface.

EXPERIMENTAL METHODS

Samples were obtained by radical polymerization of a solution of both monomers PEA/PMA with ratio 100/0, 70/30, 50/50, 30/70 and 0/100, using 1wt% of benzoin as photoinitiator. DSC, DMA and water contact angle experiments were performed to characterise the properties of the copolymers. Conformation and amount of adsorbed FN were quantified by AFM and western blot respectively using two different concentrations of FN (5 and 20 µg/ml).

Focal adhesions formation (vinculin) and cell morphology were analysed after 3 h of culture on FN-coated samples by immunofluorescence (IF). For myogenic differentiation, C2C12 cells were cultured on FN coated samples for 4 days; cell differentiation was quantified by IF against sarcomeric myosin followed by image analysis.

RESULTS AND DISCUSSION

DSC and DMA characterisation show no phase-separation in the copolymers. When the amount of methyl acrylate (MA) increases, the glass transition shifts to higher temperature and the elastic modulus at 37 °C rises from 620 to 3000 kPa. Small differences in wettability have been found ($85 \pm 6^\circ\text{C}$)

The assembly of FN on the copolymers was modulated by the EA/MA ration. Fully interconnected FN fibrils were organised upon adsorption from a solution of concentration 20 µg/mL on PEA 100. The interconnection degree among fibrils decreased as the amount of MA increases (Figure 1).

Figure 1. Material-driven FN fibrillogenesis on PEA/PMA copolymers. FN concentration 20 µg/ml and adsorption time 10 min. Phase AFM images (1µm x 1µm).

Both cell morphology and focal adhesions formation depend on the degree of fibrillogenesis attained on the different surfaces: Cell size decreases and circularity increases as the interconnection of FN is lost when the amount of MA in the system increases (Figure 2).

Figure 2. Cell size (♦) and circularity (▲) in C2C12 adhesion culture.

In cellular myogenic differentiation, FN-coated samples show significant differences compared to control (collagen I-coated glass) and differences between the copolymers were also found, with enhanced differentiation for samples with higher interconnected FN fibrils.

CONCLUSION

We demonstrated that the degree of fibrillogenesis can be modulated by controlling the percentage of PEA in PEA/PMA copolymers. When the amount of PEA decreases, fibrillogenesis degree decreases as well, which influences cell adhesion and differentiation.

INTRODUCTION

Treatment of coronary artery disease often involves deployment of an intravascular stent to treat the culprit vessel. The main limitation of this treatment is in stent restenosis which is caused by neointimal proliferation following deployment of stents and subsequent vessel damage.¹ Stents represent a possible platform for localised delivery of therapeutic agents to target neointima formation. This has been exploited in the context of drug eluting stents (DES), although due to the lack of cell specificity of the drugs, DES have led to additional complications such as late stent thrombosis.² In this study we aimed to develop a system for coating stent materials, Stainless Steel (SS) and Poly Lactic Acid (PLA) in adenovirus 5 (Ad5) or miRNA in order to develop an effective delivery system for localised gene or miRNA based therapies.³ This will enable us to take advantage of the stents proximity to the target tissue and to explore the scope for gene/miRNA therapy for coronary heart disease.

EXPERIMENTAL METHODS

- PLA and SS used as model stent materials.
- Bovine Type I collagen (5 mg/mL) was diluted to (3mg/mL) with NaOH (1 M).
- Ad5 CMV *lacZ* (4.6×10^9 VP) or premiR 145 precursor (20 μ M, 1.5uL) incubated with SiPort Neo FX (3uL) was added to collagen and vortexed.
- Surfaces were coated with collagen solution (25 uL) and incubated at 37°C for 1 hour, RT for 1 hour.
- Surfaces were washed with PBS and placed on rat A10 smooth muscle cells and incubated for 72 hours.
- Surfaces were removed and cells were washed.
- Transduction of Ad5/miRNA from the surfaces was quantified by β -gal reporter assay/qRT-PCR.

RESULTS AND DISCUSSION

Adenovirus coated SS and PLA

After *in vitro* culture of the collagen-Ad5 coated PLA and SS discs, Ad5 was able to transduce A10 cells from both surfaces. PLA retained 71% of Ad5 administered to the gel whereas 37% was retained from the SS, this is likely to be because the collagen gel could not adhere as well to the SS surface.

Figure 1. *In vitro* virus transduction of Ad5 from Ad5-collagen gel coated surfaces (n=3/group). β -gal activity of Ad5 transduction of A10 cells from a PLA, SS surfaces and control Ad5 in solution. A10 cells were seeded at 200,000 cells per well in a 12 well plate, and transduced at 21500 VP/cell. Error bars represent standard error of the mean of three individual samples. (**= $p < 0.01$, ***= $p < 0.001$ versus Ad5). Microscope images of the XGAL stained cultures are displayed underneath at 10x magnification.

miR145 mimic coated PLA

In vitro testing was also conducted from PLA surfaces by coating with a miR145 mimic collagen gel. After incubation of the PLA miRNA coated surfaces an upregulation by 14 fold of miR145 expression was observed. This indicates this method of coating the PLA with collagen gel is effective for encapsulation and release of miRNA in addition to Ad5.

CONCLUSION

It has been demonstrated that mixing Ad5 and miRNA with collagen prior to gel formation creates a coating which the virus and the miRNA can be eluted from into A10 cells. This method of coating is particularly suitable for PLA surfaces and therefore has scope to be applied to biodegradable PLA stents to provide localised delivery of genetic material to the vasculature.

Composite bone cement to improve the primary stability of orthodontic mini-screws

Alberto Lagazzo, Fabrizio Barberis, Elisabetta Finocchio, Cristian Restano, Marco Capurro
Department of Civil, Chemical and Environmental Engineering (DICCA), University of Genoa, Italy
alberto.lagazzo@unige.it

INTRODUCTION

Mini-screws are temporary anchorage devices used in orthodontic treatments¹, namely the practice of preventing and correcting irregularities of the teeth or skeletal structures. In comparison with the endosseous implants² used as fixing systems, the mini-screws do not require osseointegration and thus they can be immediately loaded, inserted and removed easily and, thank to their dimensions ($\varnothing 1.3\text{--}2.0\text{ mm}$), placed into the interradicular sites without patient compliance³. The mini-screws stability is yet strictly dependent on the cortical bone thickness and linked to the bone quality of the patient treated⁴. Others problems are the progressive decrease of their stability due to bone relaxation⁵ and a possible necrosis of the adjacent bone due to an excess of compression caused by the mini-screw⁶. In order to solving, at least partially, these inconveniences, in this work we have adopted a new method consisting in the inclusion of a composite bone cement inside a preliminary drilled hole made in the implant site.

EXPERIMENTAL METHODS

Amorphous glass fibres ($\varnothing 10\text{ }\mu\text{m}$, 5 mm in length) were introduced in a hole of 2 mm and depth 10 mm, preliminarily created with a drill in a thoracic pig rib, and then filled with a composite material prepared with powder of PMMA (20 %wt.) mixed with brushite before setting. The brushite was obtained from β -TCP, MCPM and water solution (0.5 M) of Na-citrate (s/l=2:1). The amount of glass fibres was about 10 %wt. Then two types of mini-screws (TomasTM and NovaxaTM) were manually introduced inside the hole without screwing and, after the cement setting, the samples were stored in physiological solution. The cement after the setting and the amount removed from the mini-screw surface after the pull out, at 1 week, from the hole were tested with FTIR in KBr. Primary stability was measured with a specific device used for dynamic mechanical analysis. The test, performed with an apparatus developed in the DICCA laboratory⁷, consisted in a transversal loading of the mini-screw head with a low frequency (2–5 Hz) oscillating force of 0.5 N of amplitude. By processing the time records of force and displacement via a Frequency Response Function (FRF), the complex compliance was obtained. The lower is the elastic compliance (real part) the higher is the stability of the screw.

For comparison, the same procedure was adopted to prepare and to test samples with self-tapping mini-screws directly inserted in the bone, without preliminary hole and without the use of bone cement.

RESULTS AND DISCUSSION

In Fig. 1 are represented the behaviour against the time (days) of the elastic compliance of mini-screws TomasTM and NovaxaTM, when they are directly screwed in the bone (DS) and when inserted in a pre-

hole filled with composite cement (CC). The choice of adding PMMA and glass fibres was done in order to confer more plasticity and tenacity to the brushite. FTIR spectra reveal the presence of brushite phase both at the setting and also inside the hole after 1-week storage of the sample in physiological solution.

Fig. 1. Comparison of compliance of mini-screws inserted in bone with (CC) and without composite (DS).

It can be noted how, initially, the stability of the CC is very close to the one of the DS and how the CC samples maintain low values of the compliance also after one week. Moreover, a standard deviation of the stability values for CC, very lower than the one for DS, evidences a positive effect of the composite cement. As expected, the cement makes the support (bone) more homogeneous, reducing the influence of the cortical bone thickness in the stability of the mini-screws.

CONCLUSION

The use of composite cement coupled with orthodontic mini-screws to avoid inflammation and damage of the bone appeared to be encouraging. The compliance of the mini-screw are comparable with the one obtained for drilled mini-screws. Besides, no reduction of the stability after one week and a more homogeneous response of the inserting site (no effect of the cortical bone thickness) were observed.

INTRODUCTION

Bioresorbable phosphate-based glasses have been investigated for varying tissue engineering applications¹. The degradation rate of these glasses can be tailored by doping with varying metal ions such as Mg, Fe, Ti, and B². In this study, boron was added at varying quantities in place of phosphate. The effect of boron addition on the glass thermal properties, chemical durability and cytocompatibility was investigated.

EXPERIMENTAL METHODS

Glasses with three different compositions were produced, denoted as P48B12, P45B15 and P40B20. The thermal processing window T_{pw} (i.e. onset of crystallisation temperature T_{con} minus glass transition temperature T_g) of the glasses was investigated via Differential Thermal Analysis. The chemical durability was characterised in phosphate buffer saline at 37°C for 60 days. The cytocompatibility of the glasses was studied by culturing the human osteosarcoma cell line (MG63) directly onto the glass surface for 14 days.

RESULTS AND DISCUSSION

The thermal properties of the glasses in Table 1 revealed that T_{con} and T_c values decreased with the addition of B₂O₃, whilst only slight increases were observed for the T_g values. The thermal processing window (T_{pw}) was observed to decrease with increasing boron content, thus increased glass crystallisation tendency and reduced thermal stability³.

Table 1: thermal properties of glasses with B₂O₃ variation.

Glass code	$T_g/^\circ\text{C}$	$T_{con}/^\circ\text{C}$	$T_{pw}/^\circ\text{C}$	$T_c/^\circ\text{C}$
P48B12	545	800	255	860
P45B15	550	780	230	825
P40B20	555	750	195	770

The degradation study revealed the dissolution rate of P48B12 glass at $3.64 \times 10^{-5} \text{ kg cm}^{-2} \text{ hr}^{-1}$, which increased to $4.23 \times 10^{-5} \text{ kg cm}^{-2} \text{ hr}^{-1}$ for P45B15 and then have a further increase to $5.92 \times 10^{-5} \text{ kg cm}^{-2} \text{ hr}^{-1}$ for P40B20 (Figure 1). The decrease of chemical durability with boron addition was suggested to be due to the P₂O₅ content being replaced by B₂O₃, boron units BO₃ and BO₄ introduced into glass system while BO₃ units were not as resistance as BO₄ units⁴. For all three glasses, the metabolic activity of MG63 cell line (Figure 2) was seen to increase throughout the 14 days culture period. The metabolic activity of cells on P48B12 glasses and

P40B20 glasses were significantly close to tissue culture plastic (TCP).

Figure 1: Weight loss vs time for glass compositions investigated.

Figure 2: Metabolic activity of MG63 cells, (Alamar Blue assay).

CONCLUSIONS

Thermal stability and chemical durability of borophosphate glass decreased with the addition of boron in place of phosphate. Cell culture studies suggested all glasses produced had good cytocompatibility with the MG63 cell line.

INTRODUCTION

The development of targeted drug delivery systems (DDSs) represents a valuable option to overcome the typical drawbacks associated to conventional systemic administration, which is not specifically directed to the organ or tissue to be treated. This means that the drug has to cross different biological barriers, often causing undesirable side-reactions or being partially inactivated¹. It is also well known that this approach implies fluctuating drug levels in the body, poor efficacy, and the administration of a high dose of drug to ensure that the required amount of agent eventually reaches the site of action². In addition, it is not possible to control the concentration, duration and bioavailability of bioactive substances, thus limiting the expected therapeutic outcome. On the other hand, DDSs can lead to a significant therapeutic efficacy, as the selected agent can be delivered to the target tissue in the optimal amount and in the right period of time, causing little toxicity and minimal side effects. An improved pharmacological strategy can be therefore planned, allowing a controlled and localised release of drugs, a reduction of the total amount required and a constant delivery over time. In this context, microspheres made of natural polymers, as here proposed, can be regarded as a valuable means to support this approach.

EXPERIMENTAL METHODS

Microspheres preparation

Microspheres were prepared by water-in-oil emulsion. Gelatin powder was added to distilled water, heated at 80 °C and gently stirred until complete dissolution, to produce a 10% w/v polymeric solution. In order to crosslink microspheres, genipin (1% w/v), was added to the solution that was then injected into the oil phase, preheated at 80 °C. The resultant emulsion was stirred, at the same temperature, for 1 h at 800 rpm. Microspheres were collected on a nylon filter in vacuum condition, and washed with acetone. Finally, the microspheres were air dried.

Chitosan microspheres were prepared using the same protocol with the difference that chitosan was dissolved in aqueous acetic acid solution (2% w/v). Blend microspheres were also prepared (chitosan/gelatin ratio: 1/5).

Finally, collected microspheres were loaded with methylene blue (MB).

Characterization

Morphological characterization of microspheres was performed by means of scanning electronic microscopy (SEM). The average diameter was determined from SEM micrographs (ImageJ, NIH).

In vitro MB release assays were performed by UV spectrophotometry.

CAM assay

Chicken embryo chorioallantoic membrane (CAM) assay was considered to evaluate the angiogenic properties of loaded microspheres. Microspheres were allowed to release MB in phosphate buffer saline (PBS) solution for three days at 37 °C. Treated PBS was then loaded into gelatin sponges to be placed on the CAM.

Statistics

Results are expressed as mean±standard deviation. Data analysis was performed with non-parametric tests (Kruskal-Wallis and Mann-Whitney U tests). *p* values less than 0.05 were considered significant.

RESULTS AND DISCUSSION

SEM analysis revealed homogeneous microspheres with a diameter distribution in the range 42-54 µm. Depending on the nature of the polymers here considered, the 100% MB release ranged from about 3 days (gelatin) to 30 days (chitosan) and can be correlated to the antiangiogenic properties of gelatin microspheres (CAM assay). Chitosan and blend samples were surrounded by allantoic vessels that developed radially towards the implant in a spoke-wheel pattern. This occurrence was not verified for gelatin and the control case (MB solution).

Fig. 1 –MB cumulative release from gelatin, chitosan and blend microspheres

CONCLUSION

The proposed microspheres can be a promising platform for drug delivery, allowing to modulate the expected outcome by properly selecting the polymers used for their preparation.

⁴Biomaterials Department, INNOVENT e.V. Jena, Germany

INTRODUCTION

The extracellular matrix (ECM) has a complex, tissue specific composition with collagen and glycosaminoglycans (GAGs) like hyaluronan (HA) being important components of skin and bone ECM. The modification of HA with sulfate groups (sHA) leads to an increased interaction with growth factors like TGF- β 1¹ and BMP-4². Collagen-based artificial ECMs (aECMs) containing high-sulfated HA support the growth of human dermal fibroblasts (dFb)³, enhance the osteogenic differentiation of human mesenchymal stromal cells⁴ and inhibit osteoclast differentiation and resorption⁵. Combining low- and high-sulfated HA derivatives and collagen type I to develop multi-component aECMs should lead to a better mimicry of the *in vivo* situation in comparison to aECMs with one GAG derivative. The purpose of this study was to engineer these aECMs and to reveal their effects on dFb and osteoclast-like cells.

EXPERIMENTAL METHODS

aECMs were prepared by *in vitro* fibrillogenesis of rat collagen type I alone or in the presence of low- (sHA1, degree of sulfation (D.S.) ~ 1, average number of sulfate groups per disaccharide repeating unit of HA) and high- (sHA4, D.S. ~ 4) sulfated HA derivatives as well as a combination of both to provide *in vivo* like ECM structures. DMMB assay, fluorescence measurement, Lowry assay and OPA assay were used to characterise the composition and release behaviour of the aECMs. Furthermore, the morphology was studied via AFM. The initial adhesion of dFb on aECMs after 60 min of incubation, their proliferation for 48 h and the viability of RAW264.7 cells after 24 h of cultivation was analysed.

RESULTS AND DISCUSSION

Design and characterisation of multi-component aECM
Using sHA1 and sHA4 with different fluorescence labels offers the possibility to distinguish between these GAGs while the DMMB assay can only determine the total GAG amount. Fig. 1 shows the composition and release behaviour of the multi-component aECMs after incubation in PBS at 37°C for up to eight days. The highest GAG release occurs during the first hour. Longer desorption in PBS results only in a slightly further decrease of GAG content. The results are in good agreement with the results of the DMMB assay. The AFM images of the aECMs reveal a decrease in fibril diameter with increased GAG concentration and sulfation as already shown for collagen type II⁶.

Effects on cells

GAG-containing aECMs show an increased adhesion and proliferation of dFb compared to the collagen reference. The proliferation of dFb and the viability of RAW264.7 cells are affected differently by the single- and multi-component-aECMs. Although previous studies revealed the ability to influence cellular behaviour by single-GAG-aECMs containing differently sulfated GAGs^{3,5}, these results show the potential of multi-component aECMs to modulate the cellular behaviour in a more defined manner allowing the precise adjustment of cellular actions.

Fig. 1. Quantification of the sHA content in the multi-component aECM via fluorescence measurement and DMMB assay. Init: sHA content after two washing steps with deionized water.

CONCLUSION

GAG containing aECMs with defined physiological functions can be developed by varying their composition. These aECMs composed of collagen and sulfated HA derivatives are promising substrates for modulating the behaviour of cells relevant to wound healing.

Nanowires on Ti-6Al-4V for Creation of Antimicrobial Orthopaedic Implant Surfaces

Terje Sjöström^{1*}, Angela Nobbs¹ and Bo Su¹

¹School of Oral & Dental Sciences, University of Bristol, UK terje.sjostrom@bristol.ac.uk

INTRODUCTION

Infection at the implant surface is one of the big challenges in biomaterial research. Reducing the risk of infection during and after surgery, without using antibiotics, would be of great benefit to both patients and the healthcare system. It has recently been suggested that nanotopographies found in nature, act as antimicrobial surfaces by physically damaging bacteria¹. By mimicking such topographies on relevant materials, it may be possible to create antimicrobial implant surfaces. In this work we have produced nanowire surfaces on Ti alloy substrates which are able to impair gram negative bacteria.

EXPERIMENTAL METHODS

Ti-6Al-4V (Ti64) samples were heated to 850°C in a tube furnace under Ar atmosphere. At the final temperature, acetone vapour was introduced at 500sccm for 45 minutes, and finally the furnace was allowed to cool under Ar. The substrates were then annealed in air at 600°C for 1h to remove carbon residue. *Pseudomonas aeruginosa* and *Staphylococcus aureus* were cultured on smooth and nanowire Ti64 surfaces at 37°C for 1h. The cells were then either stained for LIVE/DEAD and examined using fluorescence microscopy, or cultured with an alamar blue assay to examine cell viability.

RESULTS AND DISCUSSION

Figure 1. Side view SEM of nanowires grown on Ti64 substrate.

Figure 2. Microscopy images of LIVE/DEAD stained *P. aeruginosa* on smooth Ti64 (left) and nanowire Ti64 (right). Green = live cells. Red = dead cells.

Figure 3. Cell viability measured with AlamarBlue, of *S. aureus* and *P. aeruginosa* on smooth Ti64 and nanowire Ti64. * $P < 0.05$.

Figure 1 shows the nanowires produced on the Ti64 substrates. The wires showed excellent surface coverage on both flat and 3D surfaces, were several micrometer long and terminated in sharp tips of approximately 20 nm.

Figure 2 shows that when *P. aeruginosa* were cultured on the nanowire surfaces, a large number of cells were killed, whereas on the smooth Ti64 surfaces most cells were still alive. These results were supported by the viability assay (Figure 3), displaying a 50% reduction of viable *P. aeruginosa* on the nanowire surfaces. On the other hand, *S. aureus* showed no reduction in viability on the nanowire surfaces. We presume that the same effect was not seen on the gram positive bacteria (*S. aureus*) because the thicker cell membrane of these bacteria makes them more difficult to physically rupture. This is in line with what was found for bacteria grown on nanotopographies on cicada wings¹.

CONCLUSION

Sharp nanowire features were produced on Ti64 alloys by a thermal oxidation technique. The nanowires were able to kill gram negative bacteria by physical means only. These surfaces have potential as use for antimicrobial surfaces for orthopaedic implants.

INTRODUCTION

Alginate is considered an important biomaterial for regenerative medicine due to its rapid ionic gelation property with divalent cations¹. However, alginate does not promote cell adhesion and possesses slow and uncontrolled degradation kinetics². We hypothesized that these limitations of alginate could be overcome by using covalently crosslinked alginate-gelatin (ADA-GEL) hydrogel. In the current study, we seeded normal human dermal fibroblasts (NHDF) on ADA-GEL hydrogel to evaluate *in vitro* cytocompatibility.

EXPERIMENTAL METHODS

Synthesis of ADA-GEL and Preparation of Films

Alginate di-aldehyde (ADA) was synthesized by periodate oxidation of sodium alginate. ADA-GEL hydrogels of different compositions were synthesized by covalent crosslinking between ADA and gelatin, as described in detail elsewhere³. Hydrogel was cast into a Petri dish, ionically gelled by 0.1 M CaCl₂ solution and cut by punching.

Swelling and Degradation and Protein Release Study

In vitro swelling and degradation studies of ADA-GEL films were carried out in Dulbecco's modified Eagle's medium (DMEM) at 37 °C for 7 days. A protein release study of ADA-GEL films was conducted in serum free DMEM and protein concentration in the medium was determined by colorimetric protein assay.

Cell Study

NHDF were seeded on the films at a density of 85000 cells/film and incubated in a humidified atmosphere of 95% relative humidity and 5% CO₂, at 37 °C. Mitochondrial activity of NHDF grown on different hydrogel films was assessed by WST-8 assay. To assess the viability of cells, live staining was performed by Calcein AM and nuclei were visualized with DAPI. To assess the morphology of NHDF, F-actin of the cells were visualized with rhodamine phalloidin and nuclei were stained with SYTOX. Morphology of the cells was further analyzed by SEM.

RESULTS AND DISCUSSION

Swelling, Degradation and Protein Release

Initially alginate and ADA-GEL films of all compositions, except the one containing the highest amount of gelatin, exhibited similar swelling pattern. After 2 days of incubation, degradation of ADA-GEL films started and exhibited the degradation pattern corresponding to gelatin content. The result can be correlated to the release of gelatin, which remained uncrosslinked in the ADA-GEL. As expected, gelatin

release (wt%) from the ADA-GEL hydrogels was found to be very low during the incubation period of the hydrogel films in DMEM due to the covalent crosslinking of gelatin with ADA.

Cytocompatibility of ADA-GEL

As shown in Figure 1, clusters of NHDF were formed on alginate hydrogels after 7 days incubation. In contrast, a very good attachment and proliferation of cells was observed on ADA-GEL hydrogels. Moreover, mitochondrial activity of NHDF on ADA-GEL was significantly higher compared to alginate.

Figure 1. Fluorescent microscopy images of NHDF on alginate (left) and ADA-GEL (right) hydrogel films after 7 days of incubation. The cells were stained for actin (red) and nucleus (green).

Typical bipolar morphology of NHDF was observed on ADA-GEL. Moreover, cells arranged themselves parallel to each other on ADA-GEL, which is also a natural characteristic of NHDF.

CONCLUSION

The synthesized ADA-GEL hydrogels possess controlled degradation kinetics with minimal release of gelatin, and support stronger fibroblasts adhesion and proliferation. Therefore, it can be concluded that the major drawbacks of alginate-based hydrogels are successfully overcome with the covalently crosslinked ADA-GEL hydrogel.

adalrosa@forp.usp.br

INTRODUCTION

The bioactive glass 45S5 favours osteoblast activities resulting in enhanced osteogenesis both in vitro and in vivo¹, but the relative poor mechanical properties restrict its use as bone substitute^{2,3}. In this context, novel full-crystallized bioactive glass-ceramics, Biosilicate[®] (Bio) and Biosilicate[®] for scaffold fabrication (Bio-sca), has been developed with better mechanical properties⁴. Considering the potential application of Bio-sca in bone tissue engineering procedures, the aim of this study was to compare the in vitro behaviour of osteoblasts at early stages of differentiation grown on 45S5, Bio and Bio-sca.

EXPERIMENTAL METHODS

Rat bone marrow cells were cultured in osteogenic medium for 5 days to obtain osteoblasts at early stages of differentiation. Then, these cells were cultured in non-osteogenic medium on 45S5, Bio and Bio-sca discs for periods of up to 17 days. Tissue culture polystyrene was used as control. Cell proliferation was evaluated by MTT assay at day 10. Osteoblastic differentiation was evaluated by colorimetric method to detect alkaline phosphatase (ALP) activity at day 10, real-time PCR to detect gene expression of runt-related transcription factor 2 (Runx2), special AT-rich sequence-binding protein 2 (SATB2), ALP, osteocalcin (OC), osteopontin (OPN) and bone sialoprotein (BSP) at day 10, and alizarin red to stain extracellular matrix mineralization at day 17. All evaluations were performed in quadruplicate (n=4) and data were compared by Kruskal-Wallis and Student-Newman-Keuls test, when appropriated. The significance level was set at p≤0.05.

RESULTS AND DISCUSSION

Cell proliferation on glass surfaces and polystyrene was similar without statistically significant differences, indicating that the glass-based biomaterials did not affect osteoblast proliferation. It was observed higher ALP activity in cells cultured on all glass surfaces compared with polystyrene without statistically significant

differences among them. Despite more mineralized matrix was observed on Bio and Bio-sca, the higher ALP activity did not result in more mineralization as noticed on 45S5. Gene expression was affected in a more complex way but all evaluated genes were more expressed in cells cultured on glass surfaces compared with polystyrene. Results are presented in Table 1.

Table 1. Cell proliferation, ALP activity and gene expression at day 10 and extracellular matrix mineralization at day 17 of cells cultured on distinct glass surfaces and polystyrene expressed as mean ± standard deviation (n=4).

Parameter	Polystyrene	45S5	Bio	Bio-sca
Proliferation	0.87±0.17 ^a	0.82±0.09 ^a	0.93±0.15 ^a	0.87±0.13 ^a

CONCLUSIONS

Results showed that glass-ceramic surfaces exhibit osteogenic potential. Considering that cells were cultured under non-osteogenic conditions, it is possible to suggest that these bioactive glasses are capable of inducing osteoblastic differentiation. Taken into account that Bio-sca can be fabricated as highly porous scaffolds, this glass-ceramic is a promising biomaterial for bone tissue engineering applications.

INTRODUCTION

The osteo-inductive effects of three specific physical cues including substrate rigidity and nanotopography have been recently investigated in 2D cell culture or in 3D *in vitro* scaffolds [1]. Recent studies demonstrate that surface properties including hydrophobicity, surface charge, stiffness and roughness concur to influence specific cell materials interactions, so addressing specific features of local microenvironment in osteogenic way [2]. In this work, polycaprolactone (PCL) porous matrices processed by phase inversion/salt leaching were endowed with two types of calcium phosphates - Hydroxyapatite (HA) and Magnesium Carbonate Hydroxyapatite (MgCHA). According to recent studies [3], we suggest that inorganic phases effectively functionalize pore surfaces, promoting a better osseous tissue ingrowth towards a fully bone integration over long-term implantation. Here, we focus on correlation between *in vitro* behavior of MG63 (osteoblast-like cells) and surface properties mediated by the presence of MgCHA and HA bioactive fillers.

EXPERIMENTAL METHODS

Briefly, 0.50 g of PCL granules were dissolved in 10 ml of tetrahydrofuran (THF) and kept under magnetic stirring at room temperature for 24 h. HA and MgCHA particles were added to PCL solution before the solvent extraction to reach a volume ratio of about 3:1. To impart the required porosity to the scaffold, sodium chloride crystals - 300-500 micron sized - were also included. The size and shape of HA and MgCHA powders was analyzed by transmission electron microscopy (TEM, TECNAI120 - FEI) supported by 2D/3D image analyses. The morphological properties of the surface samples were qualitatively investigated by Scanning Electron Microscopy (FESEM, QUANTA200 - FEI) at 20kV after gold-Palladium sputter-coating and quantitatively estimated via Atomic Force Microscopy (AFM) in contact/tapping mode. MG63 cells were seeded onto HA and MgCHA cylinders (5 mm in diameter and 3 mm in width) for 3 and 7 days. At the end of experimental times, cell viability was evaluated with WST-1 test and the production of bone alkaline phosphatase (ALP), Osteocalcin (OC), Collagen type I (COL I), Transforming growth factor- β 1 (TGF- β 1) and Tumor necrosis factor- α (TNF- α) by ELISA tests.

RESULTS AND DISCUSSION

A preliminary investigation by TEM allows estimating HA and MgCHA embedded phase morphology, also calculating the elongation degree by image analysis in terms of particle aspect ratio (pAr) (e.g. width/length). pAr values equal to (0.44 ± 0.16) and (0.18 ± 0.06) for

HA and MgCHA reinforcement, indicate a higher elongation in the case of doped particles, related to the doping process conditions. Particle morphology influences the surface properties as confirmed by SEM images, in terms of roughness and surface charge, properly measured by AFM on different composite scaffolds. In particular, surfaces show a profile with a mean value of (51.7 ± 14.53) nm, (78.15 ± 32.71) nm and (136.13 ± 63.21) nm in the case of net PCL, HA and MgCHA loading samples, thus remarking the higher contribution of doped particles to roughness respect to un-doped ones. This may be ascribable to stronger constraints offered by more elongated particles to the polymer phase organization during the process. This is confirmed also by AFM phase image which allows detecting some microstructural differences in PCL matrix domains, related to different surface stiffness and elasticity which influence cell response. Despite cell viability did not present significant differences after 3 days, MG63 show higher viability after 7 days ($p < 0.005$) in the case of HA. From 3 to 7 days of culture, HAs stimulate a higher production of TGF- β 1 ($p < 0.05$) and OC ($p < 0.005$), which is also coupled to the production of the pro-inflammatory cytokine, TNF- α . Contrariwise, MgCHAs do not induce inflammatory response, but promote early osteogenic differentiation as remarked by higher ALP levels ($p < 0.005$).

CONCLUSION

Here we conclude that bioactive fillers with different chemistry and/or shape factors concur to particularize surface properties of composite scaffolds with effects on *in vitro* cell response. The set of morphological information - roughness, wettability and stiffness programmed into the scaffold surface corroborated by intrinsic bioactive cues of calcium phosphate fillers influence the osteogenic activity of MG63 as confirmed by differences in bone markers data. In comparison with HA loaded surfaces, MgCHA ones confirm a higher biomimeticity level due to the presence of Mg doped apatites which are better recognized by MG63 without production of cytokines, and promote higher ALP synthetic activity related to osteogenic differentiation.

INTRODUCTION

Electrospun fibrous materials can be used in many applications including tissue engineering, wound dressing, drug delivery, filtration, protective clothing etc. Mechanical properties play a key role in most of these applications. Gelatin is biocompatible, biodegradable and could be useful in various applications. However, the mechanical properties of gelatin are not sufficient for most applications.

Cross-linking is an efficient way to increase mechanical strength of gelatin fibres and can be carried out by chemical, enzymatic and physical means. However, cross-linking agents are generally expensive and more or less toxic. Therefore, it is necessary to investigate the use of natural, non-toxic and cheap substances as cross-linking agents.

EXPERIMENTAL METHODS

Fibrous gelatin scaffolds were prepared by electrospinning from aqueous acetic acid solutions and cross-linked. Only natural, cheap substances and easy, cost-effective methods were used to manipulate the properties of the material. The scaffolds were analysed by scanning electron microscopy (SEM), Fourier transform infrared microscopy (FTIR), degradation test and tensile test. Cell culture experiments were carried out to demonstrate the suitability of the material for tissue engineering applications. A model was constructed to evaluate mechanical properties of the scaffolds using only tensile test results and easily (macroscopically) measurable values.

RESULTS AND DISCUSSION

Fibrous gelatin scaffolds were prepared by electrospinning. Fibrous structure of the scaffolds was confirmed by SEM (Figure 1). Cell culture experiments confirmed the suitability of the material for tissue engineering applications. Evaluation of mechanical properties revealed that Young's modulus of gelatin can

be increased up to a little over 1 GPa using only natural substances and simple methods.

Figure 1. Gelatin fibres (SEM image)

CONCLUSION

A method has been developed for preparation of fibrous gelatin scaffolds using only natural, cheap, totally biocompatible substances and easy, cost-effective methods. Young's modulus of gelatin fibres can be increased to a little more than 1 GPa using this method.

Nanoscale Imaging and Quantitative Nanomechanical Characterization of Biomaterials by Atomic Force Microscopy

Rob Field¹, Alex Winkel¹, Elmar Hartmann², Torsten Mueller², Florian Kumpfe², Joerg Barner²

¹JPK Instruments Ltd., Cambridge, United Kingdom, field@jpk.com

²JPK Instruments AG, Berlin, Germany

Topography, roughness, and mechanical properties of biomaterials are crucial parameters affecting cell adhesion/motility, morphology, and mechanics as well as the proliferation of stem/progenitor cells [1-4]. Nano-mechanical analysis of cells and tissue slices increasingly gains in importance in different fields of cell biology, like cancer research [5] and developmental biology [6]. Atomic force microscopy (AFM) is a powerful, multipurpose technology suitable not only for imaging a wide range of different samples with nanometer scale resolution under controlled environmental conditions, but also for mapping mechanical and adhesive properties of sample/cell systems and tissues.

To extend the versatility of AFM technology, we've been developing a new, distinct imaging mode called "Quantitative Imaging" (QITM) which is based on fast force-distance curves with intelligent control, to simultaneously obtaining topographic, nanomechanical, and adhesive sample properties. Next to this classical information, even more complex data like contact point images, Young's moduli images, or even recognition events can be achieved. In terms of biological applications, the QITM mode exhibits advantages compared to conventional AFM imaging techniques, particularly in liquid environments. Combining these remarkable capabilities with advanced optical microscopy (inverted as well as upright optical microscope techniques) allows for comprehensive characterization options of biomaterials and tissue slices.

To demonstrate the capability and flexibility of QITM, a variety of soft and hard samples have been investigated. Exemplarily, living cells as well as polymer surfaces and single biomolecules have quantitatively been analyzed. Furthermore, it is shown that challenging samples which are fragile or loosely attached, like viruses, bacteria or diatoms can reliably be measured using QITM [7]. Obviously, QITM offers new

perspectives in nanomechanical stiffness and high-resolution measurements in the field of interfaces, e.g., periosteal sheets [8]. A comparison between QITM, conventional force spectroscopy and traditional AFM imaging modes clearly reveals that supplementary information can be gained [9].

In conclusion, the traditional imaging modes demonstrated so far suffer from inherent drawbacks for challenging samples that have steep edges, as well as those that are soft, sticky, or loosely attached to surfaces. These drawbacks can impressively be overcome by using the QITM mode that is exclusively available for the JPK NanoWizard[®]3 AFM.

Transfer of CVD Graphene onto Polymer Substrates: Implications to Blood-Contacting Surfaces

Gordon Xiong¹, Antonio Castro Neto², Cleo Choong^{1,2}

¹ School of Materials Science and Engineering, Nanyang Technological University, Singapore, mxiong001@e.ntu.edu.sg

² Graphene Research Centre, National University of Singapore, Singapore

INTRODUCTION

Graphene is a single atomic layer nanosheet that has excellent electrical conductivity and mechanical strength¹. Recent advances in biology and tissue engineering have highlighted the roles of utilizing electrical stimuli to direct cellular phenotypes such as migration² and stem cell differentiation³. As such, the transfer of single-layer CVD graphene onto biocompatible polymeric substrates is an attractive proposition to create hybrid substrates that are conductive, but still retain bulk polymeric properties. We have previously modified polycaprolactone (PCL) and demonstrated their use as anti-thrombogenic surfaces⁴. In this work, we transferred CVD graphene onto polymer surfaces and performed characterization of the material's electrical properties and hemocompatibility.

EXPERIMENTAL METHODS

Raman spectroscopy was used to verify the G and 2D peaks of graphene transferred onto PCL and polyvinylidene difluoride (PVDF) substrates. Human umbilical endothelial cells (HUVECs) were seeded on graphene-PCL surfaces and graphene-PVDF surfaces (n=3 each). Cell proliferation assays over 5 days were conducted using the alamarBlue® reagent. The hemocompatibility of the substrates were assessed by 90 minutes incubation of platelet-rich plasma (PRP) on the surfaces before SEM imaging (n=2). The SEM preparation involved fixing in 2.5% glutaraldehyde (w/v) for 1 h at 4°C, followed by drying steps in an ethanol gradient and hexamethyldisilazane (HMDS). In order to ascertain that the transferred graphene layer was stable in cell culture medium, Raman spectroscopy was performed after incubation of graphene-PCL substrates after 1, 3 and 6 days in culture.

RESULTS AND DISCUSSION

Raman spectroscopy confirmed the successful transfer of CVD graphene onto the PCL surfaces (Fig. 1b). Retention of the graphene monolayer after 6 days of incubation in cell culture medium was confirmed by comparing the Raman spectra of both pure PCL with graphene-PCL substrates (Fig. 1a, b). Proliferation of HUVECs on graphene-PCL and graphene-PVDF was found to be significantly higher than that of PCL and PVDF substrates alone (Fig. 2). We postulate that it could be due to the better adsorption of growth factors in the culture media onto the graphene-polymer surfaces that led to increases in cell proliferation. Platelet incubation on native PCL surfaces resulted in an activated morphology, which could be observed under SEM, whilst those on the graphene-PCL remained inactivated.

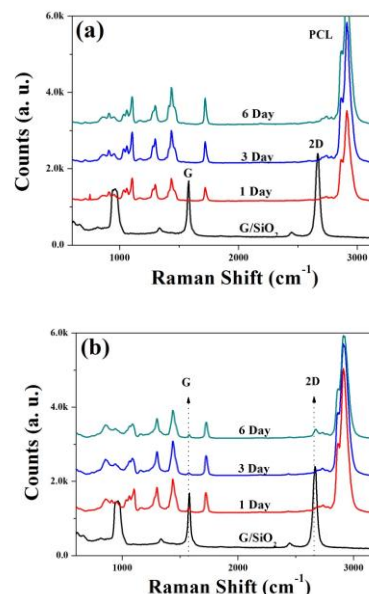

Fig. 1. Raman spectroscopy performed on (a) non-transferred PCL and (b) CVD graphene-PCL substrates at Day 1, 3 and 6 after incubation with cell culture medium. Graphene transferred on SiO₂ was used as a control to show distinct G and 2D peaks.

Fig. 2. Endothelial cell proliferation was significantly improved on graphene-PCL and graphene-PVDF over PCL and PVDF respectively.

CONCLUSION

We have successfully transferred CVD graphene onto biocompatible substrates relevant for blood-contacting devices. The graphene monolayer could be retained on the surface, and exhibited improved cytocompatibility, as well as inhibition of platelet activation. Further experiments would be performed with the electrical stimulation of the graphene-polymer surfaces to elucidate any effects on hemocompatibility.

Contribution of new analgesic or antibacterial properties on an implant for parietal refection: an *in vitro* and *in vivo* evaluation

Nicolas Blanchemain^{1*}, Guillaume Vermet², Stephanie Degoutin², Feng Chai¹, Christel Rousseaux³, Christel Neut³, Bernard Martel², Frederic Hildebrand¹

^{1*} INSERM U1008, Biomaterial Research group, University Lille 2, France, nblanchemain@univ-lille2.fr

² UMET, Ingénierie des Systèmes Polymères, University Lille1, Lille

³ INSERM U995, University Lille 2, France

INTRODUCTION

The cure of hernia is the second second-most-practiced surgical act in France. The closure is carried out using a parietal reconstruction implant in the form of polyester mesh. This surgery causes pain after implantation at the abdominal level and the risk of infection is high (up to 9%)¹. Despite the IV administration of antibiotics and the use of an analgesic shoot deposited on the plate the day of the procedure, these complications remain. The solution we propose is to modify the mesh with a polymer of cyclodextrine to improve adsorption and prolonged release of the antibiotics and analgesics.

EXPERIMENTAL METHODS

Meshes (Polyethylene terephthalate, PET, Biomesh A1L[®]) were manufactured by Cousin Biotech (Wervicq Sud, France). The implants have been functionalized by a process developed and patented by Martel et al.² using hydroxypropyl-beta-cyclodextrine (Kleptose HPB, Roquette, France) and citric acid (Sigma Aldrich, France) as cross-linking agent. After functionalization, mechanical properties of implants were verified and the cytocompatibility according to ISO 10993-5 standard was evaluated with fibroblastic cells (NIH3T3). The kinetics of impregnation and release of ropivacaine (10 mg/ml, Kabi, France) and ciprofloxacin (200mg/100mL, Kabi, France) have been followed by HPLC (LC2010A, Shimadzu, France). Therapeutic activity of antibacterial and analgesic meshes was assessed *in vitro* and *in vivo* respectively. In the case of antibacterial activity, meshes were impregnated in ciprofloxacin. At regular time interval in PBS, the implants were removed and deposited onto agar seeded bacteria (*S. aureus* or *E. coli*). In the case of analgesic activity, meshes were impregnated in ropivacaine and implanted in rats at the level of the peritoneum. To assess pain, colorectal distension is practiced in rats every day³. In the same time, pharmacokinetic of ropivacaine was assessed and histological evaluation was performed.

RESULTS AND DISCUSSION

Studies of the functionalization of meshes allowed determining the optimal parameters to not change its mechanical properties and to ensure its safety. Indeed, the cytocompatibility tests showed that the NIH3T3 cell vitality was 70% with functionalized implants at 140°C for 1 hour. The functionalization rate of meshes after this process was 20%-wt.

The kinetics of adsorption of the two selected drug (ciprofloxacin and ropivacaine) were evaluated on the functionalized meshes. The resultants showed a quick

time of impregnation (< 15 minutes) to obtain the maximal amount of adsorbed drug: respectively XX mg/g of ciprofloxacin and XX mg/g of ropivacaine. The drug sorption was clearly increased compare to virgin sample, respectively an X and Y-fold improvement for ciprofloxacin and ropivacaine. Additionally, the kinetics of release carried out under SINK conditions in a paddle and flow-through cell system were prolonged with functionalized meshes (> 24 hours; virgin meshes <30 minutes).

In the case of antibacterial meshes, the *in vitro* antibacterial activity, measured by the presence of a radius of inhibition after 24 hours, is still more efficiency up to 3 days with functionalized implants against a few hours for virgin meshes. In the case of analgesic meshes, the *in vivo* evaluation (Figure 1) showed a significant reduction of pain at least for 7 days with functionalized meshes while no difference with virgin implants from the first day was observed.

Figure 1: *in vivo* evaluation of the colorectal distension of rat after implantation of meshes. (* $p < 0.05$)

The pharmacokinetics showed that the highest level of ropivacaine in blood is 1 µg/ml and the histological evaluation revealed a slight increase of inflammatory response but with still acceptable results

CONCLUSION

This study shows the capacity of functionalised meshes with a polymer of cyclodextrine to quickly adsorb and prolong the release of analgesic or antibiotics but also significantly improve the *in vitro* and *in vivo* therapeutic activity of the medical device.

Novel nano-particular calcium phosphate and carbonate phases made by electro-migration technique. A component of silica/collagen based bone replacement materials

Benjamin Kruppke, Christiane Heinemann, Sascha Heinemann, Anne Keroué, Maria Jäger, and Thomas Hanke*

Max-Bergmann-Centre of Biomaterials, Institute of Material Science, Faculty of Mechanical Engineering,
Technische Universität Dresden, Germany, thomas.hanke@tu-dresden.de

INTRODUCTION

Bone replacement materials for systemically altered (e.g. osteoporotic) bone has to meet various requirements. In case of post-menopausal high turnover osteoporosis the biomaterial should manipulate the osteoblast [Ob]/osteoclast [Oc]-ratio to the benefit of the bone forming Ob. Recently, the authors have shown that silica/collagen-biomaterials with or without added calcium phosphate phases¹ are able influence the Ob/Oc-ratio in a co-culture by controlling the extracellular calcium concentration². Furthermore, Oc-formation and activity are influenced by such composites with different calcium phosphate phases³. Here, novel calcium mineral phases (phosphate, carbonate), a newly developed electro-migration chamber as well as corresponding cell culture experiments are presented.

EXPERIMENTAL METHODS

The silica/collagen-biomaterials were prepared from bovine tropocollagen type I (GfN) and hydrolysed tetraethoxysilane (TEOS, 99%, Sigma)⁴. For the preparation of triphasic xerogels calcium phosphate or carbonate phases prepared by precipitation in a gelatin gel were used (cf. results and discussion).

For cell culture experiments hydrogels were prepared by stirring silicic acid and collagen suspension to obtain a final composition of 70% silica and 30% collagen. Triphasic xerogels were prepared by previously adding gel precipitated calcium phosphate or carbonate phases to the collagen suspension². In these cases the final composition was 50% silica, 30% collagen, 20% calcium mineral phase. Mixtures were transferred to molds and dried in an Espec SH-221 climate chamber. Finally, disc-like composite xerogels (o.d. 5 mm, h. 3 mm) were obtained that fit in cell culture well plates.

Cell culture experiments were carried out using a Ob/Oc co-culture and monocultures of each cell type as previously described².

RESULTS AND DISCUSSION

In the electro migration chamber (cf. figure) a newly developed barrier is located between two reservoirs of CaCl_2 and Na_2HPO_4 solutions. Instead of Ca^{2+} and HPO_4^{2-} other cations (Sr^{2+}) and anions (HCO_3^-) or mixtures were used, too. The barrier consists of a plastic rack with gelatine gel (10% porcine) filled openings. Various numbers of openings with different shape and size in a rack were used, according to requirements, as gel composition, type of calcium mineral to be formed, further ingredients as well as the final size and shape of the biomaterial. An electric field was applied to accelerate the opposed migrations of cations and anions, respectively, into and within the gelatine gel. Over a number of days, the mineral was formed, then collected

by removing the gelatine using several alternating steps of heating and centrifugation.

The rack with the openings of defined geometry and size as a barrier in the electro migration chamber enables us to prepare particularly good defined mineral nano-particles. The influence of the mineral phases alone onto the extracellular calcium concentration was quantified. Cell culture experiments using monocultures of hMSC- derived Ob and monocyte-derived Oc and/or co-cultures thereof have shown that the triphasic xerogels - according to which mineral phases were used - can increase or decrease both populations of Ob and Oc, independently of each other or in a co-culture, then in opposite direction regarding the cell type.

CONCLUSION

Novel nano-particular calcium phosphate and carbonate phases were used as ingredients of triphasic silica/collagen based biomaterials. They are particularly suitable for control of calcium binding and release onto/from these xerogels. Consequently, the xerogels are supposed to act in a particular effective way as bone replacement materials manipulating the ratio between the bone-forming and bone-resorbing cells.

ukezban@hacettepe.edu.tr

INTRODUCTION

Silver nanoparticles have versatile applications in many commercial products such as wound healing materials, antimicrobial coatings, fillers and medical biotextiles due to its well-known antimicrobial nature. An efficient silver ion release from these biomaterials is crucial for sustained antibacterial activity. Properties of polymer matrix such as polymer type, concentration, morphology, processing parameters and silver nanoparticle size, concentration of silver nanoparticles play a decisive role in silver ion release kinetics.

In silk based textiles and wound dressing materials, control of the silk morphology; random coil (Silk I) or β sheets (Silk II); is an important subject, which effects the release of silver ion and determines antibacterial efficiency of these biomaterials. Silk morphology can be changed and controlled by different post-treatment methods [1]. Even with the wide usage of Ag nanoparticles in medical textile materials, there are only few studies reported about silver ion release kinetics and cytotoxicity on cell lines.

In this work silver nanoparticles were *in situ* produced in electrospun fibroin nanofibers by UV reduction of silver nitrate. Composite nanofibers were treated using two post-treatment methods as follows; glutaraldehyde (GA) vapor and methanol treatment. The effect of silk morphology, random coil (Silk I) or β sheets (Silk II), on Ag⁺ release kinetics, antibacterial activity and indirect cytotoxicity were discussed elaborately.

EXPERIMENTAL METHODS

Native *Bombyx mori* silk fibers was degummed with NaHCO₃. Then rinsed with warm distilled water to extract the glue-like sericin proteins. The degummed silk fibroin was dissolved in the ternary solvent system of CaCl₂/CH₃CH₂OH/H₂O. Solution was dialyzed against distilled water using a dialysis membrane to remove the salts. After dialyzing, the silk fibroin solution was filtered and lyophilized [2]. Then different amounts of AgNO₃ (w/v 0.1%, 0.5% and 1%) was added to silk fibroin. Silver nanoparticles were synthesized by UV light (254 nm) exposure of composite nanofibers. Finally methanol and GA vapour treatments were applied.

RESULTS AND DISCUSSION

In order to obtain uniform Ag/Fibroin composite nanofibers the key processing parameters such as flow rate, applied voltage, and fibroin concentration were optimized. Ag/Fibroin composite nanofibers were in the

range between 200 to 600 nm with a smooth and uniform morphology. Presence of Ag in fibroin nanofibers was attested by EDX analysis (Fig 1).

Fig 1. SEM micrographs of nanofibers (a) Fibroin, (b) Ag(0.1)/Fib, (c) Ag(0.5)/Fib, (d) Ag(1)/Fib, SEM-EDX of Ag/Fib composite nanofibers (e) Ag(0.1)/Fib, (f) Ag(0.5)/Fib and (g) Ag(1)/Fib.

Between the two post treated composite nanofibers, the cumulative amount of silver ions released from the Ag/Fib-G was greater than the amount released from the Ag/Fib-M ones due to its amorphous structure. Evaluation of antibacterial activities were studied against three microorganisms gram (+) *Staphylococcus aureus*, *Staphylococcus epidermidis* and gram (-) *Pseudomonas aeruginosa*. For Ag/Fib composite nanofibers, it was observed that zones of inhibition are clearer against *P. aeruginosa* than *S. aureus* and *S. epidermidis* (Table 1.).

Table 1. Inhibition zones of the composite nanofibers

Type of Samples	Inhibition Zone Diameter (cm) /Sample Diameter (cm)		
	<i>S. aureus</i>	<i>S. epidermidis</i>	<i>P. aeruginosa</i>
Ag(0.1)/Fib-M	0.50/0.50	0.50/0.50	0.83/0.50
Ag(0.1)/Fib-G	0.50/0.50	0.50/0.50	0.80/0.50
Ag(0.5)/Fib-M	0.50/0.50	0.50/0.50	0.73/0.50
Ag(0.5)/Fib-G	0.50/0.50	0.50/0.50	0.83/0.50
Ag(1)/Fib-M	0.60/0.50	0.57/0.50	0.87/0.50
Ag(1)/Fib-G	0.67/0.50	0.60/0.50	0.93/0.50

CONCLUSION

Smooth and uniform Ag/fibroin composite nanofibers having antibacterial properties were obtained and release studies demonstrated that the accumulative amount of silver ions depends on the silver content of nanofibers and polymer morphology.

Sustained Release of Azithromycin from an Electrospun Polycaprolactone Membrane for Guided Tissue Regeneration

Asha Mathew¹, Cedryck Vaquette², Dietmar Hutmacher² and Saso Ivanovski¹

¹Tissue Engineering and Regenerative Medicine, Griffith University, Australia

²*Regenerative Medicine, Queensland University of Technology, Australia a.mathew@griffith.edu.au

INTRODUCTION

Periodontitis is an inflammatory disease affecting the periodontum resulting in the progressive loss of the alveolar bone around the teeth causing subsequent teeth loss [1]. For successful periodontal regeneration, the formation of periodontal ligament fibers and the insertion of these fibers into newly formed cementum on the root surface along with the adjacent resorbed alveolar bone are essential. Guided Tissue Regeneration (GTR) is a widely utilized surgical technique to promote periodontal regeneration. However, bacterial contamination on the sites undergoing GTR therapy reduces the efficiency of periodontal regeneration either by affecting the new connective tissue attachment or bone [2] or by affecting the attachment of periodontal ligament cells on the GTR membranes [3]. Therefore, this project aims at addressing a significant issue in periodontal regeneration: bacterial contamination on the sites of undergoing GTR. It is hypothesised that the local delivery and sustained release of azithromycin will significantly reduce any bacterial infection. For this purpose, the primary objective of the project is to engineer and assess a biocompatible and biodegradable polymeric matrix for the controlled delivery of azithromycin.

EXPERIMENTAL METHODS

PCL membranes are fabricated via solution electrospinning. The PCL membranes are then subjected to a calcium phosphate (CaP) coating process by successive immersion into specific reagents and solutions. Azithromycin encapsulation, release, antibacterial and cellular response when loaded onto PCL and PCL-CaP membranes are assessed on different doses of azithromycin. The statistical analysis are performed throughout the entire project using one-way ANOVA followed by a Tukey HSD post-hoc test in case of equal variance; otherwise a Games-Howell post-hoc test will be utilized.

RESULTS AND DISCUSSION

Azithromycin was successfully loaded onto PCL/PCL-CaP membranes using a novel ethanol evaporation technique. This method enables to reproducibly load azithromycin on to the electrospun membranes with a very high loading efficacy (around 75%) as depicted in Figure 1 A), which is unprecedented for such a poorly water soluble compound. PCL membrane surface topography has shown to have an effect on azithromycin encapsulation and efficiency. CaP coating on PCL membranes increased the roughness and surface area of the resulting material leading to higher loading efficacy and more uniform distribution of the antibiotic throughout the fibrous membrane. *In-vitro* release profile of azithromycin from the membrane demonstrated around 90% release from CaP coated and non-coated PCL membranes after 14 days of incubation

with PBS at 37°C (Figure 1B). This is of tremendous significance as a successful local drug delivery strategy must release the antibiotic over a defined period of time and avoid a burst release. Antibacterial activity of azithromycin loaded membranes on staphylococcus aureus suggest that the electrospun membranes loaded with azithromycin are capable to inhibit bacterial growth even after 14 days of release (Figure 2).

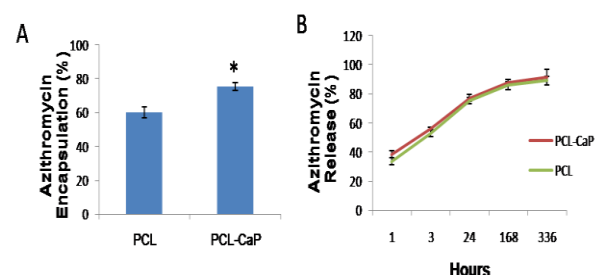

Figure 1: (A) Encapsulation efficiency of azithromycin loaded on to PCL and calcium phosphate coated PCL (PCL-CaP). n=4, p<0.05. (B) Cumulative release of azithromycin from PCL and calcium phosphate coated PCL (PCL-CaP) achieved as a continuous release over a period of 14days (n=3)

Figure 2: Growth inhibition of staphylococcus aureus after 20 hour incubation with 1mg azithromycin containing (A) PCL (B) PCL-CaP electrospun membranes after 0, 7 and 14 days release from PBS at 37°C.

CONCLUSION

In conclusion hydrophobic azithromycin was successfully encapsulated on to PCL/PCL-CaP membranes using ethanol evaporation technique. Our results have shown an excellent encapsulation efficiency of about 75% with a controlled release of 90% along with efficient antibacterial effect even after 14 days of release.

Functional Characterisation of SDF-1 α GAG Binding Variants

Nydia Panitz^{1*}, Lars Baumann², Stephan Theisgen³, Daniel Huster³ and Annette G. Beck-Sickinger¹

^{1*}Institute of Biochemistry, University Leipzig, Germany, nydia.panitz@uni-leipzig.de

³Institute of Medical Physics and Biophysics, University Leipzig, Germany

INTRODUCTION

The stromal cell-derived factor 1 α (SDF-1) belongs to the CXC chemokines and interacts with its CXC-receptor 4 and 7. It plays an important role in immune system, angiogenesis and recruitment of tissue specific stem cells. Therefore the SDF-1 is an interesting target for the regeneration of damaged tissue e.g. after myocardial infarction. Recent studies focus on the development of hydrogels, which can be integrated in this type of damaged tissue. The aim of this study is to generate a stable, long-term chemotactic gradient by using immobilised SDF-1, which leads to the recruitment of stem cells and therefore to the regeneration of the affected tissue^{1,2}. The present work focusses on the influence and characterisation of SDF-1 variants with different GAG binding properties to recruit different cell types that express the CXCR4.

EXPERIMENTAL METHODS

For the investigation of specific amino acids of SDF-1 α for GAG binding different native and artificial GAGs were used for ¹H-¹⁵N-HSQC NMR spectroscopy. The activity of SDF-1 variants was studied by migration and Ca²⁺ release assays.

RESULTS AND DISCUSSION

¹H-¹⁵N-HSQC NMR with ¹⁵N-labeled SDF-1 was used to confirm previous studies by Ziarek *et al.*³. Similar results could be obtained for the binding of artificial GAG.

NMR results identified specific lysines and arginines for the subsequent migration experiments. The results showed only weak effects of the single mutants. Next the investigation of the signaling pathway was performed by using an Ca²⁺ release assay. Distinct mutations showed a quite similar EC₅₀ and E_{max} value in comparison to the SDF-1.

The presented NMR data provide an overview on the interaction of SDF-1 with different types of GAGs. This led to the hypothesis, that the sulfation of the GAG may play an important role for the interaction with the protein. This was shown earlier for related systems^{4,5}.

Based on the NMR-measurements single amino acids were exchanged by mutations. The migration assay demonstrated that the single mutation does not influence the ability of the SDF-1 to recruit specific cells. Accordingly, certain amino acids of the GAG binding site are not involved in the interaction of the SDF-1 with CXCR4, which is in agreement with previous modelling data⁶.

To identify the influence in signaling pathways, Ca²⁺ release assays were performed. For all receptor variants a similar effect in signaling strength could be detected compared to the native SDF-1 α . This indicates that the G-protein coupled signaling by the phospholipase C is not influenced.

CONCLUSION

Additional knowledge on the specific interaction of SDF-1 with different GAGs could be achieved and the influence of the GAG binding site of the interaction of the SDF-1 with its CXCR4 could be determined in more detail. Future experiments will give further information, which can be used to generate SDF-1 variants with better and poorer GAG binding properties for hydrogels to generate a long-term and stable chemotactic gradient.

INTRODUCTION

Guided bone regeneration (GBR) is commonly utilized in dentistry for the treatment of insufficient bone or dehiscence defects. This strategy is aimed at enabling the regrowth of the damaged or compromised bone tissue in order to resume functional activity of the mandible or maxilla. GBR is based on 3 essential criteria: wound stabilization, space maintenance and selective cell repopulation for permitting bone ingrowth. This is traditionally achieved by the utilization of an occlusive membrane placed over the bony defect in order to prevent epithelial or fibrous tissue infiltration, hence fulfilling the principles of GBR [1]. To circumvent the limitations of the currently available GBR membranes (inappropriate degradation time, risk of exposure, poor handling properties), our group has developed an occlusive membrane made of a biocompatible and bioresorbable synthetic polymer (polycaprolactone, PCL) fabricated by electrospinning and subsequently bioactivated by polystyrene sodium sulfonate (PolyNaSS) grafting.

EXPERIMENTAL METHODS

Electrospinning: Biomedical grade PCL (80,000 g/mol) was used in this study to fabricate the electrospun membranes. The electrospinning conditions were 10kV, 2mL/hr, 20cm air gap, 10x10cm² aluminium collector using a 25% wt/vol PCL solution in chloroform/dimethylformamide (90/10)

PolyNaSS grafting: The grafting was carried out according to our in house protocol [2]

In vitro evaluation: The osteogenic performance of the grafted material was assessed by measuring the ALP expression, the cell adhesion and proliferation, the amount of mineralised matrix by alizarin Red S and micro-computed tomography (μ CT) over 8 weeks of in vitro culture using human mesenchymal stromal cells.

In vivo evaluation: the regenerative potential of the membranes was tested in a rat calvarial defect. Bone formation was assessed longitudinally at 2 and 4 weeks post-implantation by μ CT and by histology.

RESULTS AND DISCUSSION

Fig 1A shows the morphology of the PCL membrane and highlights the small pore size (in the micrometric range) obtained during the electrospinning process. These membranes are well suited for GBR as they can maintain the space while reaching a high degree of flexibility and resilience (Fig 1B) when bench marking against other commercial biodegradable products. The grafting resulted in up-regulation of ALP expression and higher volume of mineralisation in the case of the grafted membranes. This was further confirmed by the in vivo implantation as we demonstrated that the

PolyNaSS grafting significantly accelerated the healing response as shown in Fig 1C; full bridging of the calvarial defect was reached in the case of the grafted membrane as opposed to very little bone formation for the non-grafted membrane. The PCL electrospun membrane displayed a high porosity with a pore size small enough to prevent rapid infiltration of the fibrous tissue into the wound, hence fulfilling the principles of GBR. We observed that whilst the membrane maintained its occlusive properties in the initial stage of the healing process, the membrane was gradually colonised by the host cells permitting an appropriate tissue integration at a later stage.

Morphological features of the membrane

CONCLUSION

We demonstrated the superior performance of the PolyNaSS grafted membrane for bone formation. The grafted membrane can provide clinicians with a purely synthetic porous construct with excellent handling, biomechanical stability and fixation properties. These newly developed membranes possess significant advantages compared to existing commercially available products, such as no risk of disease transmission, controlled biodegradation, and lack of immunogenic response.

Chlorhexidine-based Antimicrobial Nanoparticles as a Coating for Dental Implants

Natalie Wood^{1*,2,3}, Howard Jenkinson², Dominic O'Sullivan², Sean Davis³ and Michele Barbour²

^{1*}Bristol Centre for Functional Nanomaterials, University of Bristol, UK, natalie.wood@bristol.ac.uk

²School of Oral and Dental Sciences, University of Bristol, UK

³School of Chemistry, University of Bristol, UK

INTRODUCTION

Titanium is the dominant component of many dental implant systems; this is due to its strength, corrosion resistance and biocompatibility.¹ Micro-roughened implant surfaces have shown a higher rate of osteoblast adhesion; however, this increased surface roughness means the implants become more susceptible to bacterial colonisation, which may increase the propensity of implant failure.²

Chlorhexidine (CHX) is a broad spectrum biocide used extensively in medicine and dentistry. It can be combined with hexametaphosphate (HMP) to yield a solid nanoparticle (NP).³ NPs are an attractive coating for dental implants due to their small size, meaning the majority of the titanium surface would be exposed and available for osseointegration. They also offer the possibility of tuneable surface coverage.

EXPERIMENTAL METHODS

Upon the addition of an aqueous chlorhexidine digluconate solution (10 mM) to an aqueous solution of sodium hexametaphosphate (10 mM), under constant stirring, CHX-HMP NPs were precipitated.

Commercially pure grade II titanium substrates were exposed to the rapidly stirred NP suspension for 30 s and rinsed for 10 s in deionised water, before being left to dry in air. Some samples were then soaked in stimulated, whole, human saliva for 2 hours to deposit a salivary pellicle (Ethics reference number: NJW161213; Saliva bank REC ref: 08/H0606/87+5).

NP size, charge and surface distribution were investigated using Dynamic Light Scattering (DLS), Atomic Force Microscopy (AFM) and Scanning Electron Microscopy. The release of CHX from the surfaces into water, with and without the addition of an acquired salivary pellicle, was monitored through the use of UV-spectrophotometry. The antimicrobial efficacy of the NP-coated surfaces against *Streptococcus gordonii*, with and without a salivary pellicle, was also investigated.

RESULTS AND DISCUSSION

The CHX-HMP NPs had an average size and charge of ~150 nm and ~ -50 mV, respectively (DLS). They readily adhered to titanium resulting in micron-sized porous plaques surrounded by titanium (AFM) (SEM), see Figure 1.

These NP-coated surfaces exhibited a steady release of CHX into water for over 50 days. The same was true when a salivary pellicle was applied; however, a lower final concentration was reached.

The adhesion and proliferation of *S. gordonii* were shown to be significantly reduced within 24 h due to the

NP coating; similar results were seen in the presence of a salivary pellicle, see Figure 2.

Figure 1. Scanning electron micrographs showing (L) uncoated titanium and (R) titanium post-NP deposition.

Figure 2. Optical micrographs of fluorescently labelled *S. gordonii*, live (green) and dead (red), on uncoated titanium (a) with a pellicle and (c) without a pellicle and on NP-coated titanium (b) with a pellicle and (d) without a pellicle, after 24 h. Scale bar is 100 µm.

CONCLUSION

CHX-HMP NPs have been synthesised and adhered to clinically relevant titanium substrates. These coated surfaces have shown a steady release of CHX from the surface for over a month, even in the presence of a salivary pellicle. All NP-coated surfaces, with and without a pellicle, exhibited a significant antimicrobial efficacy against the oral primary coloniser *S. gordonii*, within 24 h.

PEGylation as a method of modification of collagen-elastin based scaffolds for tissue engineering

Joanna Skopinska-Wisniewska¹, Anna Bajek², Justyna Sitkowska¹, Alina Sionkowska¹

¹ Faculty of Chemistry, Nicolaus Copernicus University, Torun, Poland, joanna@chem.umk.pl

² Collegium Medicum, Nicolaus Copernicus University, Karłowicza 24, 85-092 Bydgoszcz, Poland

INTRODUCTION

Collagen and elastin are a main components of extracellular matrix most of the connective tissues. The mechanical properties of these proteins are complementary and provide a resilience to all kinds of tissues. In addition, the proteins ability to improve the cells adhesion and promote the production of extracellular matrix from proliferating cells causes that collagen and elastin have been the focus of biomaterials technology and tissue engineering for many years [1-3]. The mechanical properties, swelling and degradation ability of these proteins can be modified by cross-linking. Glutaraldehyde is one of the most efficient cross-linking agent. The stable bonds between aldehyde groups and amine rests of proteins can be created in the mild conditions, at physiological pH with a good efficiency. However, the free dialdehyde molecules which can stay in the scaffold are cytotoxic [4,5]. For this reason we decided to use poly(ethylene glycol)-dialdehyde molecules. On the one hand, it ensures the efficiency of cross-linking, but on the other hand the length of the molecules will prevent the release of the reagents into the tissues.

EXPERIMENTAL METHODS

The collagen type I was extracted in our laboratory from rat tail tendons and elastin from porcine aortas. The blends containing collagen and 5% and 10% of elastin were prepared. Both types of samples were cross-linked by the addition of 5% and 10% of two kinds of poly(ethylene glycol)-dialdehyde (PEG-dialdehyde) (MW 1000 and MW 3400) from Scholtz GMB (Germany). The mixtures of all reagents were incubated 30 min on magnetic stirrer and then dialysed against deionized water.

RESULTS AND DISCUSSION

The results of swelling degree measurements showed that the non-modified collagen-elastin materials exhibit the highest swelling ability. The cross-linking using PEG-dialdehyde 1000 causes only a small decrease of the swelling degree, while the use of PEG-dialdehyde 3400 results in significantly reduced swelling capacity. Mechanical test revealed that the cross-linking causes

increase of the samples stiffness. Although the compression modulus of the material containing 5% elastin is much higher than for the sample with bigger elastin content, but after cross-linking the both materials exhibit similar value of this parameter. It suggests that the effectiveness of cross-linking is higher for elastin than for collagen chains. Also the temperatures of thermal denaturation observed during DSC analysis are higher for cross-linked materials. However, the temperature differences for various samples are not significant.

CONCLUSION

The results demonstrate that the addition of the cross-linking agent improve the mechanical properties and thermal stability of the resulting materials. However, the cross-linking with PEG-dialdehyde 3400 causes significant decrease of swelling capacity, so the use of PEG-dialdehyde 1000 is more reasonable.

INTRODUCTION

Several approaches to modify the surface of resorbable aliphatic polyesters (i.e. poly-L-lactide-co-glycolide, PLGA) in order to enhance their cell-interactive properties have been proposed in literature. These include: hydrolysis, UV-treatment, ozone and plasma treatments, etc. A very attractive and efficient method seems to be the introduction of primary amines on a polyester surface, which can subsequently be used for physisorption or the covalent immobilization of biomolecules. Such a multistep method, based on post-plasma grafting of 2-aminoethyl methacrylate (AEMA), has been recently developed for poly(ϵ -caprolactone) and it was found to positively impact rat osteosarcoma cell adhesion and viability¹. The aim of this study was to utilise a similar approach to functionalize PLGA by covalent bonding of gelatin and verify if such a treatment is beneficial for human osteoblast-like cell adhesion and growth.

EXPERIMENTAL METHODS

PLGA (85:15, $M_n=100$ kDa, $M_w=210$ kDa) foils prepared by solvent casting were submitted to a dielectric barrier discharge Ar plasma followed by air exposition and AEMA grafting under UV irradiation. Then gelatin (type B from bovine skin, obtained by alkaline process) was covalently immobilized with the use of EDC (Sigma) according to a method developed for poly(ϵ -caprolactone)¹. The surface of PLGA and PLGA-AEMA-GelB was characterized by XPS (FISONS S-PROBE), AFM (EXPLORER) and contact angle measurements (DSA10). MG-63 osteoblast-like cells were cultured on the samples for 1 to 8 days and both cell proliferation (MTT test) as well as cell morphology (after fluorescence staining by acridine orange) were assessed.

RESULTS AND DISCUSSION

The applied modification resulted in changes in PLGA surface chemistry (presence of nitrogen and decrease in carbon and oxygen), an increase in hydrophilicity and an increase in surface roughness (Tab. 1).

Tab. 1 Chemical composition, average roughness (R_a) and water contact angle of PLGA and PLGA-AEMA-GelB foils

	PLGA	PLGA-AEMA-GelB
C (at%)	68 \pm 6	64.6 \pm 0.3
O (at%)	29 \pm 5	27.8 \pm 0.8
N (at%)	bdl	7.6 \pm 0.6
N/C	0	0.118
Θ (°)	64 \pm 2	33 \pm 7
R_a (nm)	0.73 \pm 0.17	10.8 \pm 1.3

bdl - below detection limit

In vitro results show that MG-63 cell adhesion on PLGA-AEMA-GelB after 1 day was significantly higher than on PLGA. Cell proliferation was also significantly higher on day 8 (Fig.1), but still the cell proliferated better on TCPS. Microscopic observations show that the cells on PLGA-AEMA-GelB were more homogenously distributed and their flattened morphology was similar to that on TCPS. Contrarily, the cells cultured on PLGA tended to aggregate (Fig.2).

Fig. 1 Proliferation of MG-63 evaluated by MTT test after 24 h, 3 and 8 days. Asterisks indicate significant differences ($p^{***} < 0.001$) between PLGA and PLGA-AEMA-GelB.

Fig. 2 Cell morphology on PLGA (A), PLGA-AEMA-GelB (B) and TCPS (C) after 8 days of culture.

CONCLUSIONS

Post-plasma AEMA grafting followed by gelatin B covalent immobilization had a significant influence on chemistry, topography and wettability of PLGA surfaces. The surfaces become rougher and more hydrophilic upon gelatin immobilization. As a result, MG-63 osteoblast-like cells, adhere and proliferate better than on non-modified PLGA.

INTRODUCTION

Mesoporous materials with pore sizes in the range 2-50 nm and surface reactive functionalities have experienced an outstanding development during the last years due to their exciting prospects in bone tissue engineering^{1,2}. More in detail, titania and silica mesoporous thin films have been proven to promote *in vivo* an enhanced initial bone contact and better distribution of bone tissue due to their highly ordered arrays of monodisperse pores, high specific surface areas and bioactive properties³. On the other hand, it has already been demonstrated that pharmacological compounds can upregulate the intrinsic growth factors to stimulate bone growth. Thus, for instance, topically applied simvastatin, has been shown to stimulate BMP-2 and VEGF mRNA expression in osteoblasts and promote bone growth over mouse calvaria⁴. The main objective of the present work was to evaluate the MC3T3-E1 pre-osteoblasts response to mesoporous silica and titania nanoscaled thin films both loaded with different concentrations of simvastatin to determine the optimal range doses to ensure a pro-osteogenic activity.

EXPERIMENTAL METHODS

Silica and titania mesoporous thin films were produced by spin-coating using 125 µL of the precursor solution on top of a glass slide at a spinning rate of 4000rpm. The technique, previously reported², was based on the mesoporous-induced self-assembly (EISA) strategy using an inorganic precursor and a surfactant template in ethanol solution. Sterilized samples of 1x1cm² loaded with simvastatin dilutions in ethanol of 5mg/ml, 1mg/ml, 0.1mg/ml, 0.01mg/ml y 0mg/ml were seeded with 1.7x10⁵ cells/ml of MC3T3-E1 pre-osteoblasts in osteogenic medium. Cells morphology (SEM), cytoskeleton organization (CLSM), proliferation (MTT assay) and early differentiation (alkaline phosphatase, ALP) were evaluated up to 21 days of incubation. Tissue culture polystyrenes (TCP) were used as controls. Data are presented as mean ± standard deviation. Significant differences between groups were assessed with the Student's *t*-test, where ** corresponded to significant difference of *p*<0.01.

RESULTS AND DISCUSSION

Early differentiation of cells to osteoblasts on both mesoporous silica and titania films without simvastatin was quantified and, for instance, after 14 days of incubation (Fig.1a) the ALP activity was significantly higher on silica than on titania films and TCP controls. When differentiation was evaluated on simvastatin-loaded titania films results showed that again after 14 days (Fig.1b) statistically significant higher osteoblastic activity was obtained in the titania films with simvastatin doses of 0.01mg/ml. The dose of 0.1mg/ml

also promoted a higher ALP activity when compared with the 0mg/ml titania mesoporous films. These results proved the clear osteoinductor potential of silica films, which corresponded to previous results at literature related to the benefits in bone regeneration of certain silica based materials, as Bioglass®⁴.

Figure 1. ALP activity for 0mg/ml silica, titania and TCP (a) and for all simvastatin doses on titania (b).

CONCLUSION

The biocompatibility of mesoporous silica and titania thin films has been proven, where, at the same time, silica thin films promoted higher ALP activity. Simvastatin loading in a controlled dose of 0.01mg/ml was demonstrated to improve the osteoblastic response. The threshold of cytotoxicity of simvastatin was established on ≥1mg/ml.

e-mail: psobolewski@zut.edu.pl

INTRODUCTION

The explosion of information provided by the “-omics,” (genomics, proteomics, etc.) has resulted in a pressing need to develop matching diagnostic technologies, so-called biosensors. Importantly, in addition to sensitivity and specificity, an ideal biosensor platform needs to be fast, affordable, and simple, in order to reduce the barrier of entry, especially in the developing world. Recent developments in polymer science, nanotechnology, and carbon-nanomaterials—graphene in particular—offer a great deal of promise in achieving these goals¹.

Here we present a chitosan-catechol/graphene nanocomposite suitable for use as an ink for ultrasonic, non-contact printing, for application as a matrix for the coupling of oligonucleotide molecular beacons for DNA biosensing.

EXPERIMENTAL METHODS

Chitosan/graphene dispersions utilizing 0.05% graphene oxide (GO) and chitosans of three different molecular weights (oligo, 5 kDa; low, 40 kDa; high, 890 kDa, Aldrich) were prepared in 1% acetic acid by a combination of sonication and mixing. The viscosity, conductivity, zeta potential, and stability of the dispersions was assessed, in order to determine ideal chitosan candidate for catechol modification. Catechol modification of chitosan was carried out with hydrocaffeic acid (HCA) by a carbodiimide coupling¹. Degree of modification was assessed via ¹H NMR.

RESULTS AND DISCUSSION

Oligo chitosan (5 kDa, 90% DD) solutions in acetic acid (2-4%) yielded GO dispersions of the highest conductivity (1-1,3 mS/cm), tunable viscosity in the required range for ink (up to 0,45 Pa s), high zeta potential (65 mV), and high stability over 21 days.

Fig. 1: Viscosity of chitosan/GO dispersions. Note: 0,45 Pa s is the maximum suitable for ultrasonic printing.

Fig. 2: Oligo chitosan/GO dispersions (2, 3, 4% oligo chitosan and 0,05% GO) remain stable after 21 days.

These parameters were deemed suitable for use as an ink for ultrasonic, non-contact printing, thus modification of oligo chitosan was carried out with HCA, to yield water soluble chitosan-HCA.

CONCLUSION

Novel nanocomposites consisting of water soluble, catechol modified chitosan and graphene oxide produced here will ultimately be combined with locked nucleic acid molecular beacons with the goal of producing printable DNA biosensors. The developed technology will allow fabrication of low cost, high sensitivity biosensors for point-of-care diagnosis.

Fabrication of microparticles and patterned substrates for directing stem cell growth

Y. Yang^{1,2}, L. Glennon-Alty², A. Ahmed¹, L. Qian¹, P. Murray², D. Bradshaw³ and H. Zhang¹

¹ Department of Chemistry, University of Liverpool, UK, yonghong.yang@liv.ac.uk

³ Department of Chemistry, University of Southampton, UK

INTRODUCTION

Stem cells are able to self-renew and differentiate to produce specialized progeny, and thus have enormous potential for tissue engineering-based therapies¹. The use of suitable scaffolds is critical to grow cells for proper function and tissue engineering applications. 2D substrates with patterned surfaces can be readily used to investigate the interactions between the cells and the support scaffold. In this study, we have fabricated biocompatible micro-/nano-particles and 2D substrates to support and direct stem cell growth.

EXPERIMENTAL METHODS

Emulsion freeze-drying and emulsion evaporation were used to prepare poly(ϵ -caprolactone) (PCL) microparticles and poly(lactide-co-glycolide) (PLG) nanospheres. To fabricate the 2D substrates, the PLG nanospheres were suspended in aqueous chitosan solution. The suspension was dropped on a glass slide and spread evenly. A directional freezing process was then employed on a computer-controlled freezing stage.² The frozen sample on the glass slide was then freeze-dried to produce dry surface-patterned substrates.

Both the PLG microparticles and the substrates were used for the growth of mesenchymal stem cells (MSCs). The compatibility of the materials was firstly investigated based on the survival and growth of cells. The alignment of cell growth was particularly studied on the surface patterned substrates.

RESULTS AND DISCUSSION

For the emulsion freeze-drying approach, PCL was dissolved in dichloroethane which was then emulsified in aqueous poly(vinyl alcohol) solution with the aid of a surfactant. The emulsion was frozen and freeze-dried to produce a composite material. After dissolving the composite and collecting the microparticles by centrifuging, aligned porous PCL microparticles were produced. The cell culture study showed that PCL particles could support the growth of stem cells.

The study was then focused on the fabrication of surface-patterned substrates and directional growth of MSCs. A stable suspension was firstly formed by dispersing PLG nanospheres in chitosan solution. Chitosan was chosen because it is biocompatible and insoluble in neutral water. Aligned surface patterns on glass slides were produced with the ridges of the pattern composed of chitosan and PLG nanospheres. These patterns were stable in the culture. It was observed that the growth of MSCs was orientated (Fig. 1). The contact (hence interaction) between the cells and the PLG spheres could be observed by scanning electronic microscopy. It was possible to tune the width between the ridges on the surface pattern by changing the freezing condition. This, in turn, would be able to tune the MSC growth.

Fig. 1 The aligned growth of MSCs on surface patterned substrates.

CONCLUSION

A facile directional freezing and freeze-drying approach was employed to fabricate 2D substrates with aligned surface patterns. Such substrates could be used to guide stem cell growth

Selenium-doped calcium phosphate coatings on titanium implants with inhibition properties on cancerous osteoblasts

Cosme Rodríguez-Valencia¹, Miriam López-Álvarez¹, Julia Serra¹, Pío González¹

¹ Department of Applied Physics, Institute of Biomedical Research of Vigo (IBIV), University of Vigo, 36310, Spain cosme@uvigo.es

INTRODUCTION

Nowadays, a common technique to treat bone cancer is the surgical removal and replacement of the affected tissue by an orthopaedic implant. However, cancer cells are not always completely removed and can return to the affected area after the surgery. Normally, titanium is the most used material for implants but these prostheses do not have any mechanism to prevent the reoccurrence of bone cancer. It is well known that hydroxyapatite (HA) as coatings on titanium prosthesis have osteo-inductive properties and at the same time selenium as nanoclusters² has been proven to inhibit the growth of certain types of bacteria¹ and the proliferation of certain cancerous cell lines. The objective of this study was to combine both properties, the osteoinductive of calcium phosphates and the anti-cancer of Se, in the same material as a coating (Se-CaP) to allow the prevention of the occurrence and reoccurrence of bone cancer and promote the healthy bone tissue growth.

EXPERIMENTAL METHODS

Following our previous work³, Ti6Al4V discs were coated with Se-CaP layers (0.6 and 2.5 at.% Se) by Pulsed Laser Deposition (PLD) technique and exposed to gamma radiation to their sterilization. In this study, healthy mouse pre-osteoblasts (MC3T3-E1) and human cancerous osteoblast (MG63) were cultured on coated titanium discs. To evaluate the behaviour of healthy osteoblast and cancerous osteoblast on the Se-CaP coatings, both cell types were stained with CFSE and Vybrant DIL fluorescent dyes, respectively. MC3T3-E1 and MG63 cells were seeded in the appropriated media (α -MEM and EMEM, respectively) at 5.000 cells/ml and then, were placed in an incubator under standard cell culture conditions. After the desired time period, media were exchanged and the cells were rinsed thrice with PBS. Both types of cells were observed under confocal laser microscopy (CLSM) at 1, 2 and 3 days. The number of the cells was counted in five random fields and averaged for each substrate. Uncoated and non doped HA coated substrates were used as controls.

RESULTS AND DISCUSSION

The MC3T3 culture assay showed an increasing cell proliferation along of time of culture, being more intense on coated titanium discs. After three days of culture, the MC3T3-E1 cell number was higher on Se-CaP coatings than on the controls, showing significantly difference ($p < 0.05$) on discs with 0.6at.% of selenium. On the other hand, there were more cancerous osteoblasts on controls than on the Se-CaP coatings. Also, on the non doped hydroxyapatite coatings was significantly higher ($p < 0.05$) than on the Se-CaP coatings with 2.5at.% of selenium.

The CLSM images showed normal healthy pre-osteoblasts (MC3T3-E1) proliferation and after 3 days of incubation, a greater number of cells were observed on Se-CaP coatings. In contrast, cancerous osteoblast densities were lower on Se-CaP coatings. In the case of SeCaP coatings with 2.5at.% of selenium, CLSM images showed that the cancer cell density decreased while healthy cell density increased, compared to the controls after 3 days of incubation.

Fig.1. Cells stained in green, MC3T3-E1 on titanium (A), non doped HA (B), 0.6Se-CaP (C) and 2.5Se-CaP (D). Cells stained in red, MG63 cells on titanium (E), non doped HA (F), 0.6Se-CaP (G) and 2.5Se-CaP (H). Both cell types, after 3 days of incubation.

CONCLUSION

The biocompatibility of Se-CaP coatings with 0.6 and 2.5 at.% of Se was demonstrated. Particularly, those Se concentrations have been proven to promote the inhibition of cancerous osteoblastic cell line. At the same time, the healthy pre-osteoblasts proliferation was promoted, being in both cases statistically significant ($p < 0.05$). A new promising biomaterial based on selenium doped calcium phosphate coatings with interesting anti-bacterial and anti-cancer properties is proposed to improve the performance of the current commercial orthopaedic implants.

Effects of stirring condition and fluid perfusion on the in-vitro degradation of calcium phosphate cement

Jie An, J.G.C.Wolke, S.C.G.Leeuwenburgh, J.A.Jansen

Department of Biomaterials, Radboud University Medical Center, The Netherlands
Jie.An@radboudumc.nl

INTRODUCTION

Calcium phosphate cements (CPCs) are the predominant type of bone substitute material used for reasons of injectability and hence perfect filling potential for bone defects. Recent studies have demonstrated that injectable CPCs combined with poly (lactic-co-glycolic) acid (PLGA) microspheres induced fast degradation¹. Many factors can affect PLGA degradation; molecular weight, chemical structure or geometric characteristics of the material or the characteristics of the surrounding medium. Currently, the in vitro degradation tests are performed in non-moving (static) soaking conditions, considering the extent flow in the physiological environment in vivo, dynamic soaking condition is probably more representative. Therefore, the aim of the present study is to investigate the in vitro degradable properties of PLGA/CPC composite tested under static and dynamic conditions in a bioreactor system and in a flow chambers.

EXPERIMENTAL METHODS

The CPC powder consisted of a mixture of 95% α -TCP, and 5% precipitated HA. PLGA (MW=17kDa, acid terminated, L:G=50:50) was used to prepare dense microspheres. PLGA/CPC formulations were prepared by adding 40%wt PLGA microspheres (mean particle size $94 \pm 29 \mu\text{m}$). PLGA/CPC composite was injected into teflon molds (cylinders $4.5 \times 9\text{mm}$).

For the degradation studies, the PLGA/CPC samples were placed in: (1) a bioreactor, static condition (BS), (2) a bioreactor, dynamic condition with a speed 200 rpm (BD) and (3) flow chambers, dynamic condition with a flow rate of 1.1 ml/min (FD). Phosphate buffered saline (PBS) was used as the soaking medium at 37°C. for 1, 2, 4 and 6 weeks (n=7). pH measurements of the PBS was performed directly after removal of the samples. The compressive strength was measured by using a testing bench with a crosshead speed of 0.5 mm/min (n=5). X-Ray diffraction (XRD) was used to determine the crystal structure. The morphology of the different formulation was determined by using scanning electron microscopy (SEM). Significant differences were determined using analysis of variance (Anova) and results considered significant if $p < 0.05$.

RESULTS AND DISCUSSION

The change of pH under each condition is shown in figure 1. After 6 weeks soaking the medium of the FD group shows a minimal pH decrease, this was higher than the bioreactor groups, where the pH decreased around 6.4. The compressive strength was given as a function of the degradation time (Fig 2). The FD group showed an increase in compressive strength upto 2 weeks soaking, while the BS and BD groups decreased already after 1 week soaking in PBS. It is clear that

during PLGA degradation lactic and glycolic acidic monomers are released and for the bioreactor groups the decrease in pH will accelerated cement degradation. XRD results showed after one week that the α -TCP phase was changed into an apatite phase, occasionally for all the groups upto 4 weeks an additional brushite phase was present. SEM examination demonstrated that after 4 weeks incubation for all the groups the microspheres were almost completely degraded.

Fig 1: pH change of the PBS as a function of the degradation time in weeks.

Fig 2: Compressive strength as a function of the degradation time in weeks.

CONCLUSION

The results indicated that the dynamic and static conditions influence the degradation of PLGA/CPC composite. The in vitro degradation of PLGA/CPC composite decreased in the order bioreactor static > bioreactor dynamic > flow chamber.

Ultrastructural features of mesenchymal stem cells in calcium alginate hydrogel during osteogenic differentiation by means of FIB-SEM

Jakub Grzesiak^{1*}, Krzysztof Marycz^{1,2}, Agnieszka Śmieszek^{1,2}, Anna Siudzińska¹

¹Electron Microscopy Laboratory, Wrocław University of Environmental and Life Sciences, Poland,

*grzesiak.kuba@gmail.com

² Wrocław Research Centre EIT+, Poland

INTRODUCTION

Three-dimensional hydrogel culture systems are more and more common in biomedical research. However, the evaluation of ultrastructural features of both cells and materials is remarkable challenge. In our work we present the huge potential of focused ion beam combined with scanning electron microscope for evaluation of ultrastructural features in cells and hydrogel during osteogenic differentiation. The FIB milling allows for observation the cellular interior with minimal invasiveness during sample preparation. Additionally, this device also allows for evaluation of changes in hydrogel's structure after osteogenic differentiation.

EXPERIMENTAL METHODS

Bone marrow- and adipose tissue-derived stem cells isolated from rat were encapsulated in 2% calcium alginate and put into the osteogenic culture conditions for 3 weeks. After culturing, samples were fixed in glutaraldehyde, dehydrated in acetone row, dried using critical point drying, and put for FIB milling and SEM observations, using Auriga 60 (Zeiss).

RESULTS AND DISCUSSION

Observations showed significant differences in both cellular and material's morphology between osteogenic-differentiated (OG) and non-differentiated (non-OG) specimens. In OG group, cells were arranged in groups and created cellular cavities within the calcium alginate. Cells showed high microvesicle release and were rich in lamellipodia (figure 1A). In non-OG group cells were arranged more individually, and did not create cavity, rather were embedded in alginate (figure 1B). Calcium alginate after osteogenic differentiation was rearranged, with decreased porosity and visible structures between fibres, probably the bone-like ECM synthesized by cells during osteogenic differentiation (figure 1C). In alginate from non-OG group, the alginate fibres were arranged regularly, with visible pores and no ECM-like features deposited by encapsulated cells (figure 1D).

Figure 1. Morphology of cells in calcium alginate after osteogenic differentiation (A), and without osteogenic differentiation (B). The morphology of calcium alginate from osteogenic (C) and non-osteogenic (D) conditions.

CONCLUSION

We showed that focused ion beam combined with scanning electron microscope constitutes an excellent tool for evaluation of hydrogels with encapsulated cells during various bio-assays.

High Throughput Production and Analysis of Tissue Engineering Scaffolds prepared using Combinatorial Chemistry

Erwin Zant¹, Maarten M. Blokzijl¹, Dirk W. Grijpma^{1,2}

¹ Department of Biomaterials Science and Technology, University of Twente, The Netherlands, e.zant@utwente.nl

² Department of Biomedical Engineering, University Medical Centre Groningen, The Netherlands

INTRODUCTION

The current high throughput (HT) production of 3D scaffolds is limited to gradients of just two polymers at a time¹. A straightforward method involving thermally induced phase separation of polymer solutions inducing crystallization of the solvent allows the very fast production of porous structures². Mixing low molecular weight macromers and subsequent photo-crosslinking can produce huge libraries of different materials³. Furthermore, a newly developed HT mechanical screening (HTMS) device can assess the mechanical properties of multiple samples simultaneously⁴. Here a combination of a new HT scaffold production technique and HT screening method was evaluated. Poly(trimethylene carbonate-dimethacrylate), poly(D,L-lactide-dimethacrylate) and poly(ethylene glycol-dimethacrylate) macromers solutions in ethylene carbonate (EC) were combined to eventually fabricate 63 scaffolds with highly diverging mechanical properties. The compression moduli of wet scaffolds were measured in both a conventional and the novel HT fashion.

EXPERIMENTAL METHODS

Linear trimethylene carbonate (TMC) and D,L-lactide (DLA) based oligomers were synthesized by ring opening polymerization. These oligomers and polyethylene glycol (PEG) were functionalized using methacrylic anhydride to form methacrylate end-functionalized macromers. Six different macromers with molecular weights of 4 and 10 kg/mol were obtained. HT fabrication of scaffolds was performed by mixing the macromers (25 wt.%) in EC in 63 different combinations, solvent crystallization at 21°C, 20 minutes of photo-crosslinking at 365 nm and solvent extraction in water. Irgacure® 2959 was used as photoinitiator (1 wt.% to macromer). The samples were dried and swollen in distilled water for 48h. Compression tests were performed on a Zwick Z100 (single sample) and on the HTMS device. Compression modulus (E_{comp}) was recorded at 8% compression on the tensile tester and equilibrium modulus was measured on the HTMS device⁴.

RESULTS AND DISCUSSION

Mixing the macromers PTMC-dMA 4k, PTMC-dMA 10k, PDLLA-dMA 4k, PDLLA 10k, PEG-dMA 4k and PEG-dMA 10k in EC yielded 63 combinatorial scaffolds with comparable morphologies, an example is shown in figure 1. Overall, the obtained scaffolds were 50 vol.% porous and the pores were of hexagonal shape. Scaffolds with extremely varying water uptakes (1-1700 wt.%) and compression moduli (0,01-60MPa). The compression moduli were recorded using a (conventional) single sample test method and the

HTMS device. Results for the scaffolds ($E_{comp} < 1\text{MPa}$) are presented in figure 2.

Figure 1: Scanning electron micrograph of a scaffold produced from PTMC-dMA 10k

Figure 2: Comparison of E_{comp} between single sample testing and HTMS of wet scaffolds.

CONCLUSION

A new HT approach was successfully applied to produce numerous scaffolds hugely varying in hydrophilicity and mechanical properties. Furthermore, a new HT mechanical device was assessed showing a linear relation to conventional tests.

Relationship between physical properties and biological response in tyrosine-derived polyarylates explored by association rules

Daniela C. Soto¹ and Loreto M. Valenzuela^{1,2*}

¹Department of Chemical and Bioprocess Engineering, Pontificia Universidad Católica de Chile, Chile

² Research Center for Nanotechnology and Advanced Materials “CIEN-UC”, Pontificia Universidad Católica de Chile, Santiago, Chile *lvalenzr@ing.puc.cl

INTRODUCTION

Polymers are widely used in several medical applications, from degradable scaffolds to drug delivery systems. Nowadays the focus is to design polymers with specific properties for each application¹. To achieve this goal, it is necessary to find relationships between polymer chemistry and properties (glass transition temperature (T_g) and air-water contact angle), polymer response in physiological environment (degradation, erosion and water uptake) and biological response of the host (protein adsorption and cell adhesion-proliferation).

Combinatorial chemistry has enabled the generation of polymer libraries¹. Several techniques have been used to build discrete² and numerical^{3,4} models for some of these polymer libraries. These studies only correlate the physical properties and chemical structure of polymers with protein adsorption or cell response separately. In this study, we used association rules to find relevant patterns between all of these properties on the L-tyrosine derived polyarylates library. Knowing these relationships would guide future experimental research, making easier to find polymers with desired properties.

EXPERIMENTAL METHODS

We used a polymer library of 112 polyarylates created by Kohn and coworkers⁵. The information available include T_g and water-air contact angle for all polymers of this library⁶, half degradation time for 23 of them, water uptake equilibrium (WU_{eq}) for 19⁷, fibrinogen adsorption for 45⁸, albumin adsorption for 41, normalized metabolic activity of rat lung fibroblast (RLF) for 69, and human normal foreskin fibroblast (NFF) for 94 of them². Only 5 polymers are fully characterized in terms of these properties.

Association rules were used to find patterns in the dataset, which was discretized using EM clustering⁹. This methodology recognizes when certain conditions occurred simultaneously. We set the minimum support as 10% or 8% (i.e., a rule must contain a pattern present at least in 10% or 8% of the polymers, respectively), and the confidence as 90% (i.e., the presence of certain condition(s) imply the presence of other condition(s) in at least 90% of the cases). The data-mining package WEKA (Waikato Environment for Knowledge Analysis) was used in this study¹⁰.

RESULTS AND DISCUSSION

The use of support of 10% corresponds to the most strict analysis, where for each rule at least 12 polymers must fulfill it. With this criterion, the value of T_g is

inverse to the one of contact angle, as observed previously⁶. Earlier, Abramson et al.² observed a strong relationship between T_g and RLF growth, which was observed in our study as well. They observed that higher values of T_g were correlated with higher values of NFF growth. However, our study suggests that with high T_g it is also required a high value of fibrinogen adsorption in order to have high NFF growth.

With a less restrictive analysis, considering a support of 8% (i.e., 10 polymers for each rule), we observed that higher values of NFF growth are related with lower values of half degradation time (i.e., faster degradation). This relationship is important because the growth of NFF was obtained after only few hours of incubation, while degradation was followed through time up to several months.

With our restrictions on the association rules, we did not find any relevant correlation between water uptake and other properties. We think that more data will be needed to build rules including this property.

CONCLUSION

There are relationships between different properties of a set of polymers, which can be explored through association analysis. Filtering relevant rules is the most challenging task in this methodology. Having the complete set of experimental values for all polymers, or a prediction of them, will allow more and better association rules that will in turn allow a better selection of polymers for different applications.

A novel application of LDI-MS (Laser Desorption/Ionisation-Mass Spectrometry) for the direct identification of functionalised compounds containing groups such as -COOH, -OH, and -C(O)H on the oxygen plasma treated parylene C surface is proposed. Such a modification is crucial from the medical point of view because it leads to higher hydrophilicity, and provides adhesion centres and further determines the bond strength between the cells and polymer surface. As a result, the polymer material is transformed into a highly valuable finished biomimetic interface.

INTRODUCTION

Parylene C is an excellent protective coating material for metal implants due to its *in vivo* compatibility, mechanical properties and stability in body fluids^{1,2,3}. It is not only corrosion resistant, but it substantially decreases the release of hazardous metal ions from metal implants into the body. However, for good attachment of cells and/or drug-loaded biodegradable polymers, their surface must be adjusted via introduction of functional groups, which are tangible adsorption sites. Taking that into consideration, there is a strong need for surface modification methods, which can transform popular materials into highly valuable final products. Low pressure plasmas are considered one of the universal options for such surface treatment, where the chemical structure of a top polymer layer can be tailored⁴. By adjustment of the plasma parameters the modification is confined to a shallow surface layer (~10 nm) of the polymer. The final polymeric material is uniformly modified over the whole surface. In this study, we investigated what kinds of oxygen containing groups are generated on the parylene C surface upon oxygen plasma treatment (Fig.1).

Fig. 1 The schematic representation of the experimental methodology.

EXPERIMENTAL METHODS

Parylene C (8 µm of thickness) films were prepared by CVD technique. The samples were provided by ParaTech Coating Scandinavia AB. In order to modify the parylene C surface, the oxygen plasma treatment

was carried out using a Diener electronic Femto plasma system (Diener Electronic GmbH, Nagold, Germany). The surface analysis of unmodified and oxygen plasma treated parylene C was performed on a Bruker UltraFlex time-of-flight (TOF) mass spectrometer with a SCOUT-MTP ion source (Bruker Daltonics, Bremen, Germany) in reflector mode and equipped with a 337 nm nitrogen laser.

RESULTS AND DISCUSSION

The LDI-MS analysis revealed that insertion of oxygen to the polymer backbone took place exclusively in the linker between the aromatic rings of the polymer chain. This is important for keeping the stable crystalline structure of parylene C, which prevents extensive penetration of the oxygen active species into the bulk during plasma treatment. Additional confirmation of stability of aromatic rings with chlorine substituent is provided by characteristic splitting of the main line of 2 m/z due to the presence of the natural abundance of ³⁵Cl and ³⁷Cl isotope. Moreover, the LDI-MS method allows for direct identification of the groups -COOH, -OH, and -C(O)H in functionalised polymer.

CONCLUSION

We demonstrate that the mild oxygen plasma technology provides a direct route for facile engineering of polymeric biointerface. The LDI-MS method provided a direct way to analyse the oxygen containing functional groups and their speciation formed on the parylene C surface, as well as their location in the polymer chain. Thus, LDI-MS was shown to be a versatile and powerful tool for direct characterisation of modified surfaces.

Controlled Drug Delivery From Bioresorbable Magnesium Orthopaedic Implants

Jessica A. Lyndon¹ and Ben J. Boyd², Nick Birbilis¹

¹Department of Materials Engineering, Monash University, Australia

²Monash Institute of Pharmaceutical Sciences, Monash University, Australia, jess.lyndon@monash.edu

INTRODUCTION

Bioresorbable implants challenge the paradigm of permanent metallic implants where the implant can support and facilitate the remediation of dysfunction in bone trauma. Magnesium is a standout material for degradable implants as it is non-toxic, biocompatible, biodegradable and has mechanical properties similar to bone. Furthermore the degradation rate of magnesium can be fine-tuned by altering its composition¹. Degradable implants are advantageous over traditional permanent implants and present the possibility to utilise the implant as it corrodes as a local drug delivery system. If resorbable magnesium implants can be exploited to deliver pharmaceutical agents they can provide drug delivery to the implantation site with many benefits over systematic drug delivery. This paper outlines the proof of concept study in order to determine the drug release kinetics using a degradable magnesium drug/device system.

EXPERIMENTAL METHODS

Materials

Samples comprised of high purity magnesium, were wire cut to 20 mm in length, 5 mm in width and 5 mm in depth. 9 holes 1 mm in diameter were drilled 2 mm apart and filled with powdered ibuprofen sodium salt (Sigma Aldrich). One side of the sample was exposed by polishing to 1200 grit with ethanol.

Figure 1: a) Epoxy mounted magnesium sample and b) magnesium surface before immersion in MEM.

Solutions

Experiments were carried out in Minimum Essential Media (MEM, Life Technologies) with 2.2 g/L sodium bicarbonate (Sigma Aldrich) buffer.

Ibuprofen Calibration Curve

1 mg/mL ibuprofen sodium salt was dissolved in MEM and characterised by UV-Vis spectroscopy (EnSpire Multimode Plate Reader, Perkin Elmer). When a typical absorption wavelength was found, known concentrations of ibuprofen were analysed at the typical wavelength and the intensity measured to generate a linear calibration curve.

Drug Release Study

Mass loss tests were conducted in 200 mL of MEM in a carbon dioxide atmosphere at 37 °C using a CO₂ Incubator (Sanyo MCO-15AC). Every 2 days 1.5 mL of the solution was frozen for UV-vis analysis, the depth

of degradation (as a measure of corrosion rate) and pH of solution were recorded and the solution replenished.

RESULTS AND DISCUSSION

Calibration Curve

The calibration curve generated in Figure 3 was used to determine the amount of ibuprofen present in the drug release study solutions.

Figure 2: UV-Vis spectrum of 1 mg/mL ibuprofen sodium salt in MEM.

Figure 3: Calibration curve of ibuprofen sodium salt in MEM. Inset: data presented in log scale.

Drug Release Study

Initial results suggest that the ibuprofen is released when the degradation of the magnesium sample reaches the drug filled reservoir, as highlighted by the empty reservoir in Figure 4.

Figure 4: Surface of magnesium sample after 10 days in the incubator.

CONCLUSION

This pilot study indicates the promise of degradable magnesium orthopaedic implants as drug delivery devices.

Effect of Different Crosslinking Treatments on the Physical Properties of Collagen-based Scaffolds

Luca Salvatore¹, Deborah Pedone^{1,2*}, Emanuela Calò¹, Valentina Bonfrate¹, Marta Madaghiele¹

¹Department of Engineering for Innovation, University of Salento, Italy

^{2*}Dhitech Scarl – Distretto Tecnologico High Tech, Lecce, Italy, deborah.pedone@dhitech.it

INTRODUCTION

Collagen-based materials are widely used in the biomedical field due to their excellent biocompatibility and low antigenicity. In tissue engineering, collagen substrates are well known to modulate various aspects of cell behaviour like adhesion, proliferation and differentiation. However, major drawbacks such as rapid degradation and poor mechanical properties limit the number of possible applications¹. Collagen crosslinking and/or blending with other materials can be effective methods to overcome these constraints. The aim of this work was to investigate the influence of several crosslinking treatments on the physical properties of collagen-based scaffolds. Five different crosslinking agents (*i.e.* carbodiimide (EDC), glutaraldehyde (GTA), formaldehyde (FA), genipin (GP) and dimethyl suberimidate (DMS)) were selected to crosslink collagen following a standard dehydrothermal (DHT) treatment. The scaffolds were then assessed for swelling ratio, primary amine group content, denaturation temperature, dynamic mechanical properties and resistance against collagenase digestion. Preliminary cytotoxicity tests were also performed.

EXPERIMENTAL METHODS

Scaffold synthesis. An aqueous suspension of 3% w/v Type I collagen from bovine dermis was prepared by mixing for 5-6 hours at 10°C. Following casting and freeze-drying, porous collagen-based matrices were obtained. Several crosslinking treatments were performed (Table 1), according to established protocols¹⁻³. The matrices were then stored in phosphate buffered saline (PBS) at 4°C until further analyses.

Characterization experiments. Swelling ratio was determined through gravimetric measurements on dry and swollen matrices. The concentration of free primary amine groups (-NH₂) was determined using 2,4,6-trinitrobenzenesulfonic acid (TNBS) assay. Differential scanning calorimetry (DSC) was employed to measure the denaturation temperature (T_d) of the scaffolds. The shear modulus G of denatured samples was assessed by means of dynamic mechanical analysis (DMA) and used to estimate the elastically effective crosslink density (ρ_{xe}), according to the rubber elasticity theory⁴. The resistance to enzymatic degradation was evaluated *in vitro*, by incubating the scaffolds in bacterial collagenase solution at 37°C. The cytotoxicity of the matrices was assessed *in vitro* using a rat Schwann cell line (RSC96), by means of MTT assay. Statistical significance was determined using one-way ANOVA and Fisher's PLSD test (n=5).

RESULTS AND DISCUSSION

As expected, the crosslinking treatment was found to have a significant impact on the physical properties of

the collagen matrices. Higher values of the crosslink density, attained by the different treatments, were found to increase the shear modulus of the scaffolds (Table 1), while decreasing the *in vitro* degradation rate and the swelling capability. A good correlation between the elastically effective crosslink density and the inverse of free amine group content was detected. The thermal stability of collagen appeared to be more dependent on the specific crosslinking agent used, rather than the yielded crosslink density. Indeed, in spite of the large differences in ρ_{xe} , samples treated with GTA and DMS, which are crosslinking agents incorporated in the collagen network, showed a similar T_d value, while the highest T_d was attained by samples treated with EDC, which is conversely a 'zero-length' crosslinker. The preliminary MTT assay seemed to suggest that DMS was the least cytotoxic crosslinking agent among those tested. No significant difference in cell viability was detected between control cells and DHT samples.

Crosslink treatment	G (kPa)	ρ_{xe} (10 ⁻⁵ mol/cm ³)	NH ₂ (10 ⁵ mol/g)	T _d (°C)
None	/	/	5.6±0.7	36.9±0.9
DHT	10.0±0.4	1.2±0.0	5.4±0.1	37.4±0.5
DHT+GP	14.3±3.5	1.9±0.5	5.3±0.1	37.5±0.1
DHT+DMS	21.1±4.2	2.6±0.5	3.6±0.5	48.7±2.6
DHT+EDC	36.6±2.8	4.3±0.3	2.7±0.0	58.4±0.7
DHT+GTA	49.8±0.7	6.0±0.1	2.4±0.0	47.0±1.2
DHT+FA	52.7±0.9	5.9±0.1	2.3±0.1	50.4±0.6

Table 1. Summary of data obtained from DMA, TNBS assay and DSC (n=5).

CONCLUSION

The data obtained in this study provide further evidence that proper choice of the crosslinking agent and accurate control of the crosslinking treatment are fundamental for finely tuning the physical properties of collagen-based scaffolds, in order to tailor selected *in vitro* and/or *in vivo* applications.

Degradation and mechanical properties of biodegradable PLGA film

Reyhaneh Neghabat Shirazi^{1,2}, Yury Rochev², Peter McHugh¹

¹Mechanical and Biomedical Engineering, College of Engineering and Informatics, NUI Galway

²National Centre for Biomedical Engineering Science, NUI Galway, Ireland

r.neghabatshirazi1@nuigalway.ie

INTRODUCTION

Poly (lactic-co-glycolic) acid (PLGA) is a degradable polymer which is used for a variety of medical implant applications, including orthopaedic fracture fixation or as a coating for drug eluting stents¹. PLGA degradation is due to simple hydrolysis of the ester backbone in aqueous media. Depending on the application, the biodegradable implant can be subjected to different load and stress conditions, which may cause mechanical failure of the material. Hence the mechanical properties of the polymer during degradation are important to know to guide implant design. The specific aims of this work are to prepare a PLGA film and to characterise physical and mechanical properties of the film during the degradation.

EXPERIMENTAL METHODS

A 0.2 g mol⁻¹ solution of PLGA (50:50, $M_n=82$ kg mol⁻¹) in chloroform was prepared and casted onto a Petri dish. The samples were dried in vacuum desiccators for a week. All the films were of the same thickness (0.25 ± 0.04 mm). The specimens were placed in PBS (pH 7.4, 37°C) and characterized during degradation for water content, mass loss, average molecular weight (using GPC), crystallinity (using XRD), glycolic and lactic unit content (using FTIR) and were imaged using optical microscopy. Mechanical properties of the films were determined using nano-hardness testing with a Berkovich diamond tip over three different indentation loads. Values for Young's modulus and hardness determined based on Oliver and Pharr procedure².

RESULTS AND DISCUSSION

Figure 1 illustrates the indentation hardness and Young's modulus values of the films over three different indentation loads versus the molecular weight. As shown in Figure 1(a), the surface hardness reduced in the initial days of degradation suggesting that water acts as a plasticiser which results in reducing the yield strength of the film. Significant fluctuation in hardness value appeared during the degradation due to the high amount of surface roughness observed by optical microscopy. After a critical molecular weight (8 kg mol⁻¹), the value of hardness decreased significantly and reached less than 10 MPa.

As shown in Figure 1(b) a significant difference in Young's modulus value observed for different indentation loads due to the viscoelasticity of the film. Measurements of modulus using nanoindentation tended to increase with decreasing the applied load. The Young's modulus value from conventional tensile test (3.5 ± 0.2 GPa) for non-degraded film was found to be fairly close to the value obtained from nanoindentation

for 7 mN load. For the initial days of degradation the values of modulus remained constant. Following the degradation, it can be seen that the decrease in modulus showed down and it reduced to 0.3 GPa. All different loads showed nearly the same trend during the degradation.

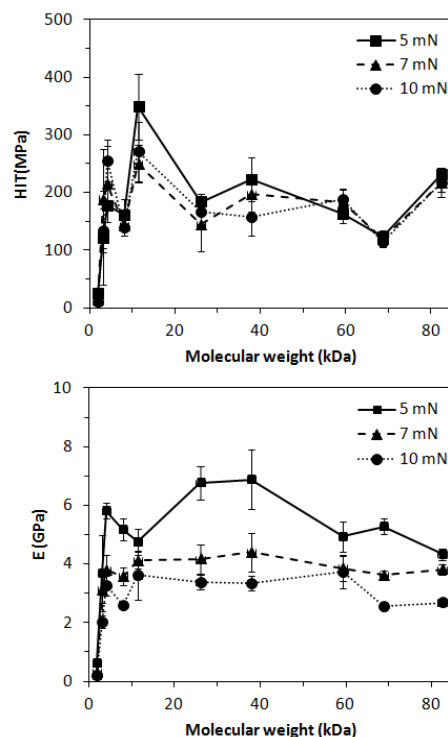

Figure 1: (a) Indentation hardness (b) Young's modulus of PLGA films over three different indentation loads versus the molecular weight (Mean \pm STDEV; n=10).

CONCLUSION

After a critical molecular weight, due to the significant degradation, the surface hardness and the Young's modulus of the films dramatically decreases and reduced to 16% and 10% of the initial values for non-degraded film, respectively. This information can be used to predict changes in the mechanical performance and degradation of PLGA film which is very useful to guide the design of biodegradable coatings.

Temporal Analysis of Dissolution By-Products and Genotoxic Potential of Spherical Zn-Si Bioglass: “Imageable beads” for Transarterial Embolization

Muhammad Sami (Hasan)¹, Sharon (Kehoe)² and Daniel (Boyd)^{1,2}

¹. Department of Applied Oral Sciences, School of Biomedical Engineering, Dalhousie University, Halifax, NS, Canada

². ABK Biomedical Inc. 1344 Summer Street Suite 212 Halifax, NS B3H 0A8 Canada. <mailto:sami.hasan@dal.ca>

INTRODUCTION

Transarterial embolization of vascular tumors is frequently performed using particles as the principal embolic agent and regarded as an effective procedure, capable of eliminating the vascular supply to target tissues such as uterine leiomyomas and hepatocellular carcinomas. Radiopacity, durability and sphericity are three key parameters for an effective embolic agent [1]. Intrinsic radiopacity obviates the need of a contrast reagent and allows the radiologist to monitor spatial distribution of the particles. Sphericity allows a precise size classification and optimal and predictable vessel embolization. Yet, radiopaque spherical particles remain to be developed for clinical use. The current study produced radiopaque glass microspheres in a broad size range (45–500µm) and investigated the degradation by-products and their contingent genotoxic effect.

EXPERIMENTAL METHODS

Glass microspheres, comprising of three particle size ranges (45-150, 150-300, 300-500µm) with narrow size distributions were produced using a flame spherodization process. Digesting the glass microspheres in mineral acids and detecting the constituent ions using ICP-AES verified the composition of the glass post-synthesis. The authors confirmed the radiopacity of the glass microspheres previously, using X-ray and axial CT scans for microspheres suspended in either PBS or filled in a glass vial. The ion release (Si^{4+} , Na^+ , Ca^{2+} , Zn^{2+} , Ti^{4+} , La^{3+} , Sr^{2+} , Mg^{2+} and Zn^{2+}) from sterilized and non-sterilized glass microspheres were immersed and incubated in sterile tissue culture water and DMSO at 37°C, and quantified using ICP-AES over extended time periods (up to 30d). The effects of surface area as well as polar and non-polar media on the ion release profiles were explored. The effect of dissolution by-products on the bacterial gene expression was also investigated using the *in vitro* Ames assay, with extracts prepared at accelerated leaching conditions at 50°C over 72h. Quantities of the subsequent leachates were further investigated for the effect of various ions and their quantities on bacterial mutation. Finally, the results were correlated with previously reported ion release profiles from irregular shaped particles of the same glass formulation (up to 120h) [2].

RESULTS AND DISCUSSION

Radiopaque, non-degradable and non-deformable spherical glass particles were produced in various particle size ranges from 45 to 500µm (Fig 1). Ions released (Fig 2) from the microspheres were dependent upon surface area to volume ratio as well as the nature of elution media. Greater ions were released from the 45-150µm-particle size range owing to its largest surface area to volume ratio (*in polar medium*). For the genotoxic bacterial reverse mutation Ames-assay, the

concentrations of all the ions were well below their therapeutic concentration reported in the literature. No mutagenic effect was observed in the bacterial reverse mutation Ames test (Fig 2).

Fig 1. SEM micrographs of various sized glass microspheres.

Fig 2. Representative graphs from Ion release (left) and genotoxicity (right) evaluations

CONCLUSION

Radiopaque glass microspheres (45-500µm) were successfully produced using the flame spherodization technique. However, larger particles were found difficult to spherodize using current setup. Approximately 80-95% of Gaussian distribution can be achieved by simple sieving. The ions released from the microspheres were dependent upon surface area to volume ratio as well as the nature of elution media. As expected, greater ions were released from the smaller particle size ranges in polar medium. However, concentrations for all ions were reported well below the therapeutic concentration reported in the literature. Most significantly, this is reflected in their benignity as observed in bacterial reverse mutation Ames test. Hence, it can be concluded that the glass microspheres produced in this study provide a non-mutagenic and safe choice for use as a potential embolic agent.

A modular flow-chamber bioreactor as a tool for the analysis of degradable materials

Frank Feyerabend¹, Ralf Pörtner² and Regine Willumeit¹

¹Institute of Materials Research, Helmholtz-Zentrum Geesthacht, Germany, frank.feyerabend@hzg.de

²Institute for Bioprocess and Biosystems Engineering, Technical University Hamburg Harburg, Germany

INTRODUCTION

Bioreactors are widely used for 3D-tissue engineering purposes in different setups. Animal trials have to be replaced by cell culture assays, preferably by test systems with human material. This is especially true for biodegradable materials, in this case magnesium and its alloys. Here it is known that there is a discrepancy between observations *in vitro* compared to *in vivo*¹. Dealing with orthopaedic applications of the materials the next challenge is that there is not much known about the flow regime in bone, however it should be much lower than for e.g. vascular applications.

The aim of this feasibility study therefore was to develop a modular bioreactor system applicable for (I) material screening purposes and (II) implant prototype analysis. This system should be operated under cell culture conditions, cover a range of low flow conditions and it should be possible to vary the environmental conditions to approach the physiological conditions comparable to *in vivo*. Advantages of this reactor concept can be seen in removal of toxic reaction products, high cell densities, and improved metabolism². Specifically for degradation studies it should moreover reduce the local effects of high pH, osmolality and H₂-production.

EXPERIMENTAL METHODS

The environmental control was established by placing a custom made cell culture environment with highly precise CO₂ and O₂-regulation (C-Chamber system, Biospherix Ltd., US) in an incubator for temperature regulation (INE 600, Memmert, Germany).

Two designs are available (Fig.1): (I) A 24-well plate-based modular bioreactor (Medorex, Nörten-Hardenberg, Germany) for the analysis of 4 samples per row and (II) a modified version for the analysis of one prototype per row (maximum dimensions of prototypes: 8 cm length, 1 cm width). This bioreactor chamber has the option to install vessel-like structures by additional in- and outlets. Gas supply is granted via surface aeration directly in the chamber, medium supply is done by a circulation loop from reservoir bottles via peristaltic pumps.

RESULTS AND DISCUSSION

The whole system is fully autoclavable. The assembly can be performed under sterile conditions and the whole system afterwards be transferred to the cell culture environment. First experiments could demonstrate that the system could be kept sterile for more than 14 days. Due to the use of 4-channel peristaltic pumps it is possible to analyse two different flow rates at the same time with statistically relevant amount of samples

(n=8). Currently first degradation experiments of magnesium-silver alloys at flow rates up to 1 mL/min are performed. Additionally, a simulation of the flow conditions in this system is under way.

Fig. 1: The two designs of the modular flow chamber applied in this study

CONCLUSION

The introduction of flow should bring *in vitro* observations closer to *in vivo*. Due to the modularity of the system it is not only suitable for degradation studies, but also for the application of various cell models during degradation.

Use of a PTMC-PEG-PTMC coated PTMC film as a postoperative adhesion barrier

Vincent Verdoold^{1,2,*}, Ruben R.M. Vogels³, Kevin W.Y. van Barneveld³, Nicole D. Bouvy³ and Dirk W. Grijpma^{1,4}

³Department of General Surgery, Maastricht University Medical Centre, Maastricht, the Netherlands

⁴University of Groningen, University Medical Center, Groningen, Dept. of Biomedical Engineering, the Netherlands

INTRODUCTION In abdominal surgery, the incidence of postoperative adhesions is up to 95%. In these cases, the most severe complications are the result of small bowel obstructions 60-70% [1]. To prevent this, resorbable barrier membranes have been developed [2]. Such membranes are often fixed using sutures, staples and tackers. However, this can lead to additional postoperative adhesions of tissue [3].

Here we present a biocompatible poly(1,3-trimethylene carbonate) (PTMC) film [4], coated with a PTMC-PEG-PTMC tri-block copolymer as a tacky bonding agent for initial fixation of the PTMC film, as a novel postoperative adhesion barrier.

EXPERIMENTAL 1,3-Trimethylene carbonate (TMC, Foryou Medical), poly(ethylene glycol) (PEG) with Mn 3000 g/mol and stannous octoate (Sigma Aldrich) were used as received.

PTMC with an Mn of 250 kg/mol was prepared by ring opening polymerization of TMC using stannous octoate as catalyst at 150°C. The residual TMC content was less than 2 %, the stannous octoate content was less than 100ppm. PTMC films with an average thickness of 200µm were prepared by compression moulding at 160°C without additional purification of the polymer.

A PTMC-PEG-PTMC tri-block copolymer (Mn 1500-3000-1500 g/mol) was prepared by ring opening polymerization of TMC using stannous octoate as catalyst and PEG as initiator. A triblock copolymer film with an average thickness of 175µm was prepared by compression moulding 70°C.

The PTMC film was then coated with PTMC-PEG-PTMC by moulding the films onto each other at 70°C. The coating was applied to either one side or both sides of the PTMC films. The coated films were then sterilized in vacuum by 25 kGy gamma irradiation.

Table 1. Overview of the different experimental groups.

PTMC-PEG-PTMC-coated PTMC film	Orientation of the coating	Experimental group
Single side coated	Coated side faces organs	Organs
Single side coated	Coated side faces abdomen	Abdomen
Both sides coated	Coated sides face organs and abdomen	Double
No PTMC film		Control

The anti-adhesion performance of PTMC films coated with PTMC-PEG-PTMC was assessed in vivo using a validated peritoneal ischemic button model in the rat [5]. A midline incision of approximately 5-6 cm was made, and on each side 3 ischemic buttons were made (1 cm apart and 1 cm from the midline, 6 buttons per rat). To cover the visceral organs, a coated PTMC film

measuring 6x9 cm was implanted in each rat. The extent of adhesion is expressed as the relative number of ischemic buttons to which tissue has adhered.

An overview of the different PTMC-PEG-PTMC-coated PTMC films and the way they were implanted is given in Table 1. Eleven male Wistar rats per experimental group were used.

RESULTS AND DISCUSSION The formation of adhesions to the ischemic buttons was assessed upon termination of the animals after two weeks. The results are shown in Figure 1.

Figure 1. The extent of tissue adhesion after two weeks using PTMC-PEG-PTMC coated PTMC films for the different experimental groups.

All implanted PTMC films resulted in a significant reduction of the number of ischemic buttons to which tissue had adhered. The adhesions that had formed were either to ommental- or to scrotal fat. No adhesions between the buttons and the cecum nor between the cecum and the midline incision were observed.

Upon explantation, no remaining coating was visible on the PTMC films. The coating had transferred to the organs or to the peritoneum, likely contributing to the prevention of the formation of tissue adhesions. For all coated PTMC films, the adhesions formed to the ischemic buttons were approximately only 10%. The adhesions formed in the non-treated control group were significantly higher (approximately 62%). This indicates that use of these physical barriers is beneficial to prevent adhesions.

CONCLUSIONS Using an ischemic button rat model, use of PTMC films coated with PTMC-PEG-PTMC lead to significant decrease in adhesion formation. These novel anti-adhesion barriers could be highly beneficial in the clinic.

Comparison of Sr-substituted Hydroxyapatite Obtained of Various Precursors through Neutralization Reaction: Characterisation at the Bulk and Particle Level

L. Stipniece*, K. Salma-Ancane and L. Berzina-Cimdina

*Institute of General Chemical Engineering, Riga Technical University, Latvia, liga.stipniece@rtu.lv

INTRODUCTION

Hydroxyapatite (HAp) are biocompatible and bioactive and thereby considered to be promising bone replacement material¹⁻⁴. It is known that Sr may replace Ca to form Sr-substituted HAp (Sr-HAp)¹. Sr ions with a radius greater than Ca ions significantly affects the morphology of a synthetic HAp, e.g. reduces the specific surface area (SSA)^{1,2}, low Sr concentrations (up to 25 %) results in the decrease of crystallite size, while higher amount of Sr substitution promotes the increase of HAp crystallite sizes³. Partial substitution of Ca ions with Sr ions greatly enhances the biological properties of HAp⁴. The most popular synthesis methods used to obtain Sr-HAp are wet chemical methods, which have been widely modified by changing the starting materials and technological parameters¹⁻⁴. As far as we know, there have not been published detailed studies cross-referencing the various precursor effects on Sr-HAp products. Thus, the main goal of this work was to synthesize Sr-HAp series through the neutralization reaction, and to evaluate the effect of various precursors on the synthesis product characterization in bulk and particle level.

EXPERIMENTAL METHODS

The HAp powders containing various amounts of Sr were synthesized through neutralization route. Two methods were used. The fundamental difference between these methods is variety in (Ca^{2+}) and (Sr^{2+}) sources. The solution of H_3PO_4 was used as a source of (PO_4^{3-}) in all synthesis. 2M H_3PO_4 was added at a slow addition rate (~ 0.75 ml/min). The stirring speed was 100 rpm, synthesis temperature – 45 °C.

Method A: Starting suspension were prepared by dissolving $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ and/or $\text{Sr}(\text{NO}_3)_2$ in deionised H_2O in various ratios. The pH of the synthesis mixture was kept around 9, using 25% ammonia solution.

Method B: Starting suspensions of $\text{Ca}(\text{OH})_2$ and/or $\text{Sr}(\text{OH})_2$ were prepared of CaO and/or SrO, and deionised H_2O by “lime slaking” process followed by homogenization in planetary ball mill. The pH of the synthesis mixture was adjusted to 9. The ammonia solution was used, if needed.

The precipitate was left overnight to mature, filtered, and washed with deionised H_2O three times if needed. Finally, the precipitate was dried at 105 °C for ~ 24 h and grounded. The obtained powders were uniaxially pressed (10 kN) in cylindrical tablets (\varnothing 10 mm) and sintered in air atmosphere at 1100 °C for 1 h.

Comprehensive characterization techniques were used to investigate the effect of Sr substitution on molecular, phase and chemical composition, crystallite size,

thermal stability, morphology and microstructure of as-synthesized powders and sintered bioceramics.

RESULTS AND DISCUSSION

XRD analysis confirmed the formation of pure apatite phase. In the case of *method A* changes in the crystallite sizes was observed with increasing the added amount of $\text{Sr}(\text{NO}_3)_2$ in the synthesis media, which coincide with the literature data indicating an initial crystallite size reduction followed by a rising with increasing the concentration of Sr in the samples³. However, in the case of *method B*, with the increase of SrO content in the synthesis media, the XRD peaks shift to smaller 2θ values were observed with no change in XRD peak intensities. Afterwards the reduction of crystallite sizes occurred, as indicated by the apatite phase characteristic XRD peaks shift to higher 2θ values, followed by an increase in the crystallite sizes. These results were confirmed by the SSA measurements. The morphology of synthesized powders was similar in the case of all synthesis products. With increasing Sr concentration in the samples, the particles became more elongated.

CONCLUSION

A series of Sr-HAp were successfully synthesized of various precursors by two routes. The results showed that high concentrations of Sr substitution promote destabilization of HAp structure, the disappearance of structural symmetry, and the changes of a phosphate surrounding environment. It is possible to conclude that the use of *method A* can lead to more efficient incorporation of Sr ions into the HAp structure, as the precursors used in the method have high solubility in H_2O that provide efficient interblending of them. The main disadvantage of the *method A* is the need for usage of ammonia solution to ensure alkaline pH. Thus, comparing the two methods, it can be concluded that the main advantage of *method B* is simplicity.

Hybrid Multi-layered Coatings for Surface Functionalization of Magnesium alloys for biomedical applications

Laura Córdoba^{1,2}, Christophe Hélar², Thibaud Coradin², Fátima Montemor¹

¹ICEMS/DEQ, Instituto Superior Técnico, Technical University of Lisbon, Av. Rovisco Pais, 1049-001 Lisboa, Portugal

²UPMC Univ Paris 06, CNRS, Chimie de la Matière Condensée de Paris, Collège de France, 11 place Marcelin Berthelot, F-75005 Paris, France, laura.cordoba_roman@etu.upmc.fr

INTRODUCTION

Magnesium alloys have attracted great attention as a new kind of temporary biodegradable implants¹. Their rapid corrosion rate can be taken as an advantage provided that an accurate control and knowledge of their degradation process can be achieved. In addition, the bioactivity of the implant surface is a major issue to be considered. An interesting strategy relies on the design of coatings that are able to slow down the corrosion rate while favoring cell adhesion and proliferation². In the present work a hybrid multi-layered coating was developed and applied to AZ31 and ZE41 commercial alloys, showing promising properties towards the safe application of Mg-based materials as biodegradable implants.

EXPERIMENTAL METHODS

AZ31 and ZE41 substrates (discs Ø25.4 mm x 3 mm thick) were prepared by mechanical polishing up to 1000 SiC grit paper and pre-treated with 12% HF solution for 15 min. A multi-layered coating was applied in two steps: (1) a bottom sol-gel layer composed of 3-glycidoxypyrrol-aminomethane (GPTMS) and titanium (IV) isopropoxide (TIP); (2) and a top layer of type I collagen deposited under acidic conditions. For the morphological characterization scanning electron microscope (SEM) and atomic force microscope (AFM) were used.

Electrochemical impedance spectroscopy (EIS) tests in simulated body fluid (SBF) were used to characterize the corrosion behaviour of the sol-gel coated alloys.

To evaluate the cell behaviour, fibroblasts in DMEM medium were seeded onto bare and coated samples. In particular, alloyS (alloy + sol-gel, e.g. AZ31S) and alloySC (alloy + sol-gel + collagen) were evaluated. The cells were cultured during 3 days at 37°C and 5% CO₂ and characterized for viability/proliferation by the alamarBlue® assay at 1 and 3 days.

RESULTS AND DISCUSSION

After optimization of the GPTMS:TIP ratio, an homogeneous crack-free sol-gel layer 3 µm-thick could be deposited on both alloys. After implementation of the collagen thin film deposition process³ an additional 1 µm-thick structured protein layer could be achieved. The sol-gel coating was found to efficiently protect the alloys against corrosion over two weeks, with a better resistive behavior towards ZE41 than AZ31 once the surface under the coating is exposed to the solution. Preliminary results suggest that fibroblasts can adhere on the sol-gel coated samples but exhibit low

proliferation rates afterwards. Moreover compared to the control, cell growth was confined on specific locations of the surface rather than homogeneously spread. This was independent on the composition of the alloy and was also observed for sol-gel coated glass substrates.

Fig. 1. AFM images of (a) ZE41S and (b) ZE41SC and microscopic images of fibroblasts attached on day 3 to (c) control, (d) sol-gel on glass substrate, (e) and (f) ZE41S (magnification 10X).

CONCLUSION

Our result show that coating Mg alloys with sol-gel formulations provide an efficient way to slow down their corrosion process without detrimental impact on fibroblast viability. However, cell proliferation is not favored. In this context, the successful subsequent coating by collagen should allow to overcome this issue and to extend our experiments to other relevant cells, such as osteoblasts.

Degradation in the Jar: Optimising the *in vitro* enzymatic degradation of collagen-based devices

Ayelén L. Helling¹, Eleni Tsekoura¹, Gerard Wall^{1,2}, Yves Bayon³, Abhay Pandit¹, Dimitrios Zeugolis¹

¹ Network of Excellence for Functional Biomaterials (NFB), National University of Ireland Galway (NUI Galway), Galway, Ireland; ²Department of Microbiology, NUI Galway, Galway, Ireland; ³Sofradim Production, Covidien, Trevoux Cedex, France, dimitrios.zeugolis@nuigalway.ie

INTRODUCTION

Collagen-based materials, used in soft tissue repair, are naturally degraded in the body by the complementary action of proteolytic enzymes¹, primarily MMP-1 and MMP-8, which are commonly encountered during physiological wound healing². However, customarily *in vitro* degradation assays, the composition of the device and the target host microenvironment are not taken into consideration, frequently resulting in overestimation of the device self-life. Herein, we aim to develop a collagen-based devices specific *in vitro* assay that would most closely imitate the *in vivo* degradation.

EXPERIMENTAL METHODS

Commercially available tissue grafts (fig.1) derived from porcine skin [PermacolTM (Covidien), non-cross-linked PermacolTM (Covidien) and StratticeTM (Life Cell)] were subjected to enzymatic degradation using MMP-1 (Sigma C0130) and MMP-8 (Invitrogen 17101015). The degradation assays were performed under three concentrations of each enzyme (50, 100 and 200 U/ml) and two pH values (5.5 and 7.4) at 3, 6, 9, 12 and 24 hours. The extent of degradation was assessed by visual inspection (fig 2); weight loss (table 1); hydroxyproline assay; and differential scanning calorimetry (DSC) (Table 3). Analysis are performed using statistical software MINITABTM, Minitab, Inc., State College PA.

RESULTS AND DISCUSSION

Fig 1. Environmental scanning electron microscope ESEM images of PermacolTM, non-cross-linked PermacolTM and StratticeTM surfaces before degradation.

Fig 2. Images of PermacolTM (A: not degraded, B: 24h of degradation), non-cross-linked PermacolTM (C: not degraded, D: 24h) and StratticeTM (F: not degraded, G: 24h).

Table 1. Degradation with MMP-1(A) and MMP-8 (B) of the materials to different time points, 200 U/ml and pH 7.4 using weight loss assays.

Table 2. Denaturation temperature measured with differential scanning calorimetry (DSC) of PermacolTM, non-cross-linked PermacolTM and StratticeTM before degradation and after 3 hours of degradation with MMP-8. (Anova: P<0.05)

The results showed a significant increase in the degradation with the time and with the concentration of the enzyme at pH 7.4. Also, the degradation of non-cross-linked materials is significantly higher than the cross-linked after 24 hours. The degradation temperature of the collagen-based meshes, measured with DSC, significantly decreases after enzymatic degradation.

CONCLUSION

The natural degradation of collagen-based meshes can be recreated *in vitro* in order to predict future results after implantation.

INTRODUCTION

A focus on resorbable bone implants is growing, especially for malleable forms allowing surgeons easier and efficient handling to adjust to each type of defect. Spine fusion and general orthopaedic or maxillo-facial reconstruction need specific galenic shape whose strips, plugs and putties are the most innovative thanks to their handling and dissolution properties. Resorbable biopolymers by enzymatic digestion, such as Chitosan and Collagen, are from major interest¹. Combining these polymeric phases with osteoconductive crystallographic phases offers composite materials with relevant mechanical, resorption (ionic and osteoclastic) and osteoconductive properties². Granules of bioceramics can then be embedded into 3D polymeric matrix, which could be proposed either as a scaffold or as a membrane. In spite of same clinical indications, large differences in the micro-macrostructure of these composite can be observed. This study compares 6 composite samples (plugs, strips) approved in Asia or USA, in terms of physicochemical properties.

EXPERIMENTAL METHODS

Commercially available strips, plugs, 3 from Asia and 3 from US market, (Table 1) were quantitatively analysed in terms of spatial distribution homogeneity of bioceramics granules, bioceramics granules size and both intergranular and intragranular porosity by microtomography (μ -CT). Microstructures visualization was performed by scanning electron microscopy (SEM). Crystallographic phases of embedded bioceramics granules were identified by x-ray diffraction (XRD). Mechanical testing after immersion in physiological solution at 37°C of plugs and strips was performed.

Table 1: Samples analyzed

Sample	Size
Asia Strip1	15 x 50 x 3.5 mm
Asia Strip 2	20 x 20 x 3 mm
Asia Plug 3	Ø8 x 15 mm
USA Strip 1	115 x 75 x 3 mm
USA Strip 2	50 x 30 x 3 mm

RESULTS AND DISCUSSION

All samples were highly porous but only few of the samples have high intragranular macroporosity (Table 2). The smaller the bioceramics granules, the higher their spatial distribution in collagen matrix. But the less macroporous they are. Macropores are considered having a seminal role in bone remodelling as osteoconductive niche³. The association of microporous and macroporous structures is even considered as

potentially osteoinductive⁴. Moreover the total porosity is crucial for body fluids penetration, angiogenesis and cell colonization which provide a quality bone remodelling⁵.

Table 2: Micro-CT characterizations

Sample	Granules size (mm) / Homogeneity of spatial distribution (Coefficient of Variation)	Granules Volume ratio / Macropores presence
Asia Strip1	0.43 / 20%	22% / Medium
Asia Strip 2	0.42 / 35%	7% / Low
Asia Plug 3	0.34 / 38%	8% / Low
USA Strip 1	0.20 / 12%	26% / None
USA Strip 2	0.40 / 45%	27% / Medium
USA Strip 3	0.45 / 18%	25% / High

Although the finality of plugs and strips analysed is the same, that is to say, the bone filling, it is clear that the physicochemical and mechanical properties are various between the different commercial samples. The method of preparing the collagen with crosslinking or not, with prior dissolution (Atelocollagen) or not, leads to totally different properties of malleability, ductility and dissolution kinetics. Embedded synthetic bioceramic granules can be also differ in the volume ratio granules/collagen, nature, with or without macropores, with or without micropores, which will have high impact in terms of efficiency of bone regrowth⁶.

CONCLUSION

It is suitable for surgeons to be aware of these fundamental physicochemical differences necessarily involving different biological responses, bone remodelling efficacy and requiring clinical protocols adapted to each type of bone substitute.

Development of Artificial Stem Cell Microenvironments for Tissue Engineering Applications

Ilida Ortega Asencio¹, Sheila MacNeil², Aileen Crawford¹, Paul Hatton¹, Frederik Claeyssens¹

¹The School of Clinical Dentistry and ²Kroto Research Institute, The University of Sheffield, South Yorkshire, UK,
i.ortega@sheffield.ac.uk

INTRODUCTION

Stem cell niches are well-defined and intricate microenvironments that play an important role in tissue regeneration¹. To date, research has focused on characterising the stem cell niche seeking to recreate both its biochemical environment and its complex morphology. Our aim is advance this work by manufacturing synthetic biomaterial devices containing artificial stem cell niches. These devices have potential for use in the regeneration of soft tissues (such as cornea reported here) and ultimately musculoskeletal tissues such as bone.

EXPERIMENTAL METHODS

Poly (lactide-co-glycolide) (PLGA) microfabricated scaffolds were made using a combination of additive manufacturing techniques (microstereolithography) and electrospinning² (fig.1). Biological evaluation was performed using rabbit limbal tissue and a 3D rabbit cornea model. Cells were characterized using CK3 (differentiation marker) and P63 (stem cell marker).

Figure 1. Schematic of the manufacturing process used for creating the corneal outer rings. The process is based on a combination of techniques. Firstly, additive manufacturing techniques are used for creating a non-degradable mould and, secondly, the underlying surface provided by the mould is replicated using electrospinning.

RESULTS AND DISCUSSION

The inclusion of microfeatures within the constructs affected both epithelial cell migration and morphology. The presence of a population of slow-cycling cells (positive for P63) was identified when tissue explants were cultured inside the pockets and placed on 3D

models (fig.2); this was not observed when using cultured limbal epithelial cells (RLE) suggesting that the enclosed microenvironments and the presence of native stromal cells within the explants play an important role in stem cell maintenance.

Figure 2. 3D Cornea model (a). Wounded cornea showing the absence of epithelium (b). Histology image of tissue engineered cornea using microfabricated scaffolds (c). Electrospun horseshoe-shaped niche containing a tissue explant (d). CK3 staining for cells growing out from a limbal explant (e). P63 staining for cells located in the proximity of a tissue explant (f).

CONCLUSION

This work focuses on the fabrication of novel biomaterial devices containing stem cell microenvironments. We have demonstrated that the presence of microfeatures has a direct effect on migration and directionality, as well as other parameters such as cell morphology and stemness³. The data shown here is based on a soft tissue model (corneal model), but the system is predicted to be adaptable to other tissues including bone.

Fabrication of dispersible nanocrystals of bioceramics via a modified Pechini method under non-stoichiometric condition

Yuko Omori¹, Masahiro Okada^{2*}, Shoji Takeda², Naoyuki Matsumoto¹

¹Graduate School of Dentistry, Department of Orthodontics, Osaka Dental University, Japan

^{2*}Department of Biomaterials, Osaka Dental University, Japan, okada-m@cc.osaka-dent.ac.jp

INTRODUCTION

Hydroxyapatite (HAp; $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$; stoichiometric Ca/P molar ratio of 1.67) is a kind of bioceramics and exhibits excellent cell adhesion because of favorable adsorption capacity of the HAp surface for bioactive substances. The nanoparticle form of HAp has attracted great interests for application as filler materials of cell scaffolds, drug/gene carriers, and coating agents for medical polymers. When low crystallinity HAp nanoparticles, which are generally obtained via a wet chemical process, are calcined to increase thermal and chemical stability, the particles sinter into large agglomerates consisting of polycrystals [1].

Here, we report a modified Pechini method with an initial Ca/P molar ratio greater than 1.67 for the fabrication of dispersible HAp nanocrystals. We hypothesized that the presence of Ca ions in a concentration that exceeded a Ca/P ratio of 1.67 leads to the formation of HAp nanocrystals embedded in CaO matrix and that the nanocrystals can be dispersed at the nanoscale after the CaO matrix is removed (Figure 1b).

EXPERIMENTAL METHODS

After $\text{CH}_3\text{COO})_2\text{Ca}$ and $(\text{NH}_4)_2\text{HPO}_4$ were dissolved in poly(acrylic acid) (PAA) solution in water (initial Ca/P molar ratio: 1.67–13.0), the volume of the solution was reduced on a hot plate at 80°C. The resulting yellowish resin was thermally treated at 1000°C (heating rate, 10°C/min) for 1 h, and then washed centrifugally with NH_4NO_3 aqueous solution until the pH of the aqueous medium decreased to almost 7.0, followed by washing with water three times. The particle morphology, the particle size in liquid media, and the crystal phase of the samples obtained were evaluated using scanning electron microscopy (SEM), laser-diffraction particle size analyzer, and X-ray diffraction (XRD), respectively.

RESULTS AND DISCUSSION

Before the samples were washed, the XRD patterns of each sample indicated the presence of a binary crystalline phase consisting of only HAp and CaO. The HAp wt.% of the product tended to be smaller than the theoretical value calculated from the initial Ca/P ratio,

suggesting that the rate of conversion into HAp decreased because of the lower PO_4^{3-} concentration. After the samples were washed with aqueous media, only a single HAp phase was observed, which indicates that the CaO matrix could be completely removed.

SEM observations revealed that most of the HAp nanocrystals sintered into micron-sized polycrystals in the case of the stoichiometric Ca/P value of 1.67 (Figure 1a). The content of micron-sized polycrystals decreased with increasing initial Ca/P ratio, and almost no polycrystals were observed in the cases where the initial Ca/P molar ratio was greater than 6.67. In higher-magnification images, each crystal exhibited a spherical or polygonal morphology (Figure 1b), and the crystal size decreased with increasing initial Ca/P molar ratio. The crystal size also varied with the thermal treatment temperature and time.

The particle size distribution in aqueous media was also evaluated. As expected, the particle size of powders dispersed in aqueous media decreased with increasing initial Ca/P molar ratio. The number-averaged size of the dispersed particles approximately corresponded to the crystal size measured from SEM images in cases where the initial Ca/P molar ratio was greater than 6.67, which indicates that most of the nanocrystals were dispersed as a single crystal.

CONCLUSION

We showed that the Pechini method under non-stoichiometric conditions led to the formation of binary crystal phases (*i.e.*, HAp and CaO), and high crystallinity bioceramic HAp nanoparticles that can be dispersed in liquid media mostly as single crystals are obtained by dissolving one crystal phase (*i.e.*, CaO). The modified Pechini method described here should be applicable to a wide range of the nanoceramic powders, and have significant benefits over existing technologies, because the methods is facile, inexpensive, and amenable to scale-up and processing.

Titanium with Nanotopography Drives Mesenchymal Stem Cells to Osteoblast Differentiation through miR-4448, -4708 and -4773 Downregulation

R.B. Kato¹, B. Roy², F.S. de Oliveira¹, E.P. Ferraz¹, P.T. de Oliveira¹, M.Q. Hassan², A.L. Rosa¹, M.M. Beloti¹

²Department of Oral and Maxillofacial Surgery, School of Dentistry, University of Alabama at Birmingham, USA
mmbeloti@usp.br

INTRODUCTION

The nanotopography produced by H₂SO₄/H₂O₂ on titanium (Ti) surfaces enhances the osteoblast differentiation of cells grown under both osteogenic and non-osteogenic conditions¹. Considering the demand for novel implant surfaces that may favour the process of osseointegration, it is of relevance to investigate the intracellular mechanisms involved in the osteogenic potential of this nanotopography. As microRNAs (miRs) have recently risen as one of the most important post-transcriptional mechanisms involved in osteogenesis², here, we tested the hypothesis that Ti with nanotopography induces osteoblast differentiation by regulating the expression of miRs.

EXPERIMENTAL METHODS

Human mesenchymal stem cells (hMSCs) were cultured on both Ti with nanotopography and untreated (control) Ti discs under osteogenic conditions for periods of up to 21 days. Osteoblast differentiation was evaluated by real-time PCR to detect the gene expression of runt-related transcription factor 2 (Runx2), alkaline phosphatase (ALP), osteocalcin (OC) and osteopontin (OPN) at day 4, western blot to detect ALP protein at day 17, and alizarin red to stain extracellular matrix mineralization at day 21. At day 4, miR-sequencing analysis was performed and based on the results miR-4448, -4708 and -4773 were selected for further investigations. Gene expression of these miRs and their putative targets identified by bioinformatics, SMAD1 and SMAD4, key transducers of bone morphogenetic protein 2 (BMP-2) signalling, was evaluated by real-time PCR. To investigate the role of these miRs on the osteogenic potential of Ti with nanotopography, MC3T3-E1 cells were transfected with miR-4448, -4708 or -4773, or non-silencing (NS) miR and the gene and protein expression of SMAD1 and SMAD4 were evaluated, in addition to Runx2 and OC gene expression, at 48 hours. Also, MC3T3-E1 cells cultured on both Ti with nanotopography and control Ti discs were treated with either 100 ng of BMP-2 or vehicle and the gene expression of Runx2 and OC were evaluated at day 4. All experiments were carried out in triplicate (n=3). Data were analysed by Mann-Whitney U-test to compare hMSCs grown on Ti with nanotopography with control Ti, or each miR with NS miR in transfected MC3T3-E1 cells or MC3T3-E1 cells treated with either BMP-2 or vehicle. The level of significance was established at p≤0.05.

RESULTS AND DISCUSSION

It was noticed that Ti with nanotopography favours osteoblast differentiation of hMSCs compared with

control Ti as evidenced by higher Runx2, ALP, OC and OPN gene expression (p≤0.05), and ALP protein expression, in addition to a non-significant increase of extracellular matrix mineralization (p>0.05). The miR-sequencing analysis revealed that 20 miRs were upregulated (>2 fold) while 20 miRs were downregulated (>3 fold) in hMSCs grown on Ti with nanotopography compared with control Ti. Three miRs, miR-4448, -4708 and -4773 were significantly downregulated (>5 fold) by Ti with nanotopography and affected osteoblast differentiation of hMSCs. These miRs directly target SMAD1 and SMAD4, which were upregulated by Ti with nanotopography (p≤0.05). Overexpression of miR-4448, -4708 and 4773 in MC3T3-E1 cells noticeably inhibited gene and protein expression of SMAD1 and SMAD4 (p≤0.05) and by targeting them, these miRs repressed the gene expression of Runx2 and OC (p≤0.05). Treatment of MC3T3-E1 cells with BMP-2 upregulated the gene expression of Runx2 and OC on Ti with nanotopography and of OC on control Ti (p≤0.05). While BMP-2 treatment increased gene expression of Runx2 (1.1-fold) and OC (1.6-fold) on control Ti, the same treatment increased 1.4- and 2.3-fold, respectively, on Ti with nanotopography.

CONCLUSION

The results showed that the Ti with nanotopography directs hMSCs differentiation toward the osteoblast lineage. In addition, we have identified 3 miRs that target SMADs and play critical role in the osteoinductive effect of this nanotopography on hMSCs. By downregulating miR-4448, -4708, and 4773, Ti with nanotopography attenuates SMAD1 and SMAD4 degradation, intensifying BMP-2 signal transduction, which stimulates osteoblast differentiation. This novel mechanism involving a miR-SMAD-BMP-2 network in the nanotopography-mediated osteoblast differentiation is a major step for developing Ti surface modifications to modulate the osseointegration process.

Semi-interpenetrating polymer networks (SIPNs) incorporating polygalacturonic acid as biocompatible materials for implantable medical devices

A. O' Carroll, C. McCoy, and L. Carson

School of Pharmacy, Queen's University Belfast, United Kingdom, l.carson@qub.ac.uk

INTRODUCTION

Over 200 million people in the US are living with an implantable medical device¹, with similar figures anticipated for Europe. Complications associated with medical device implantation include the Foreign Body Response (FBR) and bacterial biofilm-mediated infection. The FBR is an inflammatory response to the implanted material and involves a complex sequence of events, including adsorption of host proteins and adherence of macrophages (MΦ) on the material surface. Both the FBR and device-associated infection can have detrimental consequences on the structural and functional integrity of the medical device^{2,3}, often necessitating removal. Materials are sought to mitigate both the FBR and device-related infection, leading to improved biocompatibility. The present work involves the synthesis of a polyelectrolyte hydrogel containing polygalacturonic acid (PGA), a biopolysaccharide similar in structure and charge to hyaluronic acid (a component of the extracellular matrix), with the aim of developing biomaterials with improved biocompatibility for medical devices.

EXPERIMENTAL METHODS

Synthesis and characterisation: SIPNs were formulated using 2-hydroxyethylmethacrylate (HEMA) and 2-methacryloxy ethyltrimethyl ammonium chloride (METAC) with aqueous PGA. AIBN (0.1%) was used as a thermal initiator. Control materials used the same volume of dH₂O in place of PGA solution. The resulting polymer films (final concentration 1% PGA) were characterised in terms of contact angle, swelling, and SEM analysis of surface topography.

Protein adsorption: PGA-incorporated polymers and controls were incubated in a solution of 10% BSA in PBS at 37°C for 2 hours after which adsorbed protein was sonicated into 1% SDS in PBS, and quantified by micro BCA Assay (Pierce).

MΦ adherence and cytotoxicity: Sterilised samples were seeded with 1x10⁴ RAW 264.7 murine MΦ. After 72h adhered MΦ were stained with DAPI/Rhodamine-phalloidin and examined by fluorescence microscopy. Direct contact and medium elution cytotoxicity studies were carried out against L929 murine fibroblasts, following ISO 10993-5 methodology.

Bacterial biofilm formation: Biofilm formation was assessed by incubation of samples with 1x10⁶ cfu/ml in Mueller Hinton Broth (MHB) of *Staphylococcus epidermidis* ATCC 35984 or *Escherichia coli* ATCC 11303 at 37°C for 24h, after which samples were stained with Live/Dead BacLight (Molecular Probes) for analysis by fluorescence microscopy, and quantification of biofilm by image analysis (Image J, NIH).

All experimentation described was performed in at least triplicate and data analysed using the statistical software package GraphPad Prism 5.

RESULTS AND DISCUSSION

Swelling studies revealed a high degree of water uptake (>100%), while a contact angle of 39.23° indicated a hydrophilic surface. Cryo-SEM of the hydrated materials showed a micro-textured PGA polymer surface, compared to the smooth appearance of the control material. While no significant difference in protein adsorption was observed compared to material control, MΦ adherence was significantly reduced on the PGA polymer, while maintaining no toxicity towards L929 fibroblasts. *S. epidermidis* biofilm formation was significantly increased on the PGA material when compared with control. PGA is composed of D-galacturonic acid residues that may potentiate *S. epidermidis* lectin-carbohydrate interactions. This promotion of biofilm formation was, however, not observed for *E. coli*.

Figure 1 A. Number of adhered MΦ per 570 μm² field of vision (n=9, graph displays means ± SD), B. and C. *S. epidermidis* biofilm on control and PGA-incorporated polymer, respectively. Scale bars represent 5 μm.

CONCLUSION

This PGA-incorporated SIPN exhibits acceptable biocompatibility for future *in vivo* investigation, and shows a low level of MΦ adherence, holding promise for potential attenuation of the FBR. We are currently continuing to characterise the behaviour MΦ on these materials, particularly MΦ fusion towards foreign body giant cell (FBGC) formation. While promising results have been obtained for *in vitro* biocompatibility, the increased biofilm formation of *S. epidermidis* highlights a concern in terms of the potential for device-associated infection. Future work will focus on the improvement of an anti-infective surface whilst upholding biocompatibility.

INTRODUCTION

Methicillin-resistant *Staphylococcus aureus* (MRSA) is an important nosocomial pathogen acting in a global endemioepidemic state. The options for treatment of bone infections due to methicillin-resistant *S. aureus* (MRSA) are limited by pharmacokinetic factors (such as penetration into bone tissues) and susceptibility pattern of the causal bacteria. For the treatment of prosthetic joint infections, continuous irrigation and antibiotic impregnated bone cement beads have become popular because of higher antibiotic concentration in soft tissue, bone, and/or joints.

In a recent contribution to this field, we have presented a new biomaterial having applications as implant in orthopaedic surgery and allowing the release of an antibiotic (the Gentamicin Sulphate ; GS) only in case of infection [1, 2]. A cleavage reaction of the active particle-active molecule bond, activated by the contact of material with the physiological medium or by a modification of the pH, induces controlled release of the bioactive molecule in its native form.

Release kinetic profiles and *in vitro* bacterial growth inhibition have been established and in this presentation, we prove the *in vivo* efficiency of these materials.

EXPERIMENTAL METHODS

Nanoparticles are obtained by Ring-Opening Metathesis CoPolymerization (ROMP) of norbornene with α -norbornenyl poly(ethylene oxide) macromonomers ω -functionalized with either carboxylic acid groups or GS through a pH-sensitive amine bond. Their colloidal stabilities were shown by Dynamic Light Scattering measurements. Titanium discs ($\varnothing = 4$ mm ; h = 20 mm) were activated by functionalization with amine groups using aminosilane molecules (APTES). The NPs were covalently linked onto the titanium surface through the formation of an uncleavable amide bond between the carboxyl group of the NPs and the amide group of silane molecules available onto the surfaces of the disks activated by NHS and DCC. The grafting was characterized by Scanning Electron Microscopy (SEM).

The aim of this study is to assess the *in vivo* efficacy of titanium devices coated with gentamicin in an experimental model of acute osteomyelitis in rabbit [3]. Femoral trepanation of rabbits was performed, followed by injection of 1 mL 10^9 CFU MRSA into the knee

cavity. A surgical debridement of the infected tissues was performed 3 days later and animals were randomly assigned to control group or titanium implantation. The strain studied is an MRSA strain (BCB8) obtained from blood cultures (gentamicin MIC < 0.5 μ g/mL).

RESULTS AND DISCUSSION

	Number of rabbits	Mean $\pm \sigma \log_{10}$ CFU/g of tissue	
		Bone Marrow	Spongy bone
Perop - Control	6	7.65 \pm 0.92	8.14 \pm 0.86
Per-operative induction	7	6.47 \pm 0.64 ^a	8.15 \pm 0.40

^aP < 0.05 vs preop-control

Significant difference was found between the bacterial counts of the control and the per-operative groups for bone marrow only. Titanium devices coated with gentamicin-nanoparticles showed no antimicrobial activity in spongy bone, compared to the control group.

CONCLUSION

The use of such devices appears not to be used alone in the treatment of acute bone infections, but in addition to systemic antibiotherapy. However, bacterial contamination during surgery uses smaller bacterial loads (10^2 to 10^4 CFU/ mL). It would be of a great interest to test these implants with these inocula.

Radially Aligned Collagen Scaffolds for Deterministic 3D Models of Cancer Migration

Anke Husmann¹, Jonathan Campbell¹, Samuel Troughton¹, Robert Hume², Christine J. Watson² and Ruth Cameron¹

CCMM, Department of Materials Science and Metallurgy, University of Cambridge, UK

^{2*} Department of Pathology, University of Cambridge, UK

ah492@cam.ac.uk

INTRODUCTION

Freeze dried 3D collagen scaffolds have been used to develop complex analogues of tissue *in vitro*, for example mammary gland¹, and such models could provide important insights into cancer pathogenesis and spread. To increase model tractability the control of pore size and architecture is critical and Pawelec *et al.* have developed protocols to tailor such structures². We have extended this work by including metal nucleation sites to scaffold moulds, which has allowed us to create radially aligned collagen scaffolds. In the current study we investigate whether controlled pore architecture dictates 3D cancer cell migration.

EXPERIMENTAL METHODS

Low thermal conductive perspex and polycarbonate moulds of various geometries were designed to include metal nucleation sites. We used 1 wt% collagen slurry for our scaffolds. The freezing protocol was varied to control location and velocity of ice growth. We either used a cooling rate of 1°C/min down to -30°C or quenched the moulds by pre-cooling the freeze dryer to -40°C. Where possible, we monitored the temperature at various points on the moulds and in the slurry during cooling and freezing. The MCF-7 breast cancer cell-line was passaged under standard culture procedures. Scaffolds were sterilised in 70% ethanol and washed in PBS before loading 2x10⁶ cells in 5µl of PBS to the nucleation point. Seeded scaffolds were cultured on top of transwell chambers in a modified migration assay format (Fig 1). Cells were loaded with the live-cell marker 1µM Calcein AM for 1hr before overnight fixation and confocal image analysis.

1. Cells seeded at nucleation site

2. Ordered migration observed along directional collagen pores

Fig 1. Schematic of modified transwell migration assay.

RESULTS AND DISCUSSION

When moulds are cooled slowly and evenly to sub-zero temperatures with cooling occurring mainly through the base of the mould, ice crystallization results in isotropic pore formation. In contrast, if the metal tip is cooled faster than the thermally insulated moulds, nucleation occurs at the tip, which acts as a heat sink. This leads to a different thermal path during freezing and creates elongated and aligned pores.

Figure 2 shows an SEM image of a scaffold where we have used a metal tip as a nucleation site, which in addition, generates a funnel for cell injection. This scaffold was formed by thermal quenching of the mould. We have also produced scaffolds with combined anisotropic and isotropic regions. Inoculation of scaffolds with MCF-7 cells resulted in a tight compaction of cells at the nucleation point at 24hrs, followed by their coordinated spread throughout the scaffold by 1 week along aligned collagen pores (Fig 3).

Fig3. Confocal projection of MCF-7 cells loaded with Calcein AM (green) 1 week following seeding. Bar = 2mm

CONCLUSION

We have extended our range of collagen scaffold designs from structures with isotropic pores to radially aligned pores that are suitable substrates for studying cancer cell migration rate and proliferation dynamics. We anticipate these models may eventually be adapted to better understand complex tissue interactions within the normal and tumour microenvironment, by incorporating multiple cell types to support stem cell niche regulation and studying homing of cancer phenotypes to target organs.

Recombinant Production of Antimicrobial Spider Silk for Wound Dressing Materials

L. Nilebäck, R. Jansson and M. Hedhammar

Department of Anatomy, Physiology and Biochemistry, Swedish University of Agricultural Sciences, Sweden
linnea.nileback@slu.se

INTRODUCTION

In chronic wounds and implant sites, it is crucial to inhibit growth of pathogenic bacteria to avoid biofilm formation and extensive infections.^{1,2} Antimicrobial peptides (AMPs) from innate immune systems are less prone to induce resistance development in pathogens than conventional antibiotics and are therefore gaining interest.² In this work, we used recombinant technology to covalently link AMPs to a partial spider silk protein (spidroin). This protein assembles into silk-like materials that exhibit a unique combination of elasticity and strength. Recombinant production allows us to introduce new functions such as antimicrobial activity to the proteins already at DNA level, and to convert them into various 2D and 3D scaffolds.

EXPERIMENTAL METHODS

Fusion proteins of antimicrobial peptides and the partial spidroin 4RepCT were constructed using conventional cloning strategies and IPTG induced expression in *Escherichia coli* BL21(DE3). Target proteins, tagged with His₆ at the N-terminus, were purified using Zn²⁺ charged IMAC columns. Silk fibers and films were made according to previously reported methods.^{3,4} The number of Colony Forming Units (CFU) of *E. coli* Nova Blue before and after incubation on silk films (duplicates) was determined using the spread plate method on LB agar. Statistical significance was determined using SPSS Paired-Samples T test.

RESULTS AND DISCUSSION

Fusion proteins were constructed both with and without a solubility-enhancing domain N-terminally to AMP-4RepCT, and different expression conditions were compared to evaluate which strategy that is the most promising for recombinant production of antimicrobial spider silk. Highest yields were obtained from long-term expression at low temperatures for constructs containing the N-terminal solubility tag. Possibly, the tag at the N-terminus together with 4RepCT at the C-terminus blocks both sides of the AMP from interacting bactericidally with the membranes of the bacterial host during expression. This is in accordance with previous reports about the possibility to express AMPs recombinantly using various end-tagging systems.⁵ After expression, the N-terminal tag is removed from the product, leaving one side of the AMP free to interact with target bacteria.

Antimicrobial silk fusion proteins obtained with the described procedure could still assemble into stable films and fibers. An example of such a fiber, made from

a fusion of 4RepCT and Magainin I, an AMP from the African clawed frog *Xenopus laevis*, is shown in Figure 1.

Figure 1. Silk fiber made of Magainin-4RepCT.

The antibacterial assays imply a bactericidal effect of AMP-functionalized spider silk compared to non-functionalized references in initial trials (n=2, p<0.1).

The possibility to express AMP-functionalized spider silk recombinantly leads the way to large-scale production of antimicrobial materials that can be processed into different silk formats adapted to the aimed applications, without risks for disease transmission or side effects from chemical compounds.

CONCLUSION

We present a method to recombinantly produce antimicrobial peptides fused to the partial spidroin 4RepCT in heterologous hosts. With this design, antimicrobial materials in suitable formats for wound healing applications can be produced.

Sol-Gel Hybrids with RAFT-Polymerised Branched Methacrylate Copolymers as Organic component for Tissue Engineering

Justin Chung¹, Anthony Maçon¹, Theoni Georgiou¹, Julian R. Jones¹

¹ Department of Materials, Imperial College London, UK

Justin.chung11@imperial.ac.uk

INTRODUCTION

Sol-gel hybrids for tissue regeneration are of great interest because their nanoscale interpenetrating networks of silica and organic polymer can provide unique properties in terms of toughness and biodegradation rates.¹ Covalent coupling between the components is critical to attain these properties. Previously this was achieved using coupling agents such as glycidoxypyrpyl trimethoxysilane (GPTMS).¹ Here, polymers were synthesised that contain reactive silica groups for coupling to a silica network. Hybrids of branched co-polymer of methyl methacrylate (MMA) with 3-(trimethoxysilyl)propyl methacrylate (TMSPMA) for coupling and ethylene glycol dimethacrylate (EGDMA) as a branching agent were developed and tested.

EXPERIMENTAL METHODS

Prior to polymerisation, all monomers (MMA, TMSPMA, and EGDMA) were passed through basic alumina columns to remove inhibitors. Then they were dried over CaH₂. The branched co-polymers were synthesised by free-radical and reversible addition fragmentation chain transfer (RAFT) polymerisation using azobis-isobutyronitrile (AIBN) as an initiator. The molecular weight (MW) was regulated by introducing different ratios of thioglycerol (for free-radical polymerisation) and cumyl dithiobenzoate (for RAFT polymerisation) in the reaction chamber. The rate of branching was controlled by introducing different molar ratios of EGDMA. Tetraethyl orthosilicate (TEOS) was used as the inorganic precursor. The hybrid contained 40 wt% inorganic. Nuclear magnetic resonance (NMR) and gel permeation chromatography (GPC) were used to characterise the composition and MW, respectively, of the organic component. Fourier transform infrared spectroscopy (FTIR), compression tests and simulated body fluid (SBF) testing were performed.

RESULTS AND DISCUSSION

Both linear and branched TMSPMA homopolymer from previous studies did not improve the mechanical properties compared to conventional sol-gel derived bioactive glass. This was due to an excessive amount of covalent bonding to the silica network because TMSPMA contains alkoxysilane end groups. To solve this problem, TMSPMA units were spaced using branched pMMA (MMA-co-TMSPMA-co-EGDMA or branched pMCM). TMSPMA provided excellent coupling between the silica and the polymer. Figure 1 shows a stress-strain of the hybrids with different organic contents compared to that of bioglass 70S30C. Branched pMCM hybrids showed viscoelastic

mechanical property while sol-gel glass and TMSPMA homopolymer hybrids displayed brittle failure.

Figure 1: Stress-strain of 70S30C, linear, branched pTMSPMA, and branched pMCM hybrids.

Free-radical and RAFT polymerisation methods were used to synthesise the branched pMCM to compare the MW and branching rate. It is important to consider that polymer should be eliminated through kidney filtration of pores with a size comparable to 4 to 14 nm.² Also, the threshold of the filtration corresponds with the molecular weight ranging from 30 to 50 kDa, depending on the shape, molecular conformation, and flexibility of the polymer.³ RAFT polymerisation process gives more control of the MW and branching rate compared to that of free-radical polymerisation process.

CONCLUSION

Branched pMCM is a potential hybrid source for bone regeneration. It shows a viscoelastic mechanical behaviour and hydroxycarbonate apatite layer forms within two weeks of SBF immersion. RAFT polymerisation has demonstrated a higher control over regulating MW and branching. However, additional experiments and investigations are required to improve the mechanical property of the hybrids. In addition, replacing EGDMA with an enzymatically or hydrolytically degradable branching agent should be considered in the future.

s.pentlavalli@qub.ac.uk

INTRODUCTION

A major challenge in the repair of joint injuries is in the reattachment of the soft tissue to the bone¹. Knee injuries are common and associated with the development of osteoarthritis in later years¹. As such much investigation has taken place into the development of a scaffold with the ability to promote bone and soft tissue regeneration. Despite an understanding of the graded nature of the knee joint, only a few studies to date have focused on scaffolds that mimic this interface¹. For example, Li *et al* developed a graded calcium phosphate coating on the surface of electrospun nanofibres². However, these studies have resulted in limited success. In this study we propose a novel AAlg-g-PNIPAAm hydrogel, which has thermo-responsive properties for the delivery of self-assembly peptide (RALA) containing tricalcium phosphate (TCP) nanoparticles (NPs) with osteogenic activity.

EXPERIMENTAL METHODS

Preparation of hydrogel: Aminated alginate (AAlg) and carboxylic end capped PNIPAAm (PNIPAAm-COOH) was synthesised and coupled via amide bond linkages to form AAlg-g-PNIPAAm hydrogel with various ratios. ¹H NMR, FTIR and rheological was used to characterise the resultant hydrogels³.

Formulation of RALA/TCP NPs: NPs were prepared at a range of mass ratios, with particle size and zeta potential (ZP) measured using a Malvern Zetasizer Nano ZS to determine the optimal formulation, which was found to be a mass ratio of 10:1.

Analysis of the stability of the NPs: Longitudinal stability of the NPs prepared at a mass ratio of 10:1 across a temperature range of 4-40°C. Maintenance of particle size was the measure of stability.

Transmission electron microscopy (TEM): NPs were loaded onto a carbon coated formvar copper grid. Grids were subsequently stained using uranyl acetate for 5 min at room temperature and imaged using a Philips Tecnai TF20 D microscope.

Cell viability following treatment with TCP alone or RALA/TCP NPs: MG-63 osteosarcoma cancer cells were seeded at a density of 10,000 cells per 96-well plate and treated with different doses of TCP or transfected with RALA/TCP NPs at corresponding doses for 6h prior to replacement with complete medium. The doses used for drug only treatments were 0.75-5 µg and the doses of drug used for NP transfection were 0.75-2.5 µg.

RESULTS AND DISCUSSION

Preliminary studies demonstrate that the AAlg-g-PNIPAAm solutions exhibited increasing viscosity from 34-36°C as the aqueous solutions transformed to elastic hydrogels, which was indicative of their thermo-responsive properties. NPs prepared with a mass ratio of 10:1 were found to have a size of 51 nm ± 7.15 nm and a zeta potential of 36 mV ± 4.34 mV. The size of the

NPs was confirmed by TEM and the round shape elucidated. The NP particle size and ZP remained consistent for up to 14 days at room temperature demonstrating the physical stability of the NPs. The temperature study confirmed NP stability across a broad range (i.e. 4-40°C). Cell viability was unaffected by treatment with pure TCP at various concentrations, potentially due to TCP particle size at approximately 800 nm limiting their uptake into cells. However, encapsulation of the TCP with RALA resulted in a reduction in cell viability in the MG-63 osteosarcoma cell line, correlating with TCP dose.

Figure 1. a) Storage modulus (G') and loss modulus (G'') of 3% AAlg-g-PNIPAAm solution (insert: the LCST behaviour of polymer solution). b) Size and ZP of RALA/TCP NPs (mean ± SEM, n=3). c) TEM image of RALA/TCP (10:1) NPs.

CONCLUSION

We have successfully produced a thermo-responsive polymer with the potential to behave as both a scaffold and delivery vehicle. Furthermore, RALA peptide was capable of forming NPs with TCP, which were stable across a range of temperatures and over an extended duration. Upon fine tuning of the hydrogel formulation, the degradation pattern and NP release from the hydrogel *in vitro* will be studied. The dual functionality of the hydrogel as a scaffold for bone regeneration and a delivery vehicle for osteoconductive NPs will finally be assessed *in vivo*.

INTRODUCTION

Recently, great attention has been paid for biodegradable thermo-gelling polymers exhibiting sol-to-gel transitions as injectable polymers (IPs) in drug delivery system (DDS) or tissue engineering. The most typical molecular structures for IPs consisting of PEG and an aliphatic polyester are linear block-type architectures, but some other IPs having branched structures such as graft-type or star-shaped have also been reported¹⁻⁴. A graft-copolymer system had some advantages compared to block copolymer systems.⁴⁻⁵ Linear block copolymer-type IPs have limitations in PEG length and total molecular weight, which may be obstacles to achieve high physical properties in the gel state. Using graft-copolymer, the total molecular weight can be changed independently of the graft PEG length while retaining the sol-to-gel transition behavior.⁴⁻⁵

Although IP thermogel systems have been widely used for DDS, the release rates of water-soluble low-molecular-weight drugs are generally faster than hydrophobic and/or high-molecular-weight drugs. Recently, we synthesized a graft copolymer of poly(depsipeptide-co-DL-lactide) with PEG, poly[(glycolic acid-*alt*-L-aspartic acid)-co-DL-lactide]-g-PEG [P(GD-DL-LA)-g-PEG] exhibiting temperature-responsive sol-to-gel transitions.⁴ Using this system, the residual carboxylic acid groups can be used for further functionalization such as drug immobilization. In this study, we propose a new type of IP system, which can act as a macromolecular prodrug exhibiting sustained release of water-soluble low-molecular-weight drugs. Antibiotic levofloxacin (LEV) was chosen as a model of a hydrophilic low-molecular-weight drug. The LEV was attached to P(GD-DL-LA)-g-PEG to give a P(GD-DL-LA)-g-PEG/LEV conjugate. Temperature-responsive sol-to-gel transition behavior of the conjugate in aqueous solution and the release behavior of LEV from the hydrogel were investigated.

EXPERIMENTAL METHODS

P(GD-DL-LA) synthesized by the method reported previously⁴, LEV-ethyl-NH₃⁺Br⁻, DCC, NHS and DMAP were reacted in DMF at r.t. for 24 h. Then, MeO-PEG and DCC in DMF was added into the reaction mixture, and stirred at r.t. for 12 h. The unreacted MeO-PEG and LEV derivative were removed by reprecipitation using diethylether/methanol. The sol-to-gel transition behavior of the conjugate and P(GD-DL-LA)-g-PEG aqueous solution were investigated by the test tube inversion method.¹ The temperature-dependent rheological properties of the conjugate solution were measured by using a dynamic rheometer. The *in vitro* release of LEV from the conjugate hydrogel was investigated in PBS and compared with

P(GD-DL-LA)-g-PEG and PLGA-*b*-PEG-*b*-PLGA hydrogels physically entrapping LEV molecules. The opened vials containing the hydrogels were fully soaked in 80 mL of PBS, and incubated at 37 °C. After predetermined periods, 1 mL of supernatant was collected, and the absorbance at 287 nm was measured on a UV-vis spectrophotometer.

RESULTS AND DISCUSSION

Both P(GD-DL-LA)-g-PEG/LEV conjugate and P(GD-DL-LA)-g-PEG in PBS showed sol-to-gel transition between r.t. and 37 °C. These results indicate that the introduction of LEV into P(GD-DL-LA)-g-PEG had no significant influence on the gelation. P(GD-DL-LA)-g-PEG/LEV hydrogel showed gradual and continuous release of LEV derivatives for 11 weeks. On the other hand, the release rate of the LEV molecule from P(GD-DL-LA)-g-PEG and PLGA-*b*-PEG-*b*-PLGA hydrogel that physically entrapped LEV was significantly faster than that from the conjugate hydrogel. The release of LEV from P(GD-DL-LA)-g-PEG hydrogel was almost completed in 3 weeks. The release rate of LEV from PLGA-*b*-PEG-*b*-PLGA hydrogel was much faster. Thus, it was revealed that the release rate of a water-soluble model drug (LEV) from IP hydrogel could be sustained by using a graft-type thermo-gelling polymer [P(GD-DL-LA)-g-PEG], and further suppressed by covalent immobilization to the polymer backbone.

CONCLUSION

We developed a macromolecular prodrug-type IP system using a biodegradable graft-type thermo-gelling polymer, P(DG-DL-LA)-g-PEG. The obtained P(DG-DL-LA)-g-PEG/LEV conjugate exhibited temperature-responsive sol-to-gel transition behavior in PBS between r.t. and 37 °C. Sustained release of LEV derivative from the hydrogel was observed. The release rate of LEV from the conjugate hydrogel was much slower than that from control hydrogels physically entrapping LEV molecules. These results suggest that the covalent attachment strategy is effective for achieving sustained release of water-soluble low-molecular-weight drugs in IP systems, and can be applied to drug delivery devices for highly bioactive molecules.

Localized Corrosion Behaviour of Stainless Steel and Titanium Based Hard Tissue Implants

Ilven Mutlu* and Enver Oktay

Metallurgical and Materials Engineering Department, Istanbul University, Turkey
imutlu@istanbul.edu.tr

INTRODUCTION

Pitting is a corrosion type that results in rapid penetration at small areas. Pitting can be evaluated by critical pitting potential, which is potential above there is increase in current. Crevice corrosion occurs within cracks where acidic solution is developed. Sensitisation occurs when metals are heated at intermediate temperatures. Depletion occurs at grain boundary due to precipitation. When sensitised metal is exposed to corrosive environment, depleted regions dissolve, leading to intergranular corrosion¹⁻³.

EXPERIMENTAL METHODS

Ti-Nb-Cu specimens were produced by powder metallurgy using Ti, Nb and Cu powders. 35 w.% Nb and 3, 5, 7, and 10 w. % Cu powder was added to Ti powder. Mixtures were compacted into cylindrical specimens. Sintering was carried out at 1100 °C for 45 minutes. AISI 316 austenitic stainless steel was investigated as wrought specimens. Stainless steel specimens were heated to develop sensitisation. Heat treatments were carried out at 825 °C for 1 hour. The specimens were then water quenched.

Electrochemical corrosion studies were carried out in simulated body fluid using a potentiostat (Interface 1000, Gamry, USA). A conventional three-electrode system was used. Cyclic polarization curves were analysed in terms of breakdown potential and repassivation potential values. Critical pitting potential test determines critical repassivation potential. Experiment starts with stimulation phase. Test compares the current to current limit. If current exceeds the limit, test goes to repassivation. If constraint is exceeded the test ends. Tsujikawa-Hisamatsu electrochemical (THE) test was used to assess susceptibility to localized corrosion. Potential scanned from -500 mV to 1500 mV. Mode was then switched from potentiodynamic to galvanostatic and 200 $\mu\text{A}/\text{cm}^2$ current density was applied. After galvanostatic step, potentiostatic steps were applied until crevice repassivation. Repassivation potential is determined as potential for which current density decreases with time. Electrochemical potentiokinetic reactivation (EPR) test can be used to evaluate degree of sensitization (DOS) to intergranular corrosion. Sample is potentiostated at activation E. Sample is then potentiostated. Finally, potential is swept back to OCP. Simple EPR command was used to calculate the DOS to IGC.

RESULTS AND DISCUSSION

Increasing Cu content of Ti-Nb-Cu was increased the peak current density according to EPR test. Decreasing pH of solution was increased the peak current density of stainless steel. EPR test is used to DOS but also can be

used in pitting and crevice measurements. Precipitates can results in excess charge during cathodic scan.

CONCLUSION

Increasing Cu content of Ti-Nb-Cu alloy was increased the peak current density according to EPR test. Decreasing pH of solution was increased the peak current density of stainless steel specimens. Increasing Cu content of the Ti-Nb-Cu alloy was decreased the critical pitting potential. Increasing pH of solution was increased the critical pitting potential. Crevice repassivation potential of Ti-Nb-Cu specimens was decreased with increasing Cu content according to THE tests. Increasing pH of the solution was increased the crevice repassivation potential of Ti-Nb-Cu alloy. Increased pH of solution was also increased the crevice repassivation potential of stainless steel.

INTRODUCTION

Calcium phosphate-based glasses and glass-ceramics have high potential for use as biomaterials due to their unique properties although a high solubility of these glasses is sometimes considered a serious handicap to their use in biomedical applications.

Almost all bioactive glass-based materials contain a large amount of silica, but development of new glass-ceramic biomaterials has recently concentrated on SiO₂-free glasses. It is well accepted that phosphate-based glasses without silica and with high CaO/P₂O₅ molar ratio (>1.5) exhibit a high potential for use as biomaterials¹⁻².

Titanium oxide does not form a glass alone, but it can be incorporated in significant amounts into other glass-forming oxide systems such as phosphates. The role of TiO₂ in bioactive glasses and glass ceramics is still under discussion but addition of this oxide to phosphate glasses usually contributes to improve glass-forming ability, chemical durability and glass structure stabilization. Moreover, TiO₂ addition to CaO-P₂O₅ based glasses does not compromise development of biocompatible and bioactive phases.³⁻⁵

Previous work has shown that incorporation of TiO₂ in calcium phosphate glasses can control their degradation rate.⁴

EXPERIMENTAL METHODS

Glasses from TiO₂-P₂O₅-CaO system were prepared by conventional melting and pouring process⁴ and its amorphous state evaluated by powder X-Ray Diffraction. The glasses were studied by spectroscopic methods, Raman and ³¹P MAS-NMR (Magic Angle Spinning – Nuclear Magnetic Resonance), and immersed in synthetic plasma in order to evaluate the effect of structure on the surface reactivity of those glasses.

RESULTS AND DISCUSSION

Spectroscopic methods have revealed the features of the internal structure of glasses and showed that for TiO₂-free and TiO₂ lower contents chain phosphate units dominate the structure near the metaphosphate composition, Q², and for higher TiO₂ contents distorted Ti octahedral linked to pyrophosphate units, Q¹, dominate glass structure.

A progressive depolymerization of phosphate glass network occurs as TiO₂ content increases but the local cohesion of glass structure increases due to the

replacing of P-O-P bonds by stronger Ti-O-P bonds, figure 1.⁴

“Figure 1: Mechanism of P–O–Ti bonds formation from P=O bonds break.”

Degradation studies in synthetic physiological media showed that chemical stabilization increases with TiO₂ addition in accordance with indications of the spectroscopic structural results.

CONCLUSION

The results indicate that incorporation of TiO₂ in P₂O₅-CaO glasses may be used to control their dissolution in body fluids, thus providing a wide range of potential biomedical applications, namely in regeneration strategies or in drug delivery situations.

Studies in progress are showing that structural differences induced by TiO₂ content also influence the biological behavior of these glasses when contacting physiological fluids and cells.

Comparison of UV and EDC Cross-linking on Mechanical Properties of Collagen-based Scaffolds for Myocardial Tissue Engineering

Natalia Davidenko¹, Carlos Schuster¹, Ruth Cameron¹, Serena Best¹

¹Department of Materials Science and Metallurgy, University of Cambridge, United Kingdom, nd313@cam.ac.uk

INTRODUCTION

The concept of Tissue Engineering (TE) has led to the utilisation of 3D scaffolds as cell delivery vehicles. These biomaterials should mimic the function of ECM which not only provides mechanical support for cells, but also supplies signals that direct cell attachment, proliferation, differentiation and metabolism¹.

The objective of this work was the development of a series of collagen (Col) and gelatin (Gel)-based scaffolds with appropriate mechanical characteristics suitable for use in myocardial tissue regeneration and repair. Collagen was selected as main component as it comprises up to 80% of myocardial ECM providing the heart tissue its mechanical strength and stiffness. Gelatin, thermally denatured collagen, possesses more disorganised structure which should affect mechanical stability of resultant scaffolds. The addition of Gel to Col can tailor the mechanical properties of scaffolds and could be a design strategy for changing biochemical activity.

EXPERIMENTAL METHODS

Protein scaffolds (Col, Gel and Col/Gel= 50/50) were obtained by freeze-drying and cross-linked with EDC/succinimide (NHS) at different concentrations. EDC concentration of 11.5mg/ml (molar ratios to Col =5/2/1) was assumed as standard (100%) and was varied in the interval from 100 to 1%. UV irradiation ($\lambda=254\text{nm}$; $t=30\text{ min}$; at different light intensities) was also used for scaffold and film treatment. Compressive stress-strain analysis on scaffolds was carried out in the wet stage. The linear elastic (Young's) modulus was obtained via linear regression of the initial linear region of the stress-strain curve.

RESULTS AND DISCUSSION

The results of mechanical testing showed that EDC cross-linking and UV treatment mechanically stabilised all studied scaffolds to a different extent. Compressive modulus increases with the increase of EDC concentration for all the compositions. The reduction of standard EDC concentration (11.5mg/ml, 100%) to 10% still provides mechanical stability for all scaffolds compositions. Col matrices displayed the highest Young's Modulus. Low EDC concentrations (1%) stabilize only collagen scaffolds (Fig.1).

Fig.1 Influence of EDC concentration and composition on compressive modulus of scaffolds.

UV irradiation increases compressive properties of Col-based scaffolds while pure Gel matrices showed no differences in Young's modulus after UV exposure. The values of elastic modulus depend on the intensity of UV light and on the scaffold composition. Pure Col scaffolds showed the highest values in compressive modulus after UV treatment (Fig.2)

Fig. 2 Influence of UV intensity and composition on the Young's Modulus of scaffolds.

Relatively small increase in compressive properties of scaffolds after UV treatment (~2 times in the maximum comparing to ~4.5 times achieved with EDC XL for Col) may be related to the intrinsic limitation of UV light in forming high density network within polypeptide molecules (less than 2% of tyrosine and phenylalanine in Col molecules responsible for UV-mediated binding).

CONCLUSION

Mechanical properties may be tailored by changing composition and crosslink status of Col and Gel-based scaffolds. EDC cross-linking mechanically stabilised all the scaffold compositions while UV irradiation increased only Col-based scaffold compressive properties and to relatively small extent. Varying scaffold composition and XL method provide a simple but effective way to modulate the mechanical parameters of these scaffolds to better suit their use in specific soft tissue engineering applications.

Electrochemical Corrosion Behaviour of Highly Porous Beta-Type Ti-Nb-Cu Alloy

Ilven Mutlu^{1*}

¹Metallurgical and Materials Engineering Department, Istanbul University, Turkey
imutlu@istanbul.edu.tr

INTRODUCTION

Metal foams exhibit structure similar to bone and provide anchorage for surrounding tissue. Implants suffer from mismatch of Young's modulus with bone^{1, 2}. Ti alloys are used for high strength to density ratio, biocompatibility and corrosion resistance. However, there are disadvantages such as high Young's modulus. Ti has hexagonal close-packed (α -phase) structure that transforms to body-centered cubic structure (β -phase) at 883 °C, which can be increased by α -phase stabilizers (Al, O, N) or lowered by beta (β)-phase stabilizers (Mo, Nb, V). β -Ti alloys have low Young's modulus (close to bone) and biocompatibility. Beta-Ti stabilizer Nb is biocompatible. Cu addition enhances sinterability³⁻⁵.

EXPERIMENTAL METHODS

Foams were produced by space holder method using Ti, Nb and Cu powders. 35 wt.% Nb and 3, 7, and 10 wt. % Cu powder was added to Ti powder. As a space holder, carbamide was used. Mixtures were compacted at 200 MPa. Specimens were immersed in water and then carbamide was leached out. Sintering was carried out at temperatures between 1000 and 1250 °C for 45 minutes. Amounts of reagents for preparation artificial saliva are 0.4 g/l NaCl, 0.79 g/l CaCl₂·H₂O, 0.4 g/l KCl, 0.005 g/l Na₂S 9H₂O, 0.78 g/l NaH₂PO₄·H₂O, 0.35 g/l Urea.

Electrochemical corrosion studies were carried out in artificial saliva using a potentiostat (Interface 1000, Gamry, USA). A conventional three-electrode system was used. Open circuit potential was measured before carrying out experiments. Potentiodynamic polarization was carried out from -500 mV to +1500 mV. Tafel curves were obtained by polarizing the specimens from -250 mV to +250 mV. Corrosion density, Tafel slopes, corrosion rate and corrosion potentials were obtained from Tafel analyses. In linear polarization resistance test, specimens were polarized from -20 to +20 mV, in order to measure polarization resistance. Cyclic polarization experiments were carried out from -500 mV to apex potential and to final potential. Electrochemical impedance spectroscopy (EIS) measurements were carried out in potentiostatic mode. EIS studies were conducted in frequency range from 100 kHz to 0,001 Hz, with 5 points per frequency decade. Impedance spectra were fitted by an equivalent circuit model using Gamry, EIS100 software.

RESULTS AND DISCUSSION

Pore size and morphology of foams replicated initial size and morphology of space holder particles and mean pore sizes of foams was about 450-500 μ m, which is suitable for implant applications. Microstructure of Ti-Nb-Cu specimens (at the cell walls) was consisted of beta-Ti phase and Ti₂Cu at grain boundaries.

Figure 1. Effect of Cu content on corrosion behaviour

EIS measurements were showed capacitive semicircle, whose size was decreased as F increased and as pH decreased. At low F level, a capacitive semicircle is shown. Diameters of capacitive semi-arcs decreased with increasing Cu content of alloy. Impedance spectra of foams are presented as Nyquist and Bode plots. Nyquist plot is characterized by incomplete semicircle, indicating capacitive response of passive film. Diameter was increased with decreasing porosity. Bode magnitude plots are characterized by two regions.

CONCLUSION

Increased F concentration of artificial saliva was reduced the corrosion protection behaviour of alloy. F ions attack the alloys and severity of attack depends on the pH of saliva. OCP measurements show active behaviour in F⁻ added saliva due to presence of F⁻ that dissolve the passive film. Stability of the specimens was decreased at high concentrations of F⁻ and at low pH. Increasing Cu content of alloy was increased the corrosion rate and current density and decreased the corrosion potential. Although Cu addition was slightly reduce the corrosion properties, Cu addition to alloys was increased the mechanical properties. Cu addition was also enhanced the sinterability.

Recombinant Affinity Silk for Presentation of Active Protein Domains

R. Jansson¹, N. Thatikonda¹, P.-Å. Nygren², M. Hedhammar¹

¹Department of Anatomy, Physiology and Biochemistry, SLU, Sweden, ronnie.jansson@slu.se

²Division of Protein Technology, School of Biotechnology, KTH Royal Institute of Technology, Sweden

INTRODUCTION

Functionalization of silk fibers via chemical or genetic incorporation of peptides or proteins with binding or enzymatic functionalities has been recognized as a promising route forward to generate novel materials for both biotechnological and medical applications. The recombinant partial spider silk protein, 4RepCT, self-assembles into macroscopic fibers under physiological-like conditions¹. Recently, cell binding peptides were genetically incorporated to 4RepCT resulting in functionalized spider silk of potential use as cell growth supports in regenerative medicine². Incorporation of larger proteins with a folding-dependent activity into chimeric 4RepCT proteins, retaining an ability to form fibers, would pave the way for additional types of functionalized silk-like materials. Thus, we have herein investigated the possibility to use recombinant DNA technology to develop functionalized silk materials that present whole functionally folded protein domains. In the present study, 4RepCT was genetically fused to the IgG binding domains Z³ and C2⁴, and to the albumin binding domain ABD⁵.

EXPERIMENTAL METHODS

The gene for 4RepCT was genetically fused to DNA encoding Z, C2 and ABD. Corresponding fusion proteins were expressed in *Escherichia coli*, purified using IMAC and silk-like fibers and films formed. Selective binding of target molecules (IgG to Z and C2, albumin to ABD) after incubation with serum or plasma were analyzed by gel electrophoresis. Distribution of target binding to functionalized silk films was analyzed by fluorescence microscopy after binding of directly or indirectly fluorophore-labeled target molecules. Selective binding of dual-functionalized Z/ABD-4RepCT silk after incubation with plasma was analyzed by gel electrophoresis. For presentation of human vascular endothelial growth factor (hVEGF) on Z-4RepCT, anti-hVEGF antibodies were first bound to Z-4RepCT films, followed by capture of hVEGF and detection by fluorescence microscopy.

RESULTS AND DISCUSSION

Three affinity domains of different origin and structure, the IgG-binding domains Z and C2, and the albumin-binding domain ABD, were all successfully produced as soluble silk fusion proteins under non-denaturing purification conditions, and able to form silk-like materials. Gel electrophoresis revealed selective binding of IgG to Z-4RepCT and C2-4RepCT silk from serum, and of albumin to ABD-4RepCT silk from plasma, implying folded and accessible affinity domains in the functionalized silk materials. Fluorescence microscopy revealed that target binding to functionalized silk films was distributed all over the

film surface (Figure 1a). Moreover, silk materials from a mixture of functionalized silk proteins showed combined binding properties, showing upon the possibility of tailor-making silk with multiple binding functionalities with defined stoichiometry.

By using a two-step approach it was possible to capture a growth factor (hVEGF) on Z-4RepCT films, by first decorating the film with antibodies against hVEGF, followed by capture of hVEGF (Figure 1b). By choosing a suitable antibody, this two-step approach could be used for decoration of Z-4RepCT silk with almost any target of interest, even complex multi-domain mammalian proteins, such as growth factors.

Figure 1. (a) Binding of fluorophore-labeled target molecules to functionalized silk films. (b) A two-step approach for presentation of growth factors to IgG decorated Z-4RepCT silk. Scale bars indicate 1 mm.

CONCLUSION

Herein we describe a novel strategy for immobilization of functional protein domains to recombinant spider silk. The chimeric spider silk proteins maintained both the ability to form silk-like materials and a folding-dependent affinity. By decoration of Z-4RepCT silk with suitable antibodies, an almost unlimited repertoire of targets can be presented, *e.g.*, growth factors. Production of silk with multiple functionalities further broadens the area of application.

INTRODUCTION

Biocompatible hydrogels based on methacrylamide-modified gelatin (GELMA) have recently attracted increasing attention due to their wide range of possible applications. While GELMA is an appealing polymerizable collagenous derivative, with all biocompatibility-related attributes, acryl synthetic monomers remain a critical component of many biomedical products. The aim of the present work is to develop a one-pot synthesis method in order to synergistically combine the well-known innate biological properties of gelatin with the practical advantages of a synthetic hydrophilic biocompatible polymer, polyacrylamide (PAA). PAA is a conventional inert synthetic hydrogel, considered appealing for the development of multicomponent superabsorbent scaffolds for various tissue regeneration uses.

EXPERIMENTAL METHODS

GELMA-PAA hydrogels were obtained through free radical network-forming polymerization of acrylamide (with/out) synthetic crosslinking agent - MBA) and GELMA [1]. GELMA acts as crosslinking agent and also as a co-monomer in the polymerization of acrylamide. Properties such as water affinity, elasticity and biocompatibility were investigated.

RESULTS AND DISCUSSION

Bicomponent hydrogels were obtained through a one step network-forming polymerization reaction of C=C bonds from AA and GELMA. The obtained GELMA-PAA hydrogels were denoted P1-P4, according to an increasing AA concentration going from 50/1 to 1000/1. A second series of GELMA-PAA hydrogels (T1-T4) was synthesized using the same procedure, after supplementing the reaction medium with a synthetic crosslinking agent. Control GELMA and PAA hydrogels (T0 and T0') were prepared using similar methods.

The swelling behaviour of the bicomponent hydrogels was found to be strongly depended on the chemical composition. Accordingly, the values of the maximum swelling degree (MSD) increased from P1 to P4; the use of synthetic crosslinker significantly increased the network density, thus decreasing the swelling ability of the resulting T1-T4 hydrogels when compared to samples P1-P4 (fig. 1a). The mechanical behaviour of the hydrogels swollen at equilibrium indicated that increasing PAA in the polymerization mixture decreased the compression modulus; accordingly the elasticity of the bicomponent hydrogels was increased. Additional crosslinking with MBA generates stronger gels, with higher compression modulus and lower

elasticity when compared to P1-P4 (fig. 1b). These data are in agreement with the swelling behaviour of GELMA-PAA in water, the elasticity of the materials being justified by the corresponding equilibrium values.

Fig. 1. MSD (a) and compression modulus (b) for the synthesized hydrogels

The biocompatibility of the synthesized hydrogels was investigated through seeding of L-929 cells on the hydrogels' surface (fig. 2).

Fig.2. Cellular response at 7 days post-seeding.

Cell adhesion was enhanced by the increase of natural polymer, confirming the cell adhesion potential of GELMA-PAA bicomponent hydrogels.

CONCLUSION

GELMA and AA were successfully covalently bound using a one-pot polymerization reaction, to obtain inexpensive hybrid hydrogels with controlled properties. The composition-properties correlation allows control over the material characteristics. It was demonstrated that the addition of PAA sequences improved the water affinity and elasticity while the presence of GELMA sequences improved the cellular response of the bicomponent hydrogels.

Bactericidal and cell compatible titanium surfaces with TiO₂ nanowires

T. Dui¹, M. Ryadnov², N. Faruqi², B. Lamarre², H. Jenkinson¹ and B. Su¹

¹School of Oral and Dental Sciences, University of Bristol, UK

²National Physical Laboratory, UK, omxhd@bristol.ac.uk

INTRODUCTION

When an implant is inserted into the body, a race between bacteria and host mammalian cells occurs in a bid to habituate the implant surface¹. For orthopaedic and dental implants, successful osseointegration occurs when host osteoblasts adhere and proliferate on the material but if it is infected with the growth of a bacterial biofilm, it will lead to a higher risk of implant removal. Implant materials with controllable cellular and bacterial activity will no doubt result in high success rates of surgical implants and surface topography has been recognised as one of the possible means. Titanium as a biomaterial substrate is a popular material of choice for dental and orthopaedic implants due to its biocompatibility and resistance to corrosion. Titanium discs that underwent a simple hydrothermal process produced TiO₂ nanowires where its dimensions can be adjusted by changing experimental parameters and were found to be compatible with mesenchymal stem cells². Physical rupture of gram negative *P. aeruginosa* cells have been observed on the nanopillars found on the wings of psaltoda claripennis³, due to the thin peptidoglycan layer on the outer membrane of *P. aeruginosa*. In this study, the TiO₂ samples were incubated with various gram positive and gram negative bacteria to test for mechanical rupture with the different morphologies of the nanowires, as well as its compatibility with MG-63 osteoblast-like cells.

EXPERIMENTAL METHODS

Fabrication of TiO₂ nanowires: Ti discs were cut from a sheet of Ti (Titanium metals Ltd) and mechanically polished. The plates were placed in 10mL of acetone and sonicated for 10 minutes and rinsed with distilled water. These were then dried in air before being placed inside a PTFE lined vessel and filled with 60mL of 1M NaOH (Sigma-Aldrich). The vessel was placed in an oven for 3 and 8hrs at 240°C, to create surfaces with sharp nanowires (3 hHT) and nanowires that formed pockets and ridges (8 hHT) respectively.

Preparation of bacteria: *P. aeruginosa*, *S. aureus*, *E. coli*, *B. subtilis*, *E. faecalis* and *K. pneumoniae* were refreshed into their appropriate media and incubated to exponential growth. The growth was centrifuged at 5000rpm and harvested twice with 10mM tris HCl buffer (Sigma). The pellet was resuspended to OD=0.30 and incubated with Control Ti, 3 hHT and 8 hHT for 1hr. Surfaces were stained with LIVE/DEAD BacLight (Invitrogen) for imaging on the confocal microscope to count the ratio of live and dead cells. Tests were done in duplicates.

Cell Culture: MG-63 human osteosarcomas were maintained in Eagle's minimum essential medium with supplements. 20k cells were seeded onto each surface sample in triplicates before incubating for 1, 4, 7 and 14 days at 37°C with 5% CO₂. PrestoBlue reagent

(Invitrogen) was used to monitor the viability of the cells by incubating PrestoBlue with the cells for 1hr before aliquotting into a 96-well plate for reading.

RESULTS AND DISCUSSION

LIVE/DEAD assays show higher kill rates for motile bacteria rather than non-motile bacteria regardless of their gram identity (Figure 1). Viability assays on MG-63 seeded on the discs indicated that both hydrothermal surfaces can support cell life for at least 14 days albeit the proliferation rate is not as fast as cells on Control.

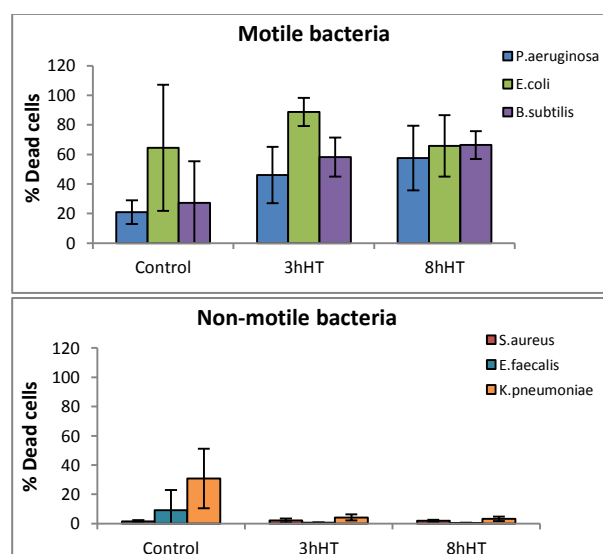

Figure 1: Higher kill rates seen on both 3 hHT and 8 hHT for motile bacteria but low percentage of dead cells found for non-motile bacteria after 1hr incubation.

CONCLUSION

TiO₂ nanowires created by hydrothermal technique have shown to be quite effective in the killing of motile bacteria due to physical means but do not affect non-motile strains. Despite this, MG-63 cells seeded on both 3 hHT and 8 hHT were found to proliferate well for at least 14 days. This is the preliminary step toward creating a surface that can simultaneously deter biofilm formation and be biocompatible with mammalian cells.

Precise Hyaluronan-tyramine synthesis for tailored cellular microenvironments

Claudia Loebel^{1,2}, Matteo D'Este¹, Mauro Alini¹, Marcy Zenobi-Wong² and David Eglin¹

¹AO Research Institute Davos, Davos Platz, Switzerland

² ETH Zurich, Cartilage Engineering and Regeneration Laboratory, Department of Health, Science and Technology, Zürich, Switzerland, claudia.loebel@aofoundation.org

INTRODUCTION

Due to its good biocompatibility, biodegradability and excellent gel-forming properties, tyramine-based hyaluronan hydrogels (HA-tyr) have great potential in regenerative medicine (1). So far, HA-tyr conjugate has been synthesized using conventional carbodiimide chemistry. The mechanical properties and gelation rate of the hydrogels have been tuned by varying the hydrogen peroxide (H_2O_2) and horseradish peroxidase (HRP) (2). However, the well-accepted HA-tyramine synthesis has the tendency for formation of byproducts and hydrogel tuning via controlled tyramine substitution has not been achieved (1). Here we demonstrate the applicability of 4-(4,6-dimethoxy-1,3,5-triazin-2-yl)-4-methylmorpholinium chloride (DMTMM) as an effective agent for the controlled synthesis of HA-tyr conjugates. Further, we hypothesised that DMTMM mediated HA-tyr conjugates enable predictive viscoelastic properties, swelling and hyaluronidase mediated degradation of HA-tyr hydrogels.

EXPERIMENTAL METHODS

HA-tyr conjugates were prepared in a one-step reaction by adding different molar ratios of tyramine, hyaluronan and DMTMM coupling agent. Degree of substitution (DS) was measured by ultraviolet visible spectrophotometry ($n=3$) and proton nuclear magnetic resonance (1H NMR). HA-tyr conjugates (2.5 w/v %) in PBS were cross-linked with H_2O_2 (0.34 mM) and HRP (1 Unit/ml) and hydrogel properties were investigated using rheology, mechanical testing, swelling and enzymatic degradation assays ($n=3$).

RESULTS AND DISCUSSION

The efficiency of DMTMM could be demonstrated and an optimized ratio of HA, DMTMM and tyramine (1-1-1 molar ratio) resulted in low amounts of byproducts as seen by 1H NMR. Various DS's were achieved depending on the reaction time and temperature.

At constant HA-tyramine concentration and increasing DS, the storage modulus (G') was linearly increased from 100 to 900 Pa with an excellent correlation ($R^2=0.729$), while maintaining constant HRP and H_2O_2 concentrations (Figure 1a). Thus, G' values can reliably be predicted by the DS of HA-tyramine conjugates ($G'=176.56 \cdot (DS, \%) - 12.72$) (Figure 1a).

A linear correlation could further be demonstrated for swelling ($R^2=0.896$) and degradation properties. Interestingly, concentrations of H_2O_2 from 0.17 mM to 0.78 mM, suitable for cell encapsulation, enable additional tuning of the hydrogel mechanical properties (Figure 1b).

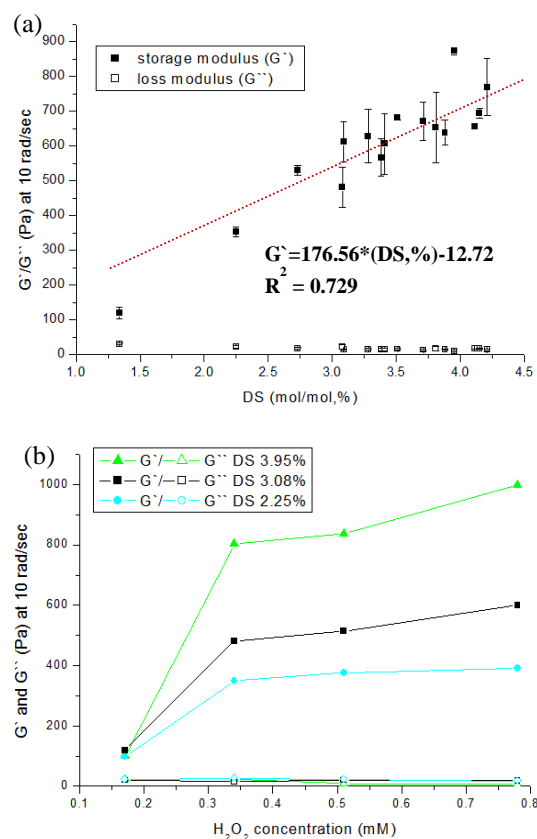

Figure 1 shows the frequency sweep of cross-linked hydrogels (2.5 % w/v) at 10 rad/sec (a) in relation to the DS in mol% ($n=3$; 0.34 mM H_2O_2) and (b) in relation to increasing H_2O_2 concentrations with storage modulus G' (filled shapes) and loss modulus G'' (empty shapes).

CONCLUSION

DMTMM conjugation is an efficient preparation method for HA-tyr derivative synthesis. The unprecedented control over DS allows for predictive hydrogel properties. HA-tyr hydrogels present excellent cell compatibility. This will be useful for the tuning of 3D microenvironment for stem cells encapsulation.

INTRODUCTION

Hyaluronic acid (HA) is not only a natural component of the extracellular matrix, but it is also heavily involved in cellular signalling. Due to the overexpression of its main receptor, CD44, in pathological phenomena such as inflammatory reactions and several types of tumours, in the past few years HA has also been seen as a potential means to target the action of an active principle. Two points are discussed here:

- The affinity of HA (in solution or on a substrate) to CD44 depends on its chain length and on its spatial arrangement, therefore the way HA is presented on a carrier structure may have profound effects on the way a carrier would bind to a receptor.
- After binding CD44 is internalized, and then it is represented only very slowly; therefore CD44-mediated endocytosis easily reaches saturation. Therefore, the amount of internalisable material depends on the interplay between limited number of available receptors and their affinity to the material, with the paradoxical result that increased affinity, i.e. higher number of receptor clustered around a carrier structure, may lead to lower internalisation.

EXPERIMENTAL METHODS

Nanoparticles were prepared by polyelectrolyte complexation of chitosan (CS) of variable molecular weight with triphosphate (TPP), and the successive coating by HA. The size and ζ -potential of the nanoparticles were measured by Dynamic Light Scattering (DLS) and their morphology was studied via Atomic Force Spectroscopy (AFM) and Transmission Electron Microscopy (TEM).

The *in-vitro* effect of the nanoparticles (cytotoxicity, uptake and uptake mechanism, induction of the production of inflammatory cytokines) was assessed on different cell lines (RAW 264.7 macrophages, XS106 Langerhans cells).

Nanoparticles were also loaded with functional plasmids or RNAs and their ability of acting as transfecting agent was compared to the one of lipofectamine.

RESULTS AND DISCUSSION

CS molecular weight (MW) influences the nanoparticle structure (higher cross-link density with lower CS MW) and thus the complexation with HA. Low MW (25 kDa) chitosan yielding nanoparticles coated by a rather extended HA *corona*. On the contrary, the more porous

core obtained with high MW CS (684 kDa), leads to a higher entanglement between the two polymers. and high MW chitosan producing nanoparticles with more tightly bound HA.¹

Fig. 1. Deflection images of CS(25)/HA (left) and CS(684)/HA (right) nanoparticles obtained via contact mode AFM. (Figure from ref. 2)

The internalization of both particles in macrophages is CD44 mediated, and better presentation (low MW chitosan) corresponded to both higher affinity and lower capacity/uptake rate.²

Using nucleic acid payloads, we observed a positive correlation between transfection efficiency and CD44 expression in different cell lines. Interestingly, despite a lower internalization, low molecular weight CS/HA particles provided higher transfection, likely due to a more efficient cytoplasmic delivery.³

CONCLUSION

HA presentation heavily influences the efficiency of CD44 targeting, but intracellular events may be more important in the overall picture of the delivery action.

INTRODUCTION

Non-viral delivery systems have become popular over the past decades, given the concerns over the long term effects of using viral systems¹. One such commonly used delivery system is dendrimers². These are hyperbranched molecules which may be synthesised from saccharides, organic molecules or amino acids. However the use of larger generations of dendrimers is associated with a higher level of cytotoxicity. To overcome this problem the use of lower generation three dendrons can be used. In this study, generation three poly (ϵ -lysine) dendrons were tested for their ability to bind DNA plasmid for potential as gene delivery carriers for *in situ* gene therapy.

To allow real-time monitoring of the binding of the DNA plasmid and dendron Optical waveguide lightmode spectroscopy (OWLS) will be used. OWLS allows for the real-time monitoring of biomolecular interactions at the nanoscale³, utilising changes in the refractive index above the surface of the waveguide region (upto 200 nm).

EXPERIMENTAL METHODS

Dendron Synthesis

Synthesis of generation three poly (ϵ -lysine) dendron (CG3K) was performed using Fmoc solid phase peptide synthesis at x4 molar. Dendrons with different root molecules (Cys) were synthesised from Fmoc-protected amino acids by solid-phase synthesis using a 4x molar excess of reagents. The dendron consisted of a root molecule (Cys), then 3 branching generations of ϵ -lysine to produce CG3K. The dendron was characterised by analytical HPLC (Waters) and microTOF mass spectrometry (Bruker).

OWLS

Using OWLS (Microvacuum), refractive index measurements (RIM) were performed to monitor the real-time binding of a DNA plasmid construct (MW 4377 kDa) containing a gene (LMP3FL-eGFP) and vector plasmid (pcDNA3.1/V5-His-TOPO, Invitrogen) to CG3K dendron.

Initially, the temperature of the system was set to 25 °C. Deionised water was pumped through the OWLS biosensor at a flow rate of 0.5 ml/minute until a stable baseline ($<10^{-8} \text{ s}^{-1}$) was achieved. Next 10 mM Tris HCl (pH 7.4) was flowed through the system at 0.5 ml/minute until a stable baseline was achieved. To activate the surface of the waveguide two injections of 2.5 % glutaraldehyde (aq) (50 and 100 μL respectively) were performed. The temperature of the system was

then increased from 25 to 37°C and once the baseline stabilised, 50 μL CG3K dendron (2 mg/ml) was then injected, the baseline then stabilised. Next an injection of 20 μL DNA plasmid (450.17 ng/ μL) was performed.

RESULTS AND DISCUSSION

CG3K (MW 2043.7) was successfully synthesised from results of analytical HPLC single peak at 10.5 minutes and mTOF MS ($[\text{CG3K}]^{4+}$ 511.4 m/z). The yield was 130 mg at <90% purity. From the OWLS experiments (Figure 1), it was found that 38.5 ng/ cm^2 of CG3K dendron was bound to the surface this was able to bind 39.4 ng/ cm^2 DNA plasmid. These surface coverage (ng/ cm^2) values equate to 1.55 ng (0.76 pmoles) CG3K dendron and 1.587 ng (3.63×10^{-4} pmol) DNA plasmid. Which equates to a molar ratio of 2093:1.

Figure 1 OWLS binding of DNA plasmid to CG3K dendron attached to surface of waveguide.

(GA = 2.5 % glutaraldehyde)

CONCLUSION

Optical Waveguide Lightmode Spectroscopy was shown to be effective in following, in real-time, the binding between the CG3K dendron and the DNA plasmid. This shows that lower generation poly (ϵ -lysine) dendrons may be utilised for the effective binding of DNA plasmids as non-viral delivery systems.

The Atomic-Scale Structure of Bio-Resorbable Glasses: $\text{Na}_2\text{O}:\text{P}_2\text{O}_5$

INTRODUCTION

Diffraction has become an important tool for determining the atomic-scale structure of materials and advanced instrumentation has made the collection of high quality data possible. However, analysis and interpretation of that data can be difficult, particularly where the material has a complicated structure. Bioactive glasses fall into this category: they are necessary amorphous and usually comprise several elements. Thus, a single experimental method is not sufficient for an understanding of their structure. Moreover, the results from such structural probe methods are intrinsically one-dimensional: models of the 3D arrangement of atoms may only be inferred.

Neutron diffraction, ND, provides a quantitative insight into the overall structure of such materials and offers some distinct advantages as a structural probe. Use of a pulsed source, for example, offers a particularly wide dynamic range to the resultant interference function and therefore unparalleled resolution to real-space pair distribution functions; neutron scattering cross sections usefully do not vary monotonically across the Periodic Table (*c.f.* X-ray diffraction, XRD) and they are, moreover, isotope-dependant.¹

Phosphate based glasses have many unique properties, the most interesting of which, from a biomedical standpoint, is their ability to dissolve completely in aqueous media; this behaviour may be controlled via the chemistry of the glasses. We present here a study of the atomic-scale structure of a $(\text{Na}_2\text{O})_{0.5}(\text{P}_2\text{O}_5)_{0.5}$ bio-resorbable and bio-compatible glass using the complementarity of ND and XRD data. The data is used within the Reverse Monte Carlo, RMC, computer modelling approach whereby the simultaneous fitting of both data sets provides a more robust 3D model structure than would be attainable with one data set alone.² Experimental data from glasses of composition $(\text{CaO})_{0.5-x}(\text{Na}_2\text{O})_x(\text{P}_2\text{O}_5)_{0.5}$, where ($x = 0, 0.1$ and 0.5), will be used to provide additional insight.³

EXPERIMENTAL METHODS

The phosphate glasses were prepared using NaH_2PO_4 , CaCO_3 and P_2O_5 . The precursors were placed in a Pt/10%Rh crucible and loaded into a pre-heated furnace at 300°C ; it was melted at 1100°C for 1 h. The molten glass was then poured into a pre-heated (370°C) graphite mould, and left to cool to room temperature. Elemental analysis (ICP-AES and gravimetric) and macroscopic density (He pycnometry) characterization was undertaken. ND data were collected on the GEM diffractometer on the ISIS spallation neutron source at the Rutherford Appleton Laboratory, UK. The samples were in the form of 8 mm diameter rods; time-of-flight

data were collected over a wide range of Q (up to 60 \AA^{-1} , where $Q = 4\pi \sin \theta/\lambda$; note: $\Delta r \sim 2\pi/Q_{\text{max}}$).

RESULTS AND DISCUSSION

“Figure 1. ND data from $(\text{Na}_2\text{O})_{0.5}(\text{P}_2\text{O}_5)_{0.5}$ glass: (a) interference function, $i(Q)$, and (b) pair distribution function, $T(r)$, (solid) together with fit (dashed)”

The results illustrated in Fig. 1 have been used within RMC modelling; they suggest that the glass has a structure based on chains of Q^2 phosphate groups. The P–O bonds to bridging and non-bridging oxygens are better resolved than in ND data from samples containing CaO, indicating a change in the nature of the bonding as the field strength of the cation increases decreases. The NaO_x polyhedra evidently share edges, leading to a well-defined $\text{Na}\cdots\text{Na}$ correlation. This model is consistent with the theory proposed by Hoppe *et al* for cation inclusion into phosphates.⁴

CONCLUSION

RMC modelling provides direct evidence of edge-sharing by the NaO_x polyhedra leading to a well-defined Na - Na correlation, as predicted by the established structural model of Hoppe.

INTRODUCTION

Hydroxyapatite (HA) being the mineral phase of bone has been widely used as synthetic material in orthopaedic and dental applications. Recently, more and more efforts have been made to explore the potential of using hydroxyapatite nanoparticles (NPs) as the carrier for drug and genes due to its good affinity to DNA and various drug molecules¹. Since gene and drug delivery are dependent on cellular uptake, understanding the interaction of HA nanoparticles with cells is crucial for such applications². Although there have been various groups that have focused their attention to studying the effect of nanoparticle size, morphology and surface charge on cells, very few works have been devoted to investigating how the composition of HA nanoparticles affect the cellular behaviour. In the present work, strontium (Sr), zinc (Zn), silicon (Si) and iron (Fe)-doped HA nanoparticles were synthesized by wet chemical precipitation, and fully characterized. The same synthesis route was applied to allow comparison of the NPs. The interaction of the various NPs with cells will be further investigated to assess their cytotoxicity and potential as delivery vehicle.

EXPERIMENTAL METHODS

To synthesize hydroxyapatite, 2.475g $\text{Ca}(\text{OH})_2$ was magnetically stirred in 100ml water to obtain a homogenous suspension. H_3PO_4 (0.2mol/L) was added dropwise (1mL/min) to the $\text{Ca}(\text{OH})_2$ suspension until the pH value was 7.9. The solution was stirred for a further 20 min and left overnight for maturation. The precipitate was then washed with milliQ water until constant conductivity and freeze dried.

For the preparation of the cation substituted HA, the salt of interest ($\text{SrCl}_2 \cdot 6\text{H}_2\text{O}$, ZnCl_2 or $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$) was first mixed with the $\text{Ca}(\text{OH})_2$ and for the synthesis of Si-doped hydroxyapatite, tetraethyl orthosilicate (TEOS) was mixed with H_3PO_4 . Various salt concentrations ranging from 1-30wt% were explored. Characterization of the NPs comprised X-ray diffraction (XRD), Fourier infrared spectroscopy, He pycnometry, N_2 adsorption and transmission electron microscopy (TEM).

RESULTS AND DISCUSSION

Analysis by XRD of all NPs showed that indeed the NPs were phase pure as only peaks corresponding to HA could be identified (Fig.1). A careful look at the peak corresponding to the (002) reflection (26° 2θ angle) showed a gradual shift depending on the concentration of the doping ion and a change in shift direction depending on the type of ion (Fig.1). These shifts were interpreted as the efficient incorporation of the doping ion in the crystal lattice of HA. The different

dimension of the doping ions is in fact responsible for the differences in shift direction. Along with the shifting of the peaks, the incorporation of the doping ions was also found to alter the crystallinity of the NPs. This was observed from a change in the width of the peaks. The morphological evaluation of the NPs as observed by TEM (Fig.2) suggested that the doping ion had little influence on the morphology of NPs as in all cases they kept their needle like structure. The specific surface area (SSA) of Zn-doped HA ($135 \text{ m}^2/\text{g}$) and Fe-doped HA ($150 \text{ m}^2/\text{g}$) were greater than the values obtained for the rest of NPs ($100 \text{ m}^2/\text{g}$). This was explained by a reduction in size of the needle-like NPs as can be seen from the TEM micrographs.

Fig. 1. XRD of the various ion-doped NPs.

Fig. 2. TEM micrographs of the NPs. Scale bar 200 nm.

CONCLUSION

Doping of HA with different contents of Zn, Fe, Sr, and Si was successfully accomplished by wet precipitation synthesis. The various NPs with different contents of doping ion show similar morphologies. These NPs will be tested for cytotoxicity to evaluate their adequacy in drug and gene delivery applications.

INTRODUCTION

Cardiovascular bare-metal stents (BMS) main drawbacks are restenosis and in-stent thrombogenicity diseases after 6 months implantation. Nano and microscale modification of implant surfaces is a strategy to recover the functionality of the artery by stimulating and guiding molecular and biological processes at the implant/tissue interface^{1,2}. However, the optimal topographical conditions that aim to induce an active and healthy endothelium without generating platelet agglomeration remain to be elucidated. Few techniques are available to create metallic surface patterns with low depths compatible with a low platelet adhesion rate, - inferior to 300 nm³. In this study, CoCr alloy surfaces are modified via laser interference surface structuring, L.I.S.S., in order to regenerate the damaged endothelium and to modulate platelet response.

EXPERIMENTAL METHODS

Polished CoCr alloy (ASTM F90) discs were topographically modified by L.I.S.S. based on a Nd:YAG laser (Spectra Physics Quanta-Ray PRO210) used at $\lambda = 355$ nm, $f = 10$ Hz and $t_{\text{pulse}} = 10$ ns. Surfaces were structured with multiple, adjacent one pulse spots of 1×1 mm² each. Laser fluencies from 0,8 up to 5,0 J/cm² were applied to obtain different pattern depths. SEM, interferometry, AFM, contact angle and XPS were used to determine surface patterns physico-chemical characteristics. Fibronectin adsorption, 40 µg/ml 4h, and HUVEC adhesion, 24 h, were visualized by classical fluorescence and SEM. Thrombogenicity was evaluated through platelet adhesion and aggregation, by circulating human blood onto patterned surfaces using a flat chamber perfusion at 75 ml/min during 5 min and 37°C to then, stain by immunofluorescence. Polished surfaces were used as control.

RESULTS AND DISCUSSION

CoCr alloy surfaces were polished ($R_a = 6.8 \pm 2.0$ nm) and successfully nanopatterned by L.I.S.S., with different periodicities P ($\approx 3, 10, 20$ and 32 µm) and depths D (Low, $L \approx 20$ nm and High, $H \approx 800$ nm). The 8 obtained patterns were named: 3/L; 3/H; 10/L; 10/H; 20/L; 20/H; 32/L and 32/H. SEM and interferometry

PSD analysis confirmed the periodicity and the homogeneity for all the obtained patterns except 3/H which showed some totally melted areas due to the application of high fluency. High depth structures, present a thicker oxide layer overall the topography, as determined by XPS. Whereas, low series show a chemical pattern with topography: valleys have a thicker oxide layer compared to control. XPS analysis indicated an increase of hydroxyl groups on patterned surfaces, which could influence surface energy and wettability. Anisotropic wetting character, due to chemical and topographical pattern, was identified. No changes of the material corrosion resistance were detected by electrochemical testing.

HUVEC cell adhesion and morphology is affected by surface topography periodicity and depth. In particular, low depth patterns stimulated cell adhesion by a higher spreading and number compared to control. Moreover, 10 and 20 µm periodicities surfaces present cell alignment morphology following pattern's lines. HUVEC cells adhered preferentially to pattern peaks on high depth structures, probably due to a higher fibronectin adsorption while at low series the protein adsorption is homogeneous, as detected by fluorescence. Platelet adhesion and aggregation was affected by topography periodicities and depths.

CONCLUSION

L.I.S.S. technique allows obtaining a CoCr surface microscale patterns with nanodepth grooves. Laser patternings affect physico-chemical surface properties according to the applied fluency. HUVEC cell adhesion and thrombogenicity can be controlled by surface nanopatterning.

Cell Spraying Approach *in vitro* for Coating of Respiratory Tissue Engineered Constructs

A. L. Thiebes¹, S. Albers¹, S. Jockenhoevel¹ and C. G. Cornelissen^{1,2}

¹Tissue Engineering and Textile Implants, AME, Helmholtz-Institute, RWTH Aachen University, Germany

²Internal Medicine I – Section Pneumology, University Hospital Aachen, Aachen, Germany, thiebes@hia.rwth-aachen.de

INTRODUCTION

Spray coating of cells was first proposed by Bahoric et al. in 1997 for application of epidermal cells to burn wounds¹. Since then, research continued with a focus on application of dermal cells in wound models. Some groups also investigated spray application of cells for tissue engineering. Kaminski et al. proposed endothelial cell spraying for coating of tissue engineered heart valves².

Here, we present an *in vitro* study on survival rates and differentiation of ovine vascular smooth muscle cells (vSMCs) and respiratory epithelial cells (RECs) after spraying with a spray system clinically used for spray application of fibrin gel. The influence of air pressure on vSMC survival was studied and the differentiation of vSMCs and survival and differentiation of RECs assessed with the best spraying pressure.

EXPERIMENTAL METHODS

For our experiments, we used the Tisseel EASYSpray Set (Baxter, USA). In the first experiment, the pressure was changed to find out the influence on vSMC survival. For all following experiments the pressure was set to 0.4 bar. For all experiments, an amount of 200 µl cell suspension was sprayed in one well of a 12-well plate with a concentration of $9.8 \cdot 10^5$ and $1.6 \cdot 10^6$ cells/mL for ovine vSMCs and RECs, respectively which corresponds to a seeding density of $5 \cdot 10^4$ and $8 \cdot 10^4$ cells/cm². As a negative control, air pressure was set to 0 bar. Living cells were stained with Calcein AM for 30-60 minutes at 37°C prior to the experiment. Afterwards, propidium iodide solution was added to stain dead cells. A sample number of 5 was used for all experiments. For automatized analysis, images were processed with a macro for counting particles in ImageJ. Statistical significance was tested with an unpaired, two-tailed student's t-test. A p-value below 0.05 was considered significant. Differentiation of the cells was shown with immunohistological stainings with antibodies against α -smooth muscle actin (α -SMA) and pan-cytokeratin.

RESULTS AND DISCUSSION

Figure 1 shows the different survival rates of varying air pressures for spraying vSMCs. In contrast to pressures between 1.2 and 2.0 bar where survival rates were 57.9-87.9 %, pressures of 0.4 and 0.8 bar have shown no significant difference on the survival compared to the control with survival rates of 99-100 %. Thus, the following experiments were accomplished with air pressures of 0.4 bar.

For RECs the survival rate with 0.4 bar was 88.5 % of the control.

Figure 1: Survival of vSMCs depending on the air pressure when spraying.

In further experiments sprayed and non-sprayed vSMCs and RECs were cultured 3-5 days and stained for α -SMA and pan-cytokeratin, respectively. Sprayed and non-sprayed vSMCs showed uniform expression of α -SMA which indicates differentiation. Same applies for RECs with pan-cytokeratin.

These results imply that spray application is highly suitable for respiratory tissue engineering. With a simple spraying system which is approved for clinical use cells could be easily sprayed. As shown by Cornelissen et al. fibrin gel proves as a good scaffold for tissue engineering of respiratory epithelial cells³. Thus, experiments will be continued by combined spraying of cells with fibrin gel to allow proper attachment of the cells to tissue engineered constructs.

CONCLUSION

This study provides the evidence that spray application of cells is suitable for respiratory tissue engineering with ovine epithelial cells. We have shown the influence of varying air pressures on survival and differentiation potential of cells after spray processing with survival rates of up to 100 % and 88.5 % compared to the controls for vSMCs and RECs, respectively.

³Dept. of Biomedical Engineering, University of Groningen, Groningen, The Netherlands;

a.i.bochynska@utwente.nl

INTRODUCTION

Meniscus tears are one of the most common knee injuries. They result in pain, swelling and locking of the knee joint, and eventually may lead to osteoarthritis. Currently, the gold standard technique to repair a torn meniscus is suturing. However, the procedure is complicated, time consuming and expensive. Furthermore, the success rate of suturing in the avascular inner zone of the meniscus is low. Therefore, there is an urgent need for a new method to repair a torn meniscus. Tissue adhesives are considered to be a promising solution, since they are easy to apply and cause minimal tissue trauma. It has been previously reported that isocyanate-terminated copolymers based on poly(ethylene glycol) (PEG) and biodegradable trimethylene carbonate (TMC) can be successfully used as such tissue adhesives¹. In this study we designed and evaluated novel hyper-branched isocyanate-terminated copolymers. The mechanical and adhesive properties of the formed networks were tuned by varying the composition and the degree of branching of the structures.

EXPERIMENTAL METHODS

Oligomers were synthesized by ring opening polymerization of TMC using PEG as initiator. Subsequently, these oligomers were reacted with different amounts of citric acid (CA) to introduce diverse degrees of branching. The hydrophilicity was adjusted by varying both the molecular weight of the PEG (200 or 600 g/mol) and the amount of TMC coupled to it (one or two units per arm of PEG). Reactive copolymers were synthesized by functionalizing the terminal groups of the oligomers with hexamethylene diisocyanate (HDI). The resulting networks were evaluated in a tensile tests and their potential as tissue adhesives was assessed in a lap shear adhesion test using bovine meniscus tissue. *In vitro* degradation both in PBS and cholesterol esterase (CE) solutions over a period of 4 weeks was evaluated. The effect of adding reactive oligomers on cell viability was assessed using bovine meniscus cells with an Alamar Blue[®] reduction assay in a trans-well system.

RESULTS AND DISCUSSION

The experimental results showed that the shear adhesive strength of the networks to bovine meniscus tissue was between 20 to 100 kPa. This shows a strong influence of the design of the network precursors on the adhesive strength of the glue. The elastic modulus of the obtained polyurethane networks varied from 1.5 to 45 MPa, which is in the same range of values as that of soft tissues. Degradation of the networks both in PBS and in CE solutions showed higher degradation rates for the networks based on PEG₆₀₀ (mass loss up to 30%) than PEG₂₀₀ (9%), indicating the effect of the different network compositions. The cell viability study after 1, 3 and 7 days showed that cell viability is dependent on the amount of reactive oligomer administered to medium with cells. At lower quantities (up to 3mg of reactive oligomer/mL of medium) cell viability was not affected, but decreased to 60% when a higher amount of 12 mg/mL was added.

CONCLUSION

We showed that the proposed isocyanate based networks are favorable candidates to be used as resorbable and biocompatible tissue adhesives for meniscus repair. They have satisfactory adhesive and mechanical properties after curing. These properties can be adjusted by varying the composition and architectural design of the copolymer precursors. In the future experiments we will focus on the biomechanical evaluation in a joint environment in cadaveric knees and *in vivo* in a relevant animal model.

Impact of Surface Treatment on the Properties of Dental Implant Materials

M. Murphy¹, R. Lindsay¹, A. Thomas² and N. Silikas³

¹School of Materials, University of Manchester, UK,

²School of Physics, University of Manchester, UK,

³School of Dentistry, University of Manchester, UK
matthew.murphy-2@postgrad.manchester.ac.uk

INTRODUCTION

Dental implant materials are being constantly developed to meet the demands of dentists and patients alike. One area of significant activity is the engineering of their surface properties to improve the reliability and rate of healing.

In this work two different commercial implants (developed by Straumann) have been studied, namely SLA and SLActive. The implants are fabricated from either CP-Ti or Ti/Zr-alloy. Both types have similar longer-term stability, but differ considerably in terms of initial osseointegration rates, i.e. SLActive achieves a much higher degree of bone-implant contact after 2-4 weeks compared to SLA¹.

Concerning surface engineering, initially both implant types are sandblasted and acid etched. The procedure only diverges in the final step, where SLActive is cleaned under N₂ and stored in saline, whilst SLA is cleaned and stored in air. Subsequent to such processing, SLActive is found to be hydrophilic, and SLA hydrophobic. It has been suggested that this difference is a result of saline immersion preventing the deposition of atmospheric carbon onto the SLActive implant, which may underpin improved osseointegration kinetics². However, further substrate characterisation is required to fully understand the performance of these implants, including the impact of nanometre-sized features previously observed on SLActive³. On this basis, the aim of this work is to further characterise these surfaces in order to understand the effect of storage in saline solution on surface structure and chemistry.

EXPERIMENTAL METHODS

Various Ti and Ti/Zr samples (~ 5 mm diameter discs) were prepared by Institut Straumann AG to facilitate studying the impact of different stages of surface engineering. Surface topography was studied using white light interferometric microscopy and SEM. XRD was used to understand the effect of the surface treatment on the bulk material, and Raman spectroscopy was employed to reveal surface phases.

RESULTS AND DISCUSSION

Clear differences were observed between samples with different surface treatments. Three tiers of structures were observed on SLActive samples: 10-20 µm pits created by sand blasting; 1-5 µm sized pits were

obtained through acid etching; 20 nm particles formed during storage in saline. The diameter of the pits and nano-size features was observed to be different on the CP-Ti and Ti/Zr-alloy samples, resulting in a difference in roughness, CP-Ti SLActive S_a=3.23 µm and Ti/Zr-alloy SLActive S_a=1.99 µm. SLA surfaces lacked the presence of the nano-size features.

Figure 1: Example of Raman spectra obtained from various areas on CP-Ti SLActive

No crystalline oxide phases were observed on CP-Ti SLA substrates, whereas all other samples exhibited a mixture of amorphous/rutile/anatase TiO₂ (see figure 1). XRD demonstrated that acid etching introduced hydrogen into the matrix, which resulted in partial conversion of α -Ti grains into δ -TiH₂.

CONCLUSION

As may be expected, both sandblasting and acid etching increase surface roughness. Non-uniform surface crystallinity was observed on all the samples except CP-Ti SLA. The SLActive treatment creates a hydrophilic surface on both CP-Ti and Ti/Zr-alloy. This treatment also creates additional nanosized features, compared to SLA. The presence of these features on SLActive surfaces and differences to surface oxide phases suggest that rather than acting as merely a protective environment, storage in saline modifies the surfaces.

INTRODUCTION

Infection limits the success of orthopaedic implants in a small but significant percentage of patients. Treatment of implant related bone infection requires high local concentrations of antibiotic over an extended period. The ability of certain strains of bacteria (e.g. *Staphylococcus aureus*) to invade and survive within osteoblasts [1] further complicates treatment, as many antibiotic agents do not penetrate the eukaryotic cell membrane. We hypothesised that by hydrophobic modification of a commonly used antibiotic, gentamicin-sulphate (GEN-SULPH), its release can be extended and intracellular targeting achieved. Here we present the preparation of monodisperse microspheres loaded with hydrophobic modified gentamicin (GEN-AOT) as a potential delivery system in the treatment of orthopaedic infections.

EXPERIMENTAL METHODS

Preparation of GEN-AOT

Hydrophobic ion-pairing of GEN with dioctyl sodium sulfosuccinate (AOT) was performed by adding equal volumes of a GEN-SULPH solution in buffer (10mM sodium acetate, KCl and CaCl₂ (pH 5)) (0.40 w/v %) to AOT in DCM (1.25 w/v %). This solution was stirred vigorously for 3h and left for 0.5h for the two phases to separate. GEN-AOT was isolated from the DCM layer.

Toxicity towards human fibroblast cell line

The effect of GEN-AOT on cell-viability was assessed by an assay with cell titer blue. Viability of hTERT BJ-1 fibroblasts was assessed after 24h and 72h culture by measuring the fluorescence intensity (FI).

Antimicrobial susceptibility testing

S. aureus NCTC 12973 (SA), *Escherichia coli* NCTC 12241 (EC) and *S. epidermidis* 103.1 (SE) were selected for testing. Antibiotic solutions were prepared in Cation adjusted Mueller Hinton broth, in a concentration range of 0.06 – 256 µg/ml for GEN-SULPH. AOT and GEN-AOT solutions were prepared in an equimolar range with GEN-SULPH. Minimum inhibitory (MIC) and minimum bactericidal (MBC) concentration were determined according to NCCLS M7-A5 guidelines for bacteria that grow aerobically.

Preparation of antibiotic loaded microspheres

For the preparation of monodisperse antibiotic loaded Poly(trimethylene carbonate) (PTMC) and Poly(D,L-lactide) (PDLLA) microspheres (MSs) a microsievetm emulsification technology of Nanomi(The Netherlands) was used. 1% PTMC and PDLLA solutions were used, to which 20% GEN-AOT was added for the preparation of GEN-AOT loaded MSs. These solutions were given into the feed for the microsievetm emulsification device.

RESULTS AND DISCUSSION

The antibiotic GEN-SULPH showed low toxicity towards fibroblasts even at high concentration. On the contrary, hydrophobic GEN-AOT, showed reduced viability at lower concentrations, at 11×10^{-6} M cell viability was reduced with ~50% (figure 1).

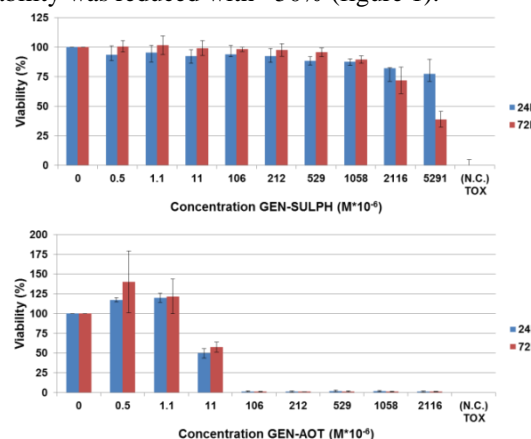

Figure 1. hTERT BJ-1 fibroblast viability

An explanation could be found in the location of action, as GEN-AOT should be able to act intracellularly.

Table 1. Susceptibilities for GEN-AOT

	S.aureus NCTC 12973		S.epidermidis 103.1		E.coli NCTC 12241	
	MIC (µg/ml)	MBC (µg/ml)	MIC (µg/ml)	MBC (µg/ml)	MIC (µg/ml)	MBC (µg/ml)
GEN-SULPH	2	8	0.5	4	8	8
GEN-AOT	5.7	22.7	1.4	1.4	11.4	22.7
AOT	242	242	242	>242	>242	>242

Both GEN-SULPH and GEN-AOT were able to inhibit SA and SE at equal molar concentration (Table 1) (2.1×10^{-6} M (SA) and 0.5×10^{-6} M (SE)). However, GEN-AOT seems to be more bactericidal for SE at lower molar concentration than GEN-SULPH.

Figure 3. Monodisperse PDLLA and PTMC MSs loaded with GEN-AOT

Highly monodisperse GEN-SULPH and GEN-AOT loaded PDLLA and PTMC MSs were produced (fig 3).

CONCLUSION

Studies are ongoing to investigate the release and bactericidal efficacy of the GEN-AOT loaded MSs. Also an intracellular infection model will be used to test the intracellular activity of GEN-AOT.

Retention of Myoblast Differentiation Capacity in 3D Culture on TIPS Microspheres

Nina Parmar, Richard Day

Applied Biomedical Engineering Group, Division of Medicine, University College London, UK
nina.parmar@ucl.ac.uk

INTRODUCTION

Faecal incontinence (FI) is often attributed to injury of anal sphincter muscles and regenerative medicine treatments are sought. Cell therapy is an emerging option but to date has been unsuccessful.

Highly porous microspheres produced using Thermally Induced Phase Separation (TIPS) have features ideally suited for cell delivery^{1, 2}. We report our findings on the study of attaching primary cultures of human skeletal muscle myoblasts (HSMM) to TIPS microspheres and the ability to retain control of cell proliferation and differentiation *in vitro*.

EXPERIMENTAL METHODS

Poly-DL(lactide-co-glycolide) (75:25) dissolved in dimethylcarbonate (1:24) (w/v) was used to fabricate TIPS microspheres measuring 250-425 μM . Static-dynamic incubation conditions were used to attach primary cultures of HSMM followed by static-dynamic incubation for 7 days in culture medium to induce either cell proliferative or differentiation.

The proliferative/differentiation status of HSMM cells was investigated using PCR and in-cell Western analysis of specific myogenic proliferation and differentiation markers (Ki67, Pax7, MyoD, myogenin, desmin, myosin and myosin heavy chain). The profile of these markers was assessed in HSMM attached to TIPS microspheres at days 1 and 7 incubation in proliferation medium compared with those incubated in differentiation medium for 7 days.

A bromodeoxyuridine (BrdU) cell proliferation assay was performed on HSMM-TIPS microspheres attached for 1-7 days.

RESULTS AND DISCUSSION

Quantitative analysis of the gene and protein profiles of myoblasts attached to TIPS microspheres incubated under proliferation conditions for either 1 or 7 days resulted in the consistent expression of myogenic proliferation markers Ki67, Pax7, MyoD, myogenin. This result was verified by data from the BrdU assay over 1-7 days. These data demonstrate the use of TIPS microspheres to retain the proliferative capacity of myoblasts *in vitro*.

HSMM-attached to TIPS microspheres and incubated in differentiation medium for 7 days resulted in the increased expression of Ki67, Pax7, MyoD, myogenin, desmin and myosin heavy chain compared with control cells incubated on tissue culture plastic.

CONCLUSION

This study demonstrates the ability to attach primary human myoblast cells to TIPS microspheres. Once attached, myoblasts retain their capacity to either proliferate or differentiate under controlled conditions. These data are important for future use in cell therapy applications.

Czech Republic, fojtj@vscht.cz

¹UJP Prague, Czech Republic

INTRODUCTION

To increase an implant lifetime, researchers are now concerned on the development of new titanium alloys with suitable mechanical properties (low elastic modulus, high fatigue strength), corrosion resistance and good workability. Titanium exhibits an excellent corrosion resistance in human body environment due to the formation of a stable oxide film on the surface. However, despite this fact and good tissue acceptance, high Young modulus of titanium is not comparable with bone. While the elastic modulus of cortical bone is close to 20 GPa, the modulus of titanium is 116 GPa. To increase implants lifetime new titanium alloys with lower Young modulus, good workability and high corrosion resistance are now developed. Corrosion resistance of these alloys should be comparable with that of pure titanium.

The aim of this project was to study microstructure, mechanical properties and corrosion behaviour of two beta titanium alloys Ti-35Nb-2Zr and Ti-35Nb-2Zr-0.4O.

EXPERIMENTAL METHODS

Metallographic study and mechanical properties measurement were based on standard procedures. Corrosion behaviour was measured in physiological saline solution and, with respect to possible use of these materials in dentistry, in the same solution with decreased pH and fluoride ions added. Electrochemical measurements consist of the open circuit potential, electrochemical impedance (60 kHz – 1 mHz, 10 mV amplitude) and potentiodynamic curves measurement. Surface chemistry was evaluated by X-ray photoelectron spectroscopy (XPS).

RESULTS AND DISCUSSION

The structure of Ti-35Nb-2Zr-0.4O (TNZO) and Ti-35Nb-2Zr (TNZ) is beta and deformed martensitic structure respectively. Tensile strength was 807 MPa for TNZ and 1227 MPa for TNZO. More important were Young modulus values. They were over twice lower in comparison with pure titanium or Ti-6Al-4V alloy - 47 GPa and 61 GPa for TNZ and TNZO respectively. It is evident that presence of oxygen has significant impact on both structure of material and its mechanical properties.

Corrosion resistance was compared with that of commercially pure titanium. Passive layer of non exposed specimens was slightly enriched, in comparison with bulk material, by niobium (XPS). Open circuit potential level of both alloys and titanium indicates passive state of all materials during exposure in physiological solution. It was also confirmed by XPS analysis - all alloys components were present in the

highest oxidation state. Addition of 5000 ppm of fluoride ions caused general decrease of corrosion resistance. This change was the most significant in the case of titanium, corrosion resistance of beta alloys was significantly higher. This behaviour is probably caused by presence of niobium and zirconium in passive layer detected by XPS.

Analysis of electrochemical impedance spectroscopy data from pure saline solution showed that surface of alloys consists of compact inner layer overlaid by porous layer. Situation was more complicated in the case of electrolytes with decreased pH and fluorides added. There was thick porous layer of precipitated corrosion products on titanium surface which negatively affected corrosion resistance of samples. Precipitation of corrosion products was detected on alloys too; however, in this case the corrosion resistance was significantly higher. There were detected increased concentrations of niobium in passive layer; therefore one can assume preferential dissolution of titanium.

Fig. 1. Impedance spectra of studied materials in physiological solution at pH 4.2 with 200 ppm of fluorides ions.

CONCLUSION

New titanium alloys with suitable mechanical properties containing niobium and zirconium were prepared. Corrosion properties were in physiological saline solution comparable with titanium. Corrosion resistance of zirconium containing alloys was significantly better than that of titanium in the presence of fluoride ions.

INTRODUCTION

Currently, the biological fixation of the bone embedded cementless implants is often improved by the application of bioactive coatings (calcium phosphates such as Hap and TCP) on the implant surface (1). However, the thin calcium phosphate layers could exhibit nonhomogeneous porosity, weak adherence to metal substrates, and/or degradation and delamination during a long-term functioning (2). Our aim is to develop a degradable thin layer on titanium (Ti) surfaces based on an alginate carrier containing nanosized bioactive inorganic components (Hap, TCP) and bifunctional bisphosphonates (BF) as a coupling interface. Bioactive components would be available for cells continuously during the coating degradation. Herein we present the results obtained for the first step of the coating process, i.e., the activation of Ti surfaces introducing active groups required for the coupling of stable BF layers following by the coating with a thin alginate layer.

EXPERIMENTAL METHODS

Commercially available Ti or model Ti surfaces were subjected to different physical (solvents) and chemical treatments (chemicals and oxygen plasma) following by a coating with 6-aminohexylidenedihydroxybisphosphonate (BP). Surface properties were analyzed using contact angle analysis, profilometry, SEM, X-ray photoelectron spectroscopy (XPS), spectroscopic ellipsometry (SE) and infrared spectroscopy. The morphology and homogeneity of the layers were revealed by SEM, profilometry and atomic force microscopy (AFM). The *in vitro* studies using human osteoblastic cell line Saos-2 are in progress.

RESULTS AND DISCUSSION

The Ti layers were exposed to two acidic and two alkaline surface treatments. Based on XPS analysis, the highest content of Ti in the form of Ti^{4+} as well as the highest content of OH groups was formed by $NH_4OH/H_2O_2/H_2O$ treatment following by exposition to oxygen plasma. The thickness of the upper TiO_2 film on the Ti surface was 21.5 ± 4.6 and the thickness of the bound BP layer was 1.7 ± 0.5 nm. The presence of BP on the Ti surface was proved by XPS (Tab.1) and the BP layer was stable in water conditions for 28 days.

The alginate film was then attached to the Ti surfaces by physisorption in the form of the polyelectrolyte complex or by covalent coupling using EDC/NHS chemistry with a coupling BP layer. The alginate immobilization led to the homogeneous hydrophilic surfaces with randomly distributed agglomerates (Fig.1).

Table 1 XPS analysis of the Ti surface modified by bisphosphonate

Modification of Ti surface	Surface composition % at. (XPS)				
	C	O	Ti	N	P
$NH_4OH/H_2O_2/H_2O$	23.0	59.0	18.0	-	-
NH_4OH treat. + BP	25.5	54.8	13.6	1.7	3.0
Ti model-BP	33.8	46.6	12.7	2.8	2.8

Figure 1 The surface topography of Ti surfaces with covalently bound bisphosphonate layer and after the alginate coating (AFM analysis, $1 \times 1 \mu m$, z-scale 50nm)

The preliminary *in vitro* experiments following the feasibility of the prepared surfaces to support adhesion and proliferation of human osteoblastic cell line Saos-2 are under study.

CONCLUSION

We have developed activation and BP-binding procedures on ‘real life’ and model Ti surfaces. Such activated surfaces were coated with alginate layers via physisorption and/or a covalent immobilization. All modification steps have been carefully investigated by surface-sensitive techniques, such as XPS, SE, IR or AFM. The successful deposition of the alginate coating opens the gate for further modifications of surfaces with biologically active compounds.

INTRODUCTION

Antisense gene therapy with the use of single-stranded oligonucleotides (ONs) holds great therapeutic potential. Especially, splice-correcting oligonucleotides (SCOs) have been recognized as capable of tackling many genetic diseases arising from mutations that produce aberrant alternative splice patterns¹. Although the use of “naked” ONs for cell delivery *in vivo* is possible, development of delivery vectors for this specific class of molecules could further improve their efficiency, attaining a controlled delivery and decreasing toxicity levels. To this end, chitosan, a biodegradable biomaterial based vector, associated with negligible toxicity effects, holds great potential as a nucleic acid carrier, although its efficiency needs further improvements. Furthermore, its potential for delivery of ONs has not been duly investigated². In this work we explored the use of a hydrophobic quaternized chitosan for ON complexation and condensation, as well as mediation of delivery of a SCO *in vitro* in a luciferase splice-correction model cell line, seen as a more reliable method for accessing delivery efficiencies of ONs by different vector types³.

EXPERIMENTAL METHODS

A trimethylchitosan (TMC₄₃, Kitozyme) (Mn 43.3 kDa, 11% DA, 30% quaternization (DQ)) was reacted with succinimidyl-modified stearate (NHS-SA) attaining a modification degree of 2±0.8% (mol%). TMC/ON complexes were prepared at different N/P ratios by a coacervation method aided by SO₄²⁻ crosslinking. Strength of interaction between TMC and ON was determined by gel electrophoresis assay. Size and zeta potential were determined by DLS. DLS was also used to verify the stability of formed complexes in serum containing medium. The extent of cellular association of TMC/ON complexes was analysed by flow cytometry. Transfection efficiency was evaluated by adding complexes to HeLa/Luc705 cells and analysing splice-correction of the mutated Luciferase gene in terms of increased luciferase activity³. All values represent means of at least 3 experiments ± SD.

RESULTS AND DISCUSSION

TMC-SA showed slightly higher interaction strength with ONs in comparison with TMC₄₃ when analysed by gel retention assay. Nevertheless, both TMCs were able to retain the ON with >90% efficiency for N/P >2. The average hydrodynamic diameter of both TMC₄₃/ON and TMC-SA/ON ranged from 100-150 nm with particles at the highest range of size given by higher N/P ratios (N/P >120). Stability of TMC/ON particles after

incubation in serum containing cell medium showed a striking difference between both TMCs. While TMC₄₃/ON particles showed an increase in average size and decreased peak intensity, TMC-SA/ON particles retained almost completely the DLS profile when comparing to non-treated control samples (Fig. 1).

Fig.1: Stability of complexes in serum containing medium analysed by DLS. TMC/ON complexes at N/P 80 were incubated at 37°C for 1h with serum containing cell culture medium.

Transfections with TMC/SCO complexes showed close to 10-fold increase in efficiency of TMC-SA in relation to TMC₄₃, and around half the efficacy when comparing to LipofectamineTM 2000 (Fig. 2)..

Fig. 2: Splice correction activity of TMCs/SCO complexes in HeLa/Luc705 cell line. SCO was used at 0.3 µM final concentration. (n=3, **P=0.019; ***P<0.001)

Flow cytometry showed similar extent of cellular interaction for TMC-SA/ON complexes and Lipofectamine pointing to other mechanisms playing a role in the transfection efficacy differences seen between both vectors.

CONCLUSION

Hydrophobic modification of TMC was found crucial for preparation of stable TMC/ON nanoparticles and produced splice-correction efficient complexes when high N/P ratios (≥80) are used. This is the first report showing the successful use of a chitosan-based biomaterial for improved delivery of a SCO in a splice correction model.

INTRODUCTION

Autologous bone grafts remain the gold standard for treatment of critical size bone defects¹. However, this approach has significant drawbacks; limited supply, a second injury site, increased infection risk. Various materials have been investigated as synthetic bone substitutes. Resorbable α -hydroxyacids are an attractive choice for controlled implant degradation. Copolymers of lactide and glycolide have been widely studied for applications such as resorbable sutures. Copolymers containing the longer chain caprolactone monomer have a longer degradation time, which is tunable with composition². Such materials may be a good choice for a bone substitute material, which should ideally resorb at a rate to match the ingrowth of new bone.

EXPERIMENTAL METHODS

Poly(lactide-co-caprolactone) dimethacrylate (LCM) materials were synthesised by stannous catalyzed ring-opening polymerisation of cyclic caprolactone and the D,L-lactide dimer, using diethylene glycol as the initiator. LCM is a tapered copolymer consisting of crosslinked oligomers of 10 (LCM6.1) or 20 (LCM3,4) monomer units. LCM4 and LCM6.1 materials have a nominal lactide content of 80wt%, LCM3 contains 70wt% lactide. After methacrylation, crosslinking was performed by two methods to give different microstructures. Disc samples were UV-crosslinked. Scaffolds samples were produced by spatially selective two-photon polymerisation, an additive manufacturing technique, to create a well-defined structure from a CAD model. Our chosen structure is a Schwartz P unit cell with cell parameter 500 μ m. Pore interconnectivity gives this structure high permeability - the scale chosen reflects optimum pore size for bone cell migration³.

Primary human osteoprogenitor cells isolated from bone tissue of patients undergoing total knee replacement were cultured for two weeks on gamma-sterilised disc and scaffold samples in 24-well microplates. Cell proliferation was monitored by alamarBlue assay throughout and cell differentiation by ALP staining at Day 7. For disc samples, tissue culture plastic discs of similar size were used as a positive control for good cell response; for scaffolds, a clinically successful bone substitute scaffold, Vitoss, was used as positive control.

RESULTS AND DISCUSSION

For disc samples (Fig 1a), cell proliferation was comparable to the control material for LCM3 and LCM4 materials, suggesting little effect of copolymer composition over the range studied. Cell proliferation

was lower for the LCM6.1 material, perhaps due to lower methacrylation efficiency resulting in an acidic oligomer component. This might be improved by increasing the methacrylate:oligomer ratio.

For scaffold samples (Fig 1b), cell adhesion was lower for the LCM materials than the control, but subsequent proliferation was significantly higher than the Vitoss control, despite its status as a clinically approved bone substitute material. There were no significant differences in attachment or proliferation between the three LCM materials tested, suggesting two-photon polymerisation improves the gel content of the LCM6.1 material compared with 'bulk' UV crosslinking.

Figure 1: alamarBlue intensity, normalised to no cell control, for disc (a) and scaffold (b) samples

Osteoprogenitor cells on all LCM materials showed ALP staining at day 7, indicating support of a more differentiated cell phenotype.

CONCLUSION

Osteoprogenitor cells showed good attachment and proliferation when cultured on the LCM materials in both disc and scaffold form. This is a promising result for the *in vivo* biocompatibility of the LCM materials.

INTRODUCTION

Current strategies for cancer treatment are to design a nanosystem for a delivery of therapeutic agents specifically to the site of tumor, therefore avoiding potential side effects. A silk biomaterial combines superb mechanical properties, biocompatibility and biodegradability [1], thus it can be used as a drug carrier. Moreover, the bioengineered silk protein may be functionalized by fusion of tumor homing peptides [2]. The aim of present study was to obtain novel drug delivery carriers based on functionalized spider silk proteins. The specific aim was the evaluation of physical as well as biological properties of bioengineered spider silk-based particles made of two different silk proteins and their blends.

EXPERIMENTAL METHODS

The bioengineered silk proteins (MS1 and MS2 based on the proteins from *N. clavipes*) and theirs Her2-directing hybrid variants were designed. Obtained proteins were processed into spheres by salting out process [3]. The MS1/MS2 blends were produced in different weight ratios. Spheres were characterized in terms of morphology, size (scanning electron microscopy), secondary structure (FTIR), Zeta potential (ZP), stability (spectrophotometry). The binding (flow cytometry and confocal microscopy) and drug delivery potential of silk particles to cancer cells were investigated. Next, the anticancer therapeutic doxorubicin was incorporated into silk spheres and the cytotoxicity of drug loaded spheres was examined by using MTT assay.

RESULTS AND DISCUSSION

Particles based on MS1 and MS2 proteins demonstrated differences in morphology, stability, zeta potential and binding to targeted cells. The increasing MS2 concentration into MS1/MS2 blend improved physical properties of spheres, however lowered their cell binding efficiency. For 80/20% blends (functionalized MS1/MS2), the binding efficiency was maintained with greatly improved sphere stability.

The spheres made of functionalized spider silk indicated significantly higher binding to the Her2-overexpressing cells (SKOV3, SKBR3) comparing with Her2-negative

cells (MSU1.1) and comparing to control spheres without the targeting domains.

	SKOV3	SKBR3	MSU1.1
MS1/MS2	14.97 (± 7.62)	13.93 (± 2.11)	3.8 (± 2.16)
H2.1MS1/H2.1MS2	64.22 (± 14.14)	74.43 (± 7.16)	14.83 (± 8.18)
H2.2MS1/H2.2MS2	78.63 (± 12.99)	74.53 (± 1.10)	7.63 (± 5.41)

Table 1: Flow cytometry analysis of cell binding assay with functionalized silk spheres indicated as % of binding ± SD.

The functionalized silk spheres loaded with doxorubicin significantly higher reduced the cell viability of Her2-overexpressing cells comparing with Her2-negative cells and comparing to control spheres without the targeting domains.

CONCLUSION

Two different bioengineered silk proteins were examined in terms of sphere formation. We showed that blending process can be used as a controlling factor of particle properties.

Moreover, spheres made of functionalized MS1/MS2 blend were loaded with the model drug and efficiently killed targeted cells.

The obtained results indicated the potential for the delivery of a therapeutic agent confined in silk spheres to the specific tumor microenvironment.

INTRODUCTION

The requirement for rapid high quality bone fusion and the difficulties associated with harvesting autologous bone represent an ever present challenge to orthopaedic surgery. Without intervention at the defect sites, automatic bone formation in such areas may not occur¹. Gold standard interventions include the addition of bone grafts, the administration of growth factors or applying low-intensity pulsed ultrasound¹⁻³. However, even these gold standard interventions are not without problems. Tissue engineering offers an avenue by which the required results can be obtained and surgical disadvantages avoided. Given that bone formation involves stepwise cell-cell and cell-ECM interactions, the regulation of the osteoblast culture microenvironments can tailor osteoblast proliferation and mineralization rates and thus the quality and/or quantity of final calcified tissue. Using substrate chemistry modifications to induce bone aggregate formation in large quantities and with variable sizes, the aim of this study is to identify the variables that control the mineralization process and the quality and spatial distribution of minerals formed in *in vitro* 3D aggregates.

EXPERIMENTAL METHODS

Aggregate Formation

An osteoblast cell line, MLO-A5, was used for aggregate formation. Aggregates of two sizes were formed by adjusting the wettability of polystyrene and creating suspension culture environments of differing hydrophilicities.

Aggregate Analysis

The aggregates were assessed on gene, protein and mineral levels using various analytical techniques. Synchrotron-sourced FTIR analysis was carried out at Diamond Synchrotron, Oxfordshire. Groups were compared using independent T-tests or one-way analysis of variance (ANOVA). A p-value below p=0.05 was denoted to indicate statistical significance.

RESULTS AND DISCUSSION

We show that the development of bone aggregates and the control of aggregate size are two important factors for rapid bone formation. The modification of culture substrate properties that force cells to aggregate can lead to the production of a high quantity of cellular aggregates in a short period of time (24 hours). The degree of substrate modification determines aggregate size (ø79-745µm). Our data demonstrate that cells in an aggregate culture, particularly in larger aggregates, can generate visible and quantifiable mineralized matrix within just 24 hours. The cells in monolayer failed to do so. Synchrotron-sourced FTIR analysis quantitatively measured mineralization levels comparing culture duration and aggregate size effects.

Figure 1: PO₄:Amide 1 ratios displaying differing calcification levels over duration and suspension culture type. CS denotes large aggregates, US denotes small aggregates.

This analysis also offered an insight into the spatial distribution of developing calcification and how it differs between aggregate size and culture duration. SEM-EDX analysis corroborated these data.

Figure 2: FTIR mapping images highlighting the PO₄ regions of 24 hour (left) and 72 hour (right) coated suspension aggregates (large aggregates).

CONCLUSION

This study confirms that aggregate culture is sufficient to induce rapid mineralization and that aggregate size determines the rate of mineralization. In addition, the spatial distribution of mineralisation can be visually identified and quantitatively measured. This bone tissue engineering approach may establish a good model to study regulation factors at different development phases of the osteoblastic lineage.

Generation of Electrospun Yarns for Use as Tissue Engineered Blood Vessel Scaffolds

Richard O'Connor* and Garrett B. McGuinness

Centre for Medical Engineering Research, Dublin City University, Ireland, richard.oconnor2@mail.dcu.ie

INTRODUCTION

Electrospinning is a polymer processing technique capable of producing continuous submicron diameter fibres¹. In a typical electrospinning process a capillary with a metallic spinneret acts as a reservoir for a polymer solution. A high voltage potential is generated between the spinneret and a grounded metallic target. A jet of polymer in turn erupts from the spinneret tip and subsequently deposits on the target². The nanofibre structures produced have been identified as potential scaffolds for tissue engineering applications due to their high surface area-to-volume ratio and high porosity levels^{2,3}. A significant trade-off however is the decrease in a scaffolds mechanical strength when porosity is increased to allow for cellular infiltration³. Studies have shown the capability of producing electrospun nanoyarn structures using dynamic liquid collection techniques⁴⁻⁶. These nanoyarns exhibit an increased porosity and fibre alignment compared to traditional electrospun structures enhancing cell infiltration rates while maintaining mechanical strength⁶. The aim of this study was to produce three-dimensional electrospun nanoyarn constructs for vascular reconstruction applications using poly(ϵ -caprolactone) (PCL) a biodegradable polyester.

EXPERIMENTAL METHODS

14wt% solutions of PCL dissolved in chloroform and ethanol (7:3; v:v) were prepared by stirring overnight at room temperature. A custom built dynamic liquid collection apparatus (Figure 1) based upon Teo *et al.*⁴ was used to produce the electrospun yarn scaffolds.

Figure 1- Dynamic liquid collector apparatus.

Briefly the dynamic liquid collector apparatus consists of a circular tank with an outlet located on the bottom surface. A reservoir tank and pump positioned below the outlet re-circulates water to the upper tank to maintain a constant fluid level. A grounded wire is

inserted into the water to remove residual charge. Electrospun material deposited on the water's surface is drawn downwards by a vortex generated by the draining fluid. This vortex aids in the bundling and alignment of the electrospun material to form a yarn structure. A traversing and rotating mandrel positioned below the outlet is used to collect the yarn material. SEM imaging was performed on samples and fibre diameter measurements ($n=30$) were taken for each scaffold.

RESULTS AND DISCUSSION

Images of an electrospun yarn scaffold and a conventional flat membrane can be observed in Figures 2(a) and 2(b), respectively. Both were produced using 14wt% PCL solutions. The yarn scaffolds exhibited a fibre diameter range of $(2.55 \pm 0.74 \mu\text{m})$ while the flat membranes showed a range of $(2.39 \pm 1.22 \mu\text{m})$. Visible differences in fibre orientation and porosity can be seen with the flat membrane showing a dense random fibre structure compared to the yarn, which exhibits a highly aligned structure with large pores between fibres.

Figure 2- Electrospun structures produced in study (a) Nanoyarn scaffold using dynamic liquid collector (b) Flat membrane using metallic plate target.

CONCLUSION

Electrospun PCL yarns containing micron scale diameter fibres and multi-scale porosity were successfully produced. Further optimisation of the scaffold morphology along with mechanical characterisation is currently being completed with the end goal being the development of a cell seeded scaffold.

Injectable Thermo-responsive Hyaluronan Hydrogel in a Rabbit Osteochondral Defect Model

D. Eglin, M. D'Este, I. Dresing and M. Alini

AO Research Institute Davos, Switzerland and Collaborative Research Partner Acute Cartilage Injury Program of AO Foundation, Switzerland. david.eglin@aofoundation.org

INTRODUCTION

Regeneration of cartilage and osteochondral defects after a trauma is still highly limited². Our main objective is to address the issue by developing a minimally invasive tissue engineered approach. For this we developed a bioresorbable thermo-responsive hyaluronan hydrogel (HApN) which allow for cells encapsulation and *in situ* application, and gelation at 30°C. In this study we assessed the safety and effect of the HApN on the defect repair.

EXPERIMENTAL METHODS

HapN was prepared as previously reported, sterilized and reconstituted at 10 w:v % in PBS¹. The *in vivo* study was approved by the Veterinary Commission of the Canton of Grisons, CH. Skeletally mature female New Zealand White animals [32± 4 weeks, Charles River, Germany] were included in this study and divided randomly into an empty group and a material group (2 x n=6). An osteochondral defect (2,7 mm diameter x 4 mm depth) was created in the central area of the medial trochlear ridge. 100µl of HApN solution was injected through a 19G needle into the defect. After 12 weeks, the rabbits were euthanized, soft tissues collected to assess biocompatibility and the defects evaluated macroscopically. Histology sections of soft tissues were stained with H&E, defects stained with H&E and Safranin-O/Fast green were prepared and scored. Aggrecan, collagen type I and II immunostaining were prepared and analysed. For statistical evaluation (SPSS) Mann Whitney U non-parametric test was performed (p 0.05).

RESULTS AND DISCUSSION

The gelation of the HapN *in vivo* occurred in less than 2 min. Temperature at the joint surface was 33±2°C before and 34±2°C after injection. After 12 weeks, observation of the kidney, liver, spleen, *inn* popliteal and joint capsule histological sections showed no difference between groups. Macroscopic ICRS Cartilage Repair Assessment System score (/12) values were 9.7± 1.0 and 11.1± 1.5 for Empty and HapN group respectively. Both groups were graded as nearly normal. HapN group had a significantly higher macroscopic score than the empty group (p=0.015). Histomorphometrical score values assessed using O'Driscoll's score (/23) were 16.3±1.3 and 18.8±2.1 for Empty and HapN group respectively. HapN group had a significantly higher microscopic score than the empty group (p=0.041). Qualitative analysis of immunostains suggested that the distribution of aggrecan, collagen type I and collagen type II was slightly improved in the HApN compared to empty group. However, collagen type I was present in the whole cartilage repair region.

Figure 1. Representative Safranin-O/Fast green stained histological images of the osteochondral defect at 12 weeks after surgery: Empty (top); HapN (bottom). Scale bar 500µm.

These results indicate the safety of the injectable HApN after 12 weeks. The injectable hyaluronan hydrogel has a potential beneficial effect on the rabbit osteochondral defect repair at 12 weeks.

CONCLUSION

HapN was injected and gelled *in vivo* in an osteochondral defect. The hydrogel was biocompatible. A significant improvement of the architecture and composition of new tissue formed was found compare to empty defect as shown by the results. This matrix could be used for the delivery of potent biologics.

Modification of Porcine Pericardium with Low-Energy Non-thermal Electron Beam

Jessy Schönfelder¹, Eberhard Spörl², Richard Funk³, Christiane Wetzel¹

¹Fraunhofer Institute for Electron Beam and Plasma Technology, Germany, jessy.schoenfelder@fep.fraunhofer.de

²Department of Ophthalmology, University Hospital Dresden, Germany

³Institute of Anatomy, Faculty of Medicine, TU Dresden, Germany

INTRODUCTION

Bovine and porcine pericardium is widely used as implant material, e.g. for heart valves, for patch closure in blood vessel reconstructions or soft tissue repair as it is highly biocompatible¹. Xenogenic biological materials are commonly chemically treated, mostly with glutaraldehyde, to induce crosslinks for enhanced stability, to decrease immunogenicity and to sterilize^{1,2}. In the past concerns arose because of the toxicity and calcification-enhancing properties of glutaraldehyde, especially in biological heart valve prosthesis, which leads to premature deterioration and failure^{2,3}. As an alternative to chemical treatment ionizing irradiation with UV, gamma and electron beam were discussed in the literature⁴. A special method of treatment is irradiation with low-energy (< 300 keV) non-thermal electron beam. The penetration depth of electron beam as well as dose and dose rate can be closely regulated. By randomly inducing radicals the electron beam is able to crosslink and sterilize the material.

The aim of this study was to investigate material alterations after low-energy non-thermal electron beam treatment of porcine pericardium.

EXPERIMENTAL METHODS

Porcine pericardia obtained from a local abattoir from 6 months old pigs were stored in cooled PBS (4...10 °C). Attached fat, blood vessels and pleura pericardiaca were removed. Samples were washed in PBS twice and stored in fresh PBS at 4 °C overnight.

The following day moist samples were irradiated with electron beam of 150 keV in nitrogen atmosphere at 1 bar with varying doses (10...500 kGy). Untreated and glutaraldehyde treated (0.2% for 30 min at RT) samples served as references.

Swelling ratio was determined by dividing the difference between sample moist mass and dry mass by the dry mass. Sample size was 10x10 mm².

Stress-strain curves were determined with a Miniature Materials Tester (Polymer Lab.) on moist 13x10 mm² samples (size between clamps ~8x10 mm²) after pre-stretching to 0.02 N with a speed of 4 mm/s.

SEM was performed on a DSM 962 (Zeiss) after dehydrating with ascending ethanol series and critical point drying with CO₂ in an EM CDP300 (Leica).

At least 6 independent experiments were performed. Mean and SD were calculated.

RESULTS AND DISCUSSION

There was a change in swelling ratio (see fig.). Samples irradiated with doses up to 150 kGy had a lower water uptake compared with untreated samples with a minimum at samples with 100 kGy. The water uptake of these 100 kGy-samples was comparable with glutaraldehyde treated samples. After irradiation with

higher doses swelling ratio was comparable (200, 500 kGy) or even higher (350 kGy) than untreated samples. Crosslinking results in a lower water uptake because of steric hindrances as observed at samples irradiated with doses up to 150 kGy.

Fig.: swelling ratio (see text for explanation)

Stress-strain curves of 100 kGy-irradiated samples were similar to those of glutaraldehyde treated samples. In general, stress-strain curves showed an elongated toe region and a decreasing slope with rising irradiation dose compared to untreated samples. This indicates that especially after irradiation with higher doses (500 kGy) there is an increasing degradation of collagen molecules. This is also supported by SEM images.

SEM revealed that after irradiation with 500 kGy the crimp structure of collagen is nearly completely vanished, whereas after irradiation with 200 kGy the crimp structure appears more aligned compared to untreated samples.

During electron beam irradiation crosslinking as well as degradation of collagen molecules occurs at the same time³. The obtained results indicate that at lower doses up to 100 kGy crosslinking is the major process and at higher doses (500 kGy) it is degradation.

CONCLUSION

Treatment with low-energy non-thermal electron beam is able to alter characteristics of porcine pericardium in a dose-dependent manner.

INTRODUCTION

Metal alloys are used extensively in implants today and there is great interest in the effect of particulate wear debris on the local tissue environment. For example, one area of great concern is the use of metal-on-metal bearings in hip implants, which is associated with significant rise in both the local and systemic levels of particulate wear debris [1,2] and increased risk of aseptic loosening. Literature highlights particles of size ~10µm as the most immunologically relevant, however few studies attempt to track and quantify interactions with the debris at the cellular level. The difficulty encountered is a consequence of the fact that debris can be visually similar to structures within the native cell itself. The focus of this work is to study the cellular uptake of metallic particles in cells, and develop a method for tracking and quantifying particle internalisation.

EXPERIMENTAL METHODS

Wear particle generation: CoCr wear particles were generated by subjecting a CoCr femoral head to 250,000 cycles in a wear simulator using fetal calf albumin as a lubricant. To assess metallic debris as a whole, manufactured metallic powders are used initially to provide a model for various appropriate size ranges.

Cell culture/imaging: MC3T3 cells were cultured, using standard techniques, in live cell imaging dishes. The particles, isolated through centrifugation and re-suspended in phosphate buffered saline with penicillin streptomycin, are then introduced. Imaging is performed through transmission and reflection mode using a Zeiss LSM 710 confocal microscope.

Image analysis: Image analysis consists of two steps, segmentation and tracking. To separate a cell from the background and also the particles close to membrane a contrast enhanced gradient field applied to a bright-field image followed by k-means clustering is used. In order to discriminate the particles from organelles within the cell this is used in conjunction with the reflectance channel. Once particles are isolated, tracking methods such as cross-correlation [3] and direct Gaussian fit [4] can be applied.

RESULTS AND DISCUSSION

Figure 1 shows preliminary segmentation of particles, however the cellular granulation saturates the bright-field image and hence no useful information is gained about particle positions. Nevertheless, the ability to discriminate particles from cells as shown is the first step leading to particle tracking through the cell. However, in order to answer the question posed, co-labelling of various organelles and inhibitory strategies

will be used thus enabling particle fate and cellular entry mechanisms to be determined.

Figure 1: (a) MC3T3 cell exposed to CoCr particles. (b) Contrast enhancement and (c) k-means clustering enabled (d) discrimination of particles (green). (e) Reflection channel (red) registered with the transmission image.

CONCLUSION

A method of metal wear debris tracking from live cell confocal reflectance and fluorescence images has been developed. The method was used as a tool for quantifying debris internalisation at the cellular level and complement immunological assay data (Queen Elizabeth Hospital, Birmingham) to explain the reported effects of metal implants at the tissue level.

INTRODUCTION

For patients with lung failure, the availability of systems for oxygenation and decarboxylation of the blood is mandatory. Currently, oxygenators containing membranes made of polymeric fibres (e.g. polymethylpentene, PMP) are used. Due to the lack of anti-thrombogenic properties of the fibre materials, the occurrence of thrombus formation is likely and decreases the gas exchange rate and the durability of the membrane. Therefore, the endothelialization of the fibre surface is pursued to obtain an anti-thrombogenic surface¹.

EXPERIMENTAL METHODS

Human dermal microvascular cells (HDMECs) isolated from skin biopsies were seeded on both sides of a unmodified PMP fibre mat. After adhesion of the cells under culture conditions, the fibre mat was put into a flow perfusion bioreactor and the cells were cultured for 2 to 7 days under dynamic conditions. Another seeded fibre mat was cultured under static conditions in parallel as a control.

Afterwards, the fibres were assessed for cell coverage and the cells were analysed in terms of viability, proliferation, metabolic activity, monolayer integrity and expression of HDMEC-specific markers. This was done via live-dead staining with fluorescamindiacetat propidium-iodide (FDA/PI), staining of antigen Ki-67, the metabolism of 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), immunofluorescence staining of vascular endothelial cadherin (VE-Cadherin), and staining of PECAM-1 and vWF, respectively. Overall cell coverage of the fibres was evaluated by determining the surface area stained with FDA/PI via ImageJ.

RESULTS AND DISCUSSION

Cell seeding resulted in the coverage of an extended part of the fibres' surface with viable cells, as shown by FDA/PI staining and quantification by ImageJ directly after the adhesion period. After dynamic culture, the cell density on the whole fibre mat was reduced due to the fact that cells were washed away by the media flow. Still, when looking at the FDA/PI staining of the individual sides of the fibre mat, it became obvious that the

cells mainly detached from the fibres' media inflow side. Looking at the opposing side of the fibres, the cells remained on the PMP and even seemed to have proliferated during the culture period. After static, as well as after dynamic culture, the cells on both sides of the fibres showed expression of PECAM-1 and VE-Cadherin. Those proteins, which are found at the intercellular junctions between endothelial cells, are important markers for the integrity of the endothelial monolayer, what is seen as a prerequisite for antithrombogenicity.

CONCLUSION

In contrast to other studies^{2,4}, the experiments showed successful seeding and static culture of endothelial cells on PMP fibres without previous surface modification. Additionally, even after culture under dynamic conditions, viable cells expressing important proteins for monolayer integrity were found on the unmodified fibres. Nevertheless, dynamic culture of the cells significantly reduced the cell number on the fibres in comparison to static culture conditions, what necessitates modification of the fibre surface for improvement of cell adhesion, even under dynamic conditions, to obtain an anti-thrombogenic endothelial cell monolayer.

Influence of TCP Content on Chitosan Agglomerated Scaffold Properties

Martyna Kucharska^{1*}, Katarzyna Walenko², Małgorzata Lewandowska-Szumiel², Tomasz Brynk³, Tomasz Ciach¹

⁴Faculty of Materials Science and Engineering, Warsaw University of Technology, Poland

INTRODUCTION

In hereby presented work a novel technique for bone scaffold preparation is described. This technique is based on the agglomeration of chitosan /composite microspheres. Previously the method was presented [1], however in this work it was modified and simplified. The improvement relied on the reduction of steps in the fabrication process and there was ceramics employed for material improvement. The next modification that was applied was the use of higher DD (deacetylation degree) chitosan, which was found to be more suitable for cell attachment and proliferation [2]. Authors present the method for scaffold fabrication, essential properties of the materials and the influence of various TCP concentrations on material morphology, mechanical properties and preliminary study on the interaction between the materials and HBDCs cultured.

EXPERIMENTAL METHODS

In the first step microspheres (CH, CH_5%TCP and CH_10%TCP) were extruded in the drop forming rate from chitosan solution into precipitation bath. When completely dried they were subjected to agglomeration in presence of acetic acid, then subsequently neutralized, washed and finally dried. In order to evaluate the influence of TCP content on materials morphology and topography they were studied by microscopic techniques. There was also porosity, pore interconnectivity investigated and an effect of ceramics content on the granules size distribution. Mechanical properties were studied by compression tests and were conducted for the materials with the same dimensions. Universal electromechanical testing stand MTS Q / test 10 was employed for the purpose. Cytocompatibility of chitosan scaffolds with three different contents of TCP (0%, 5%, 10%) was investigated in preliminary observation. Human bone derived cells (HBDCs) were cultured in vitro within the scaffolds and cell viability (XTT) was determined after 48h.

RESULTS AND DISCUSSION

The presented technique allows generating porous materials with controllable shape, pore size distribution and their interconnectivity. Volumetric porosity of fabricated materials equals about 40% . Ceramics content significantly affected material microstructure and it was confirmed that increasing TCP concentration significantly influenced the material roughness. Microspheres' size was strongly determined by TCP concentration and it was found that those extruded from pure polymer solution

were much smaller than those made of chitosan and TCP. The diameters of granules from pure chitosan reached 600 – 1000µm. On the other hand, considering CH/TCP material it was established that the diameters were mostly over 1000µm (1000-1450). It was also confirmed that CH_10%TCP material revealed higher percentage contribution (~60%) of diameters reaching out 1450 µm. The influence of ceramics was also studied during mechanical properties evaluation. Young modulus established on the basis of stress-strain curves was similar for all of the materials and reached out 250 MPa. On the other hand we found that compression strength decreased with increasing TCP concentration. Our preliminary study concerning HBDC culture did not show any clear influence of TCP concentration on the viability of the cells, but XTT measured after 48 h revealed values enclosing in the range of 60 and 85% when compared with control sample.

CONCLUSION

In contrast to other methods for porous materials fabrication that were described so far, the presented technique allows manufacturing scaffolds with well-developed surface for cell attachment and well defined architecture. Mechanical properties were found to be similar to natural bones. Satisfactory viability results of HBDCs culture in direct contact with the investigated material were obtained. For the purpose detailed studies on the interaction between the chitosan scaffolds and cells are planned .

INTRODUCTION

The body response to hydroxyapatite (HAp) coatings solely depends on the phase purity, crystallinity, topography and surface characteristics. Besides surface chemical groups, surface charge plays an important role and has shown preferential attachment of osteoblast cells to negatively charged surfaces. Negatively charged polarized HAp has increased the bone growth and implant coverage [1]. These surfaces have not been tested for surface charge and chemical groups, and it has been assumed that the charge is the governing factor in determining the greater bone growth and attachment. This work will use a new approach to introduce aligned hydroxyl groups in the surface.

The aim of this work is to investigate in-situ charge generation of HAp coatings. If HAp dehydroxylates during spraying, then perhaps rehydroxylation can occur after coating, with an additional alignment of hydroxyl groups. Rehydroxylation can be easier by orienting the grains so that hydroxyl ions will directly interface with the biological environment. This double orientation, within the microstructure and the crystal structure of the grains and hydroxyl groups, respectively, will be investigated for advanced coatings. Introducing a textured coating with a controlled hydroxyl orientation offers a new capability for enhancing the properties of HAp.

EXPERIMENTAL METHODS

The HAp powder (particle size of 44 – 55 µm) was delivered from the powder feeder (Metco 4MP-Dual, Perkin Elmer) into a flame spray torch (Casto DynDS 800) operated using acetylene and oxygen, with air as carrier gas. Commercially pure titanium substrates (grit blasted) were positioned 12 cm from the torch and preheated to 250 °C to produce round splats and ensure crystal alignment [2].

Three kinds of experiments were carried out: (1) conventional coating procedure; (2) an electric field was applied during spraying and maintained during steam generation for 10 min after spraying; (3) spraying was performed without an electrical field, but as-sprayed coatings were treated with water vapour for 10 min.

An 8 kV/cm electric field was generated using a high voltage power supply (Series 230, Bertan Associates Inc.). Steam was produced from a boiler (SC 1,050, Kärcher).

The crystal alignment and phase composition of the coated samples were analysed by X-ray diffraction (XRD). Fourier transform infrared spectroscopy (FTIR) and Raman spectroscopy allowed the detection of

functional groups and quantify the [OH] concentration. The microstructure of the samples was examined using scanning electron microscope (SEM). The surface charge was determined from the photoelectron work function measurements.

RESULTS AND DISCUSSION

XRD results showed that all coatings are hydroxyapatite with good crystal alignment and a small amount (~5%) of tricalcium phosphate.

Post treatment with water vapour to restore [OH] in the HAp structure, depleted during the high temperature spraying, was observed with FTIR spectroscopy. FTIR results showed that samples subjected to water vapour contain more [OH] groups in the structure compared to the conventional procedure for coating.

The electric field during the spraying procedure was applied to promote the polarization of the HAp particles which leads to enhanced surface charge, however the conductivity within the flame lowered the effective electric field. Analysis of the electron work function revealed the highest level for the coatings sprayed through the electrical field followed by water vapour treatment also in the electrical field. Based on previous work that shows rehydroxylation on the very surface [3], it is believed that the retention of the electric field assists the orientation of [OH] despite the absence of the higher water vapour level during the initial period of generating steam.

The combination of the oriented grains together with a [OH] guidance mechanism and higher water vapour content is important to optimize the charge on the coating surface. This will further improve the remodeling capability found with oriented coatings [2].

CONCLUSION

In-situ charge generation of thermal spray hydroxyapatite technique was developed. The retention of [OH] in the lattice requires the presence of steam after coating. A higher [OH] content in the structure and electrical field favours polarization in the HAp splats.

INTRODUCTION

Microcarrier systems have been widely used because of their practical and commercial value in the production and delivery of biological substances including vaccines, antibodies, enzymes, hormones and nucleic acids. In recent years, the microcarriers have often been preferred for cell culture studies in tissue engineering applications. Spherical particles provide large surface to volume ratio, consequently, the microcarriers reduce the required space with respect to monolayer cell culture. Suspension culture requires less cell density and culture media [2].

The aim of this study is to prepare and characterize porous hydroxyapatite (HAP) microcarrier system that will serve as both statin and cell delivery system for bone tissue engineering applications.

EXPERIMENTAL METHODS

Preparation of Microcarriers

Microcarriers were prepared by modified W/O emulsion method (1). Briefly, HAP powders were mixed with camphene (Sigma, USA) in a ratio of 1:0.9 (w/w) and stirred with a magnetic stirrer at 60°C. After that, the slurry was mixed with 10% w/v gelatin (Sigma, USA) solution in 2% PVA (Sigma, USA) aqueous solution in the ratio of 1 g HAP powder per 2 ml gelatin solution. After surfactants were added, the whole slurry was dispersed into oil phase and was stirred at 350 rpm overnight. Prepared microcarriers were rapidly solidified in ice cooled bath at 4°C for 5 min. Microcarriers were then filtered and rinsed with ethanol (Sigma, USA). Filtered products were stored at -80°C for 10 minute and camphene was sublimated in freeze dryer overnight. Dried products were sintered at 1250°C for 3 h and left to cool at room temperature.

Drug Encapsulation

Simvastatin (SIM) at a concentration of 1, 0.5, 0.1, 0.01 mg/mL (n=4) in methanol were used for drug loading. 20 mg microcarriers were soaked in a glass tube containing 1 ml of each concentration for 2 hours. Drug loading efficiency was studied by UV-HPLC (High Performance Liquid Chromatography). In vitro release studies are being conducted.

Cell culture Studies

In vitro cell culture studies using unloaded HA microcarriers were conducted with Saos-2 cells. 24 hours after cell seeding, the cells were investigated by SEM (Scanning Electron Microscopy) and CLSM (confocal laser scanning microscopy, Zeiss LSM 510). For confocal imaging, the nuclei and F-actins intermediate filaments of cells were stained with Propidium iodide (PI, red) and fluorescent phalloidin (phalloidin-FITC, green), respectively.

RESULTS AND DISCUSSION

Sintered microcarriers were examined by CLSM. Non-specific FITC staining of microcarriers was also observed. Only nuclei of attached cells were stained. After 24 hour of cell seeding, it was found that the cells were attached and spread on microcarriers surface (Figure 1). Strong signals were observed up to 63 µm from stained cells with PI (as seen in Figure 1) and the intensity of those signals diminished starting from 120 µm. The cell penetration into microcarriers suggests that the interconnectivity is high in porous carriers. Cell growth into the pores was observed in Z-stack analyses with CLSM. Drug loading efficiency decreased when 100µg/mL or lower drug concentration was used for loading.

Figure 1. a. Confocal images of cells and microcarriers. b. Z-stack images of cell attached microcarriers obtained by CLSM.

Figure 2. Sintered microcarriers were shown in SEM image

Table 1. Drug loading amounts

Stock Solution (n=4)	Loading (µg/mg microcarriers)	Drug Encapsulation efficiency
1000µg/mL(1mg/ml)	48 ± 2 µg/mg	96.1 %
500 µg/mL	23.60 ± 2 µg/mg	94.42 %
100 µg/mL	3.23± 2 µg/mg	64.63 %
10 µg/mL	0.4± 2 µg/mg	87.7 %

CONCLUSION

Microcarriers are promising options for drug and cell delivery in bone tissue engineering. Porous microcarriers and their cell compatibility were proved. According to these results, release properties of drug loaded microcarriers and their osteogenic activity on cells will be examined.

INTRODUCTION

Current implant materials may limit bone healing as a result of inflammation, poor vascularisation and improper mechanical strength and durability. Therefore there is a need for a novel material to overcome these limitations. It is hoped a new smart bioactive 3D scaffold containing a biogel with growth factors and calcium phosphate particles will address these concerns. The work presented here shows investigations carried out using monocytes to measure the inflammatory response to poly(lactide-co-caprolactone) dimethacrylate (LCM) that form the scaffolds. Where the amount of caprolactone (CL) and lactide (LA) was varied to compare the osteoconductive material characteristics of slow, acid-free degradation (CL) and a high stiffness (LA) against the disadvantages like softening of the material (CL) and fast degradation with problems of local acidification (LA). Initial work was carried out on solid discs of the material before the polymeric scaffolds were produced and also characterised using primary human monocytes.

EXPERIMENTAL METHODS

LCM was produced consisting of 10 (LCM 6.1) or 20 (LCM 3, 4) monomer units with varying ratios of lactide and caprolactone synthesized by stannous catalyzed ring-opening polymerization of cyclic caprolactone and the D,L-lactide dimer, where diethylene glycol is the starting alcohol. The materials were then either made into discs through UV cross linking or a scaffold with microstructure of 500µm Schwarz P unit cell with pore sizes of around 300µm and a total porosity of 0.66% which was generated by the two-photon polymerization with a Ti:Sapphire femtosecond laser, followed by development in acetone. Prior to use the scaffolds and discs were sterilized using gamma sterilization.

Monocytes were derived from a leukocyte cone (National Blood Service) through density centrifugation with a gradient and then labeling for CD14⁺ monocytes through CD14 antibody coated magnetic bead selection (Miltenyi Biotec). These were then seeded onto the materials (initially discs and later scaffolds) and cultured for up to 7 days, with media removed and replaced at regular intervals to measure the production of TNF- α , IL-6 and LDH. Controls were used including a positive control, lipopolysaccharide (LPS); negative control, cells seeded on tissue culture plastic (TCP); and commercial material Vitoss for scaffolds.

RESULTS AND DISCUSSION

The levels of LDH are shown in *Figure 1*. Levels were similar for each of the polymers.

Figure 1: Levels of LDH present with various samples of LCM (6.1_w indicates samples were pre-wetted, 4₁ and 4₂ indicate differing photo-initiators) and controls

When TNF- α was measured (*Figure 2*) levels were also found to be similar. The levels of IL-6 present were negligible for all samples apart from the LPS positive control (*Figure 3*). Work on scaffolds showed that there were similar responses for small samples ($\approx 8\text{mm}^3$).

Figure 2: Levels of TNF- α present with various samples of LCM (6.1_w indicates samples were pre-wetted, 4₁ and 4₂ indicate differing photo-initiators) and controls.

Figure 3: Levels of IL-6 present with various samples of LCM (6.1_w indicates samples were pre-wetted, 4₁ and 4₂ indicate differing photo-initiators) and controls.

CONCLUSION

The inflammatory response of materials made of LCM with varying monomer composition was investigated using monocytes and found to produce neither an inflammatory nor a cytotoxic response.

A comparison of two approaches to the formation of antibacterial surfaces: doping with bactericidal element vs drug loading

I.V. Batenina¹, D.V. Shtansky¹, Ph.V. Kiryukhantsev-Korneev¹,
A.N. Sheveyko¹, N.Yu. Anisimova² and N.A. Gloushankova²

INTRODUCTION

During the past decade, various advanced materials with bactericidal properties have been developed [1]. Implant-related microbial infection can be reduced by using materials with antimicrobial properties. Comparative investigation of different approaches to surface fictionalization by giving antibacterial characteristics is presented. The surface modification was fulfilled either by Ag-doped TiCaPCON film deposition or by development of a surface roughness following by drug loading. Antibacterial effects against pathogenic bacteria *S.aureus*, *S.epidermis*, and *K.pneum ozanae* were studied.

EXPERIMENTAL METHODS

The substrates intended for drug loading were produced by selective laser sintering. The Ti substrate with pre-coated Ti powder layers was scanned by laser beam in two orthogonal directions two form a network structure with square-shaped blind pores. 3 mg of lyophilized Augmentin (SmithKline Beecham PLS, United Kingdom) with ratio Amoxicillin/clavulanic acid=5:1 was dissolved in 10 ml and 1 ml of sterile Hanks solution (PanEko, Russia). Augmentin concentration was 0.3 mg/ml and 3 mg/ml, respectively. Samples were covered by 100 µl of the solution. After water evaporation, the formed precipitate was embeded into the sample relief using disposable spreader (SPL Life Science). TiCaPCON films with 0.7-4% of Ag were deposited by simultaneous sputtering of TiC-Ca₃(PO₄)₂ and Ag targets.

To evaluate chondrocytes adhesion to the TiCaPCON-Ag films, DiOC6 staining was used. The biocompatibility of films was investigated by means of MTS and Picogreen tests. The bioactivity of the TiCaPCON-Ag films and SLS/Augmentin samples was evaluated using ALP activity test.

RESULTS AND DISCUSSION

The results obtained show that the Ag-doped films did not inhibit the growth of all tested bacteria, but were able to change the bacterial colony morphology. In general, *K.pneum. ozanae* form circular mucous grayish white colonies, but in the presence of 0.7% Ag *K.pneum. ozanae* colonies take an irregular shape. In the case of materials loaded with *Augmentin*, pronounced inhibition zones were observed. When an amount of *Augmentin* was increased from 2.4 mg to 4 mg, the size of inhibition zone after 48 hours raised from 11.3 mm to 18.7 mm against *S. aureus*, from 15.7

mm to 16.4 mm against *S.epidermidis*, and from 8.1 mm to 9.7 mm against *K. pneum. ozanae*.

In vitro test showed no toxic effect of all used concentrations of *Augmentin* for MC3T3-E1 cells. The cells underwent osteogenic differentiation and exhibited a high level alkaline phosphatase activity. We did not find statistically significant differences in the ALP activity of cells cultivated on *Augmentin*-doped Ti samples.

To assess whether the drug can easily be washed away from the rough surface, the SLS samples were preliminary held in Hanks solution for 1, 2 and 3 days. The subsequent antibacterial tests showed that after 1 day immersion in Hanks solution, the bacteria growth was suppressed for 1 day compared to untreated samples which demonstrated longer effect for 4 days.

The best chondrocytes adhesion was observed on the surface of Ag-free TiCaPCON films. Doping with Ag slightly decreased the chondrocytes adhesion, but the results were not statistically different from the control (glass). According to MTS test, the presence of Ag resulted in the slowing of metabolism leaving the cells life unaffected. After 4 days of cultivation, all films had the same level of cells proliferation. It is known that Ag ions can replace the ions of microelements in the enzymes responsible for the metabolism and reproduction. This leads to disruption of cell function and its death. In the case of Ag-doped TiCaPCON films, bactericide element had a tendency to suppress the cells metabolism but did not cause the cells death.

CONCLUSION

This study evaluates antibacterial performance of two types of samples: Ag-doped TiCaPCON films and Ti materials with high surface roughness loaded with *Augmentin*. The sample with medicine can provide a strong antibacterial action at the beginning of implantation without compromise with material bioactivity. Due to the fast drug release, the antibacterial effect was limited to 24 hours. In contrast, the Ag-doped films demonstrated less effective, but longer bactericidal effect (up to 5 days).

Investigation of Factors Influencing Deposition of Nanocomposite Coating onto Open Cell Foams using Layer-by-Layer Assembly: Design of Experiment Approach

Monika Ziminska¹, Helen McCarthy², Nicholas Dunne¹ and Andrew Hamilton¹

INTRODUCTION

Sufficient structural integrity and a porous architecture that supports tissue cell in-growth are crucial characteristics for functional bone tissue scaffold designs. Scaffolds have a load-bearing function and are often exposed to high levels of mechanical stress; hence an adequate level of strength and stiffness is a fundamental requirement. A high level of interconnected porosity is also required to stimulate bone growth into the scaffold, however high porosity reduces the mechanical properties. (1) This on-going challenge can potentially be addressed by deposition of a stiff and strong polymer-nanocomposite coating assembled onto a porous template using Layer-by-Layer (LbL) deposition. LbL assembly involves the adsorption of oppositely charged polyelectrolytes onto a substrate resulting in multilayer films, and has been established as one of the most versatile means to control film properties and molecular architecture at the nanoscale level. (3).

The aim of this study was to quantify the influence of fabrication parameters on the mechanical properties of porous substrates coated with polymer nanocomposites assembled via LbL deposition. A Design of Experiments (DoE) approach was used to correlate a range of processing parameters with the compressive modulus of nanocomposite-coated foams.

EXPERIMENTAL METHODS

The processing parameters investigated include: pH of Polyacrylic Acid (PAA) and Polyethyleneamine (PEI), number of multilayer deposited between samples drying, adsorption time, and salt concentration. The ranges of interest given in Table 1 were selected based on a review of relevant literature (4), and Design-Expert Version 5.0.8 (State-Ease) (DoE) software was used to determine the parameter space for experimental investigation.

Table 1: DoE Factors

	Factor	Unit	Low	High
A	PAA pH	[H+]	4	9
B	PEI pH	[H+]	7	10
C	Drying	no. of m-layers	5	15
D	Deposition time	sec	30	45
E	Salt concentration	M	0	2

LbL deposition was conducted using aqueous solutions of 50 wt.% PEI, MW 750,000, 35 wt.% PAA, MW 100,000, and hydrophilic bentonite nanoclay, MW 180.1 (Sigma Aldrich). Solutions were prepared as previously described (5). The open-cell polyurethane (PU) foam substrates (45 PPI) were purchased from EasyFoam Ltd.

Prior to LbL deposition, the foam substrates were cut into cylinders (dia. 12.7 mm height 10 mm), rinsed with de-ionised (DI) H₂O and dried with compressed air. Substrates were then alternately subjected to cationic (PEI), and anionic (PAA and nanoclay) solutions using a custom-built apparatus that controls fluid flow through the substrates. Each solution rinse was followed by rinsing with DI H₂O to prevent intermingling of oppositely charged mixtures.

The full PEI/PAA/PEI/bentonite deposition cycle was repeated in intervals of 5 multilayers to obtain the total desired number of multilayers. The coated samples were dried for 24 h in a desiccator after each interval and the total mass of the coating was determined before subsequent deposition of additional multilayers. Mechanical properties of coated foams were determined by quasi-static mechanical testing in compression using a Texture Analyser (Manson Technology TA-XT2i) and following ASTM D1621-10 with non-standard specimen sizes.

RESULTS AND DISCUSSION

The initial set of coated samples were fabricated under the following fabrication conditions: PAA pH 9, PEI pH 10, 5 m-layers deposited between drying, salt concentration 0, deposition time 30 sec. Gravimetric results reveal a consistent increase in mass as a function of the number of multilayers deposited.

The results of mechanical tests on uncoated foams, and foams coated with 60 multilayers of nanocomposite coating indicate an increase in stiffness (166%) compared to the uncoated foams (Table 2).

Table 2: Elastic Modulus \pm SD for $n \geq 3$

	Uncoated	60 m-layers
Modulus (kPa)	70.81	188.75
Standard Dev.	18.76	54.84

Representative stress-strain curves for uncoated and nanocomposite-coated specimens (Fig. 1) illustrate this increase in stiffness derived from the coating.

Figure 1: Stress-strain curves for uncoated and nanocomposite coated PU foams.

Extending this experimental investigation over the range of processing parameters will determine the fabrication conditions for obtaining materials with suitable mechanical properties and pore structure for bone tissue scaffold applications.

INTRODUCTION

Today, the need for medical devices is higher than ever and there is an increasing demand for stronger materials allowing reduced dimensions with sustained mechanical properties. The material needs to be biocompatible in order for the long-term osseointegration to be successful. The Ti-6Al-4V alloy has long been favoured as implant material for high load applications, such as hip arthroplasty and small diameter dental implants. However, concerns have been raised about the potential harmful effect of Al and V motivating research towards the development of new materials¹.

The present work evaluates a novel Ti-Ta-Zr-Nb alloy, i.e. only consisting of elements considered non-toxic and biocompatible *in-vivo*², using a well-established rat model with an early and a late time point of 7 and 28 days, respectively.

EXPERIMENTAL METHODS

Screw-shaped implants, total length of 2.3 mm, Ø 2 mm and discs with Ø 9 mm were manufactured from cp-Ti grade IV (denoted TiGr4) and Ti-10.1Ta-1.7Zr-1.6Nb (denoted TiAlloy). All implant surfaces were modified by acid etching. The physicochemical properties of the implant surfaces were characterized by SEM (stereo), XPS and contact angle measurements. Screw-shaped implants were implanted in the rat tibia (4 implants per animal) for 7 or 28 days. Half of the implants underwent biomechanical evaluation. Thereafter all implants were retrieved en bloc and processed for histology, histomorphometry and electron microscopy.

RESULTS AND DISCUSSION

The two materials showed similar surface morphology, topography (3D-SEM) and wettability (contact angle). The surface chemistry analysis (XPS) indicates a thin (<10nm) TiO₂ oxide layer for both materials, but with enrichment of Ta and Nb at the TiAlloy surface.

Fig. 1. The histomorphometry presented as the mean bone implant contact (BIC) and the mean bone area (BA) within all threads of each implant. (Red: TiGr4, Blue: TiAlloy, standard deviations are indicated).

The quantitative histomorphometry showed significantly higher bone-implant contact (BIC) for the TiAlloy surface compared to the TiGr4 surface at 7 days, with a similar trend at 28 days (Fig. 1). The amount of bone around the implants, as judged by the bone area (BA) within the threads, showed significantly higher values for the TiGr4 implant compared to the TiAlloy at 28 days, while no difference was observed at 7 days.

Fig. 2. Maximal removal torque of individual animal retrieved implants at 7 and 28 days, respectively. (Red: TiGr4, Blue: TiAlloy).

The implant stability evaluation revealed equally high removal torque for both materials at either time point, even though the TiAlloy material showed a tendency ($p=0.0614$) towards higher stability at the later time point (Fig. 2).

CONCLUSION

The Ti alloy has proven as biocompatible as Ti grade 4 and showing good osseointegration levels. The Ti alloy displays significantly higher bone implant contact and a trend towards higher mechanical implant stability after 4 weeks *in-vivo* compared to the Ti grade 4.

³Hochschule Reutlingen, Process Analysis & Technology (PA&T), Reutlingen

INTRODUCTION

Adipose tissue is an abundant source of mesenchymal stem cells (MSCs). Two major advantages are displayed by using adipose derived stem cells (ASCs) in contrast to MSCs from bone marrow: the isolation is more comfortable for the patient and adipose tissue is supposed to have a higher frequency of stem cells (1). It would be a benefit if ASCs could be used for bone-tissue engineering.

In this study we evaluated the potential of human ASCs as an alternative cell source in 2D and 3D environments. Therefore, we characterized the cells and seeded them on planar polystyrene samples but also on porous, ammonia-plasma treated polylactid-hydroxyapatite (PLA-HA) scaffolds to analyze their osteogenic differentiation in comparison to hMSCs.

EXPERIMENTAL METHODS

Human ASCs were isolated of lipoaspirate and were characterized by FACS analysis, histochemical stainings and qRT-PCR studies.

3D-scaffolds were treated by low pressure ammonia-plasma and examined concerning cell distribution and differentiation within the scaffolds. Several time points (day 1, 7, 14 and 21) were selected to perform histological staining as well as to analyze the gene expression by qRT-PCR experiments.

RESULTS AND DISCUSSION

ASCs were successfully isolated of human lipoaspirate and characterized. MSCs isolated from bone marrow showed a higher osteogenic differentiation potential in the 2D setting, however, a similar osteogenic related marker expression was observed in the 3D environment. A nearly homogenous cell distribution within the PLA-HA-composites could be achieved and the expression of Alkaline Phosphatase (ALP), Collagen Type I and Osteopontin as well as a calcificated extracellular matrix were detected in hASCs and hMSCs seeded scaffolds (see figure 1).

Figure 1: Confocal microscopic analysis of hMSCs and hASCs cultured in NH₃-plasma treated porous PLA-HA scaffolds for 21 days in osteogenic media. Cross sectioning of the scaffold was performed on day 1 (A, E), 7 (B, F), 14 (C, G) and 21 (D, H) and immunofluorescence staining against Col Type I and Alp was conducted. Cell nuclei are stained by DAPI (blue).

DISCUSSION

Essential factors that must be considered in tissue engineering are the availability of a suitable matrix, a sufficient amount of cells and culture conditions that allow a three-dimensional (3D) culture to produce artificial tissue equivalents. The results of this study indicate the importance of a 3D setting that approaches the in vivo situation and should be further extended by e.g. mechanical stimulation or the co-culture with relevant other cells.

CONCLUSION

HASCs are able to differentiate into different tissue cells. For the use in bone tissues engineering the cells are a promising alternative to hMSCs from bone marrow. Osteogenesis related marker expression occurs in a 3D environment and is comparable to the expression of hMSCs.

kasia.kz@amu.edu.pl

INTRODUCTION

A drug carrier should fulfill requirements of biocompatibility, biodegradability, nanoscale size as well as ability to bind and release the bioactive compound. The biomaterial used to form a drug delivery vehicle should also be durable enough to transport the active compounds within an organism.

Spider silk proteins have an ability to self-assemble into spherical particles that can be utilized for drug delivery⁽¹⁾. Moreover, the bioengineered proteins can be modified by adding a new functional domain (responsible for binding drug or a cell receptor). The objective of the study was to generate the bioengineered spider silk biomaterial by expression in bacterial culture with efficient purification techniques⁽²⁾, followed by studies of drug loading and release.

EXPERIMENTAL METHODS

The bioengineered spider silk proteins: MS1 and MS2 were derived from the *N. clavipes* spidroins: MaSp1 and MaSp2, respectively. Recombinant proteins were produced in *E. coli* and purified by thermal extraction⁽³⁾. The spherical particles were produced by mixing a soluble silk protein with potassium phosphate at different conditions. Physical properties of the particles were characterized using scanning electron microscopy, infrared spectrometry and zeta potential measurements. Cytotoxicity of the spheres was investigated using a MTT assay. The binding of anti-cancer drugs to the spheres was investigated. The levels of drug incorporation and release profiles of doxorubicin, mitoxantrone and etoposide were studied spectrophotometrically.

RESULTS AND DISCUSSION

The MS1 and MS2 proteins formed spheres of different morphology and size. The size of the particles was controlled by the concentration of the silk protein mixed with phosphate, while the phosphate concentration influenced stability of the silk spheres. The MS1-spheres presented a positive, while MS2 spheres a negative zeta potential. Both particle types were non-toxic towards eukaryotic cells (fibroblasts 3T3) *in vitro*. MS1 particles showed stronger affinity to the anti-cancer drugs doxorubicin and mitoxantrone than MS2

spheres. Doxorubicin showed a pH-dependent release profile from the particles. Both types of drug carriers maintained their spherical structure after 14 days of drug release at physiological conditions *in vitro*.

Figure 1: (A) Scanning electron image of the MS2 spheres; (B) Doxorubicin-loaded MS1 spheres under a confocal microscope

CONCLUSIONS

The bioengineered spider silk proteins formed stable spherical particles. Spheres made of the MS1 and MS2 protein showed different properties and different affinity to anti-cancer drugs. The bioengineered silk spheres could target the cancer cells by using a functional domain. Moreover, they are non-toxic and biodegradable. These features, combined with the affinity to anti-cancer drugs will determine the potential of bioengineered spider silk spheres as the drug carriers for cancer therapy.

Aligned electrospun PLGA fibres reinforcing tubular small intestine submucosa

Omaer Syed¹, Richard Day² Jonathan Knowles¹

¹ Division of Biomaterials and Tissue Engineering, Eastman Dental Institute, UCL, UK

²Centre for Gastroenterology and Nutrition, UCL, UK

omaer.syed.10@ucl.ac.uk

INTRODUCTION

An artificial oesophageal replacement would provide the ability to repair damaged oesophageal tissue as a result of trauma or disease or to replace absent tissue in congenital conditions such as atresia. Tissue engineering has been applied to this problem with limited success though a better understanding of the requirements of such a construct has emerged. It was hypothesized that small intestine submucosa (SIS) would represent a suitable base material from which to form such a construct though it suffers from poor mechanical properties due to early remodeling¹. SIS was produced in a tubular form this was then reinforced with electrospun microfibers of poly(lactic-co-glycolic acid) (PLGA) on a rotating mandrel to reinforce the mechanical properties. This work would form the basis of further work into the construction of a multifaceted scaffold system.

EXPERIMENTAL METHODS

Tubular SIS samples were prepared by well-documented methods² and then decellularised using a detergent-perfusion method. Samples were then freeze dried and mounted on a rotating mandrel. Electrospinning was carried out using a 15%(w/v) solution of PLGA (in 8:2 dichloromethane: dimethylformamide). Samples were coated at the rotational speeds: 10, 500, 1000, 2000, 3000, 4000rpm.

Analysis was carried out by mechanical uniaxial tensile testing carried out in both longitudinal and circumferential directions (n=8) and extensive SEM imaging. The SEM images were analysed to determine the thickness of the electrospun layer, the fibre diameter and the alignment of the fibres. Biocompatibility studies were carried out, with human (o)esophageal smooth muscle cells (HESMC) cultured onto the scaffold samples using a MTS cell viability assay.

RESULTS AND DISCUSSION

SEM imaging showed that the fibre layer thickness and the diameter of the fibres remained largely unaffected by the variations in rotational speeds. Fibre alignment (perpendicular to the long axis of the mandrel) was found to significantly increase in the samples which were electrospun at 2000rpm and higher (the highest percentage of fibres in the 60-90° grouping of alignment

relative to the long axis of the mandrel) which has also been observed in related studies³.

The results indicate that the addition of the fibre layer produced an increase in certain mechanical testing criteria including the elastic modulus, the yield stress and the failure strain for all spun samples when compared to the control. The alignment of the fibres was found altered the properties of the samples. It was found that the failure strain and the elastic modulus of the samples increased as a result of increasing fibre alignment when tested in the direction of the alignment. This was also accompanied by a decrease in the sample properties in the perpendicular direction. A balance of improved properties was found along both testing directions at 2000rpm. The cell viability work showed that the fibre alignment did not alter the biocompatibility of the scaffolds.

CONCLUSION

It was concluded that the addition of an electrospun fibre layer resulted in an increase in the elastic modulus, yield strength and the failure strain of SIS when compared to the control. It was also shown that with rotation of the mandrel at speeds of 2000rpm or higher that the fibres became more highly aligned. The alignment of the fibres resulted in changes in the mechanical properties and it was concluded that the SIS with the layer of fibres spun at 2000rpm had the best balance of elastic modulus, yield stress and failure strain when tested longitudinally and circumferentially. It was speculated that the lower degree of entanglement when the fibres were highly aligned resulted in less mechanical reinforcement when the scaffold was stressed perpendicularly to the alignment of the fibres.

Further work in this will involve more complex characterisation of the scaffolds and a more time-extended cell culture study.

Hyaluronic Acid Regulation of Cytokine Secretion, GAG Production and Permeability in Urothelial Cells

Peadar Rooney¹ Akshay Srivastava¹, Leo Quinlain², Abhay Pandit^{1*}

¹Network of Excellence for Functional Biomaterials, ²Department of Physiology, National University of Ireland Galway, Ireland, *abhay.pandit@nuigalway.ie

Introduction: Hyaluronic acid has been used in the clinic as an injectable biomaterial treatment for interstitial cystitis (IC). IC is a chronic debilitating disease, with a significant impact on the quality of life for patients. In IC alterations in the proteoglycan composition on the luminal wall of the bladder has been proposed as the primary pathology of IC(1). Previous studies have shown that inflammatory cytokines and glycosaminoglycan levels are drastically altered in urine(2). In order to ultimately create a comprehensive tissue engineering strategy, the mechanistic effects of HA must be investigated. In this study the role of hyaluronic acid (HA) to alter inflammatory cytokines, glycosaminoglycan pathways and permeability of urothelial cells was investigated.

Experimental Methods: Urothelial cells were grown on 0.4µm transwell inserts. The effect of HA on biomolecule migration by measuring the migration of fluorescence labeled dextran, sampling at 2 hr time points. IL-6 and IL-8 ELISA (eBioscience) was performed. DMMB assay was performed for sGAG levels(3). RNA was isolated using RNeasy kit and RNA reverse transcribed using Superscript VILO (Invitrogen), RT-PCR performed using Taqman primers for CSGALNACT1/2 (Hs00218054_m1/ Hs00603821_m1) and HAS2 (Hs00193435_m1) on Lightcycler 480 system (Roche Diagnostics). Relative gene expression was determined using $\Delta\Delta C_T$ method.

Results and Discussion: HA significantly decreases the TNF α induced cytokine expression in urothelial cells (Figure 1A, 1C). Sulphated glycosaminoglycan (sGAG) expression is measured by DMMB assay shows HA significantly increases secreted sGAG (Figure 1B). RT-PCR demonstrated that HA increases the expression of key enzymes involved in the expression of chondroitin sulphate. In order to examine the effect of HA on permeability the expression of tight junction proteins by FACS analysis and permeability using transwell migration assay was performed. The results demonstrate decreased permeability when HA is present on the cells for large molecules (Figure 1D), with no increase in tight junction expression (Figure 1E), suggesting a physiochemical surface interaction, rather than a change in the cellular tight junction expression that alters permeability.

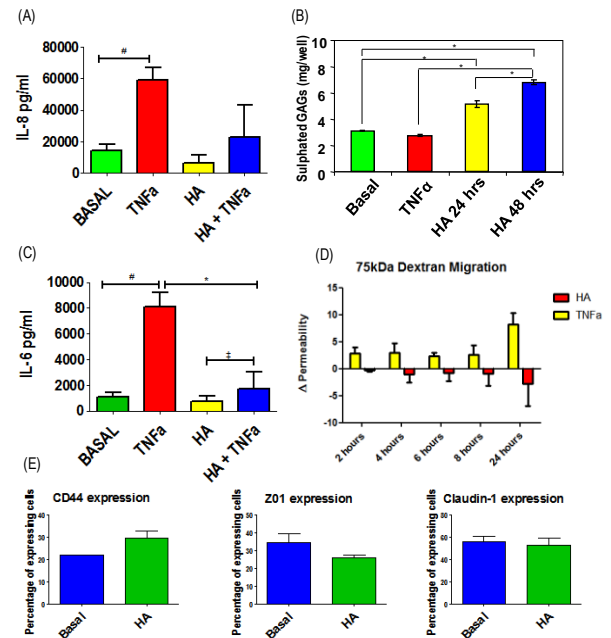

Figure: Urothelial cells secreted significantly higher levels of IL-8 and IL-6 after exposure to TNF α (10ng/ml) compared to basal. HA significantly decreased the effect of TNF α on the secretion of IL-6 (A), and dramatically decreased IL-8 secretion (C). Sulphated GAG secretion significantly increased over 24 and 48 hours when treated with HA (B). HA significantly decreased the permeability of urothelial cells to 150kDa Dextran (D). FACS used to examine the effect of HA on the expression of tight junction expression (E).

Conclusions: These results demonstrate that hyaluronic acid has an anti-inflammatory effect, increases expression of sGAG and increases permeability without altering cell surface proteins closely associated with permeability. Taken together these results show that HA has a significant effect on inflammation and GAG synthesis.

INTRODUCTION

Growing tissue from stem cells is a promising approach in tissue engineering because of their pluripotency and long-time proliferation^[1], but their use in regenerative medicine requires understanding and controlling of stem cell actions. Stem cells can be cultivated in designer scaffolds with programmed chemical and physical cues mimicking the extracellular matrix^[2]. Bioactive functionalization and mechanical properties of such scaffolds are known to impact stem cell behaviour^[3]. In this work, we demonstrate how hMSCs adhesion and commitment are influenced by periodicity and shape of a 2D synthetic nanofibrillar matrix^[4].

EXPERIMENTAL METHODS

Chiral structures with different nanometric periodicities (periodicity ~100 nm and 65 nm, respectively) and shapes (twisted vs helical) were synthesized by silica transcription of organic precursors made by self-assembly of enantiomerically pure gemini surfactant tartrates^[5], functionalized with GRGDS and covalently grafted to a glass substrate. Human mesenchymal stem cells were cultured on these substrates and their adhesion (after 24 h) and commitment (after 96 h) were investigated using SEM and immunostaining.

RESULTS AND DISCUSSION

Successful grafting of peptide-functionalized twisted and helical nanoribbons was confirmed by fluorescence microscopy and SEM. Immunostaining revealed more and stronger focal adhesions on helical nanoribbons, compared to samples with twisted nanoribbons. hMSCs on helical ribbons exhibited a lower occurrence of the stem cell marker STRO-1 and significantly stronger expression of osteogenic markers Osterix (Osx) and Osteopontin (OPN) than on the other surfaces, including twisted ribbons and control glass substrates functionalized with RGD.

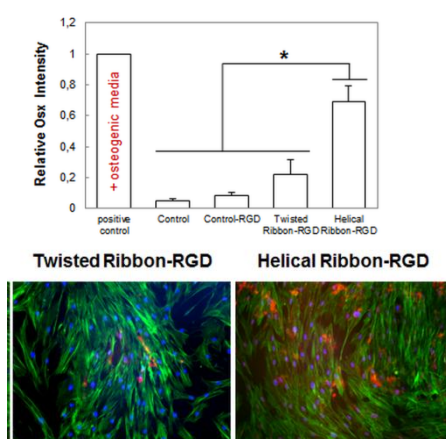

Fig. 1. *Osx* detection in hMSCs on helical ribbons, twisted ribbons, peptide functionalized and unfunctionalized glass substrates (graph, top). OPN detection from fluorescence microscopy (red emission).

Fig. 2. SEM image of hMSC interaction with helical nanoribbons grafted on functionalized glass substrate

These results imply an enhanced osteogenesis on helical ribbons compared to twisted ribbons. Osteogenic commitment was not observed when blebbistatin was added to block non-muscle myosin II, which suggests that the described effect is probably myosin II-dependent, like the cellular reaction to substrate stiffness.

CONCLUSION

Silica helical nanoribbons with the periodicity of 65 nm promote fibrillar focal adhesion and enhance osteogenic commitment of hMSCs through a non-muscular myosin II dependent pathway, whereas twisted nanoribbons with the periodicity of 100 nm had much less effect on the differentiation. It was clearly demonstrated that significant osteogenesis can be induced simply by choosing adequate nanoperiodicity and shape of our synthetic nano-fibrillar matrix. These results provide promising insight for designing scaffolds for stem cell based bone tissue engineering.

Controlling the Modulus of Gellan Gum Hydrogels for Inkjet Printing Cell Culture Substrates

Sam Moxon & Alan M Smith

Department of Pharmacy, School of Applied Sciences, University of Huddersfield, UK

INTRODUCTION

Successful culturing of tissues within polysaccharide hydrogels is reliant upon specific mechanical properties. Namely the stiffness of the gel has been shown to have a profound effect on cell viability in 3D cell cultures¹. The usual way of tuning the mechanical properties of a hydrogel to suit tissue engineering applications is to change the concentration of polymer used. In this study we have investigated using probe sonication applied at various amplitudes to control the viscosity gellan gum solutions and the viscoelasticity of gellan gum hydrogels cross-linked with DMEM. These modifications could be beneficial when applying gellan gum to bio-ink applications².

EXPERIMENTAL METHODS

Gellan solutions were prepared by dissolving low acyl gellan gum in deionised water at 85°C at a concentration of 1% w/v. Test specific concentrations of gellan were made by diluting this 1% solution accordingly (0.06% to 0.02% w/w for $[\eta]$ measurements and 0.4% w/w was used for steady shear viscosity measurements). Samples were sonicated using an ultrasonic probe at various amplitudes and rheological studies were then conducted using a Bohlin Gemini rheometer. Cooling scans to determine gelation temperature were conducted at a frequency of 10 Rad/s and a constant strain of 0.5%. Solutions were mixed 1:1 with unsupplemented DMEM and cooled at a rate of 2 °C/min and G' and G'' were measured as ions in the DMEM caused gelation of the gellan. Viscosity tests were also conducted. Intrinsic viscosity was calculated using a Rheotek u-tube viscometer and shear thinning behaviour was measured over a shear rates ranging from 0.1 s⁻¹ 1000 s⁻¹ using a Bohlin Gemini rheometer. Following the shear thinning measurements the samples were cross-linked with DMEM and frequency sweeps were conducted to determine the mechanical spectra of the gels.

RESULTS AND DISCUSSION

Table 1 – The impact of sonication amplitude on intrinsic viscosity and dynamic viscosity of gellan gum

Sonication Amplitude (%)	Intrinsic Viscosity (dL/g)	Shear rate s ⁻¹ at which Viscosity is below 0.02 Pas
0	12.927	730
20	7.875	670
40	6.021	570
100	4.991	390

Table 1 highlights that increasing sonication amplitude applied to gellan gum solutions decreased both the

intrinsic viscosity of the samples and the dynamic viscosity. For use as a bio-ink, it has been reported that the polymer solution should have a dynamic viscosity of less than 0.02 Pas³. We have showed that sonication of the samples results in a lower required shear rate to achieve such viscosities. Furthermore, the modulus of gellan gum hydrogels produced following sonication reduced in an exponential fashion as a function of sonication amplitude. Interestingly this did not alter the gelation temperature. This could enable the prediction of a DMEM cross-linked gellan gum construct by a simply determination of the intrinsic viscosity of the sample. Such effects on the gel are thought to be a result of a reduction in the molecular weight of the gellan gum as a direct result of the sonication process. The reduction in molecular weight however was not sufficient to prevent the transition from disordered polymer chains to the ordered conformation which is required for gelation. As a result, the polymer can still form gels but with reduced mechanical strength.

Figure 1 - The reduction of G' in gellan gum hydrogels as a result of sonication

CONCLUSION

In summary, we have showed that it is possible to control both the viscosity and modulus of gellan gum without changing the polymer concentration. This simple approach could be applied to predict gel stiffness in gellan gum cell culture substrates and improve the performance of gellan gum as a bio-ink for ink jet printing of cellular constructs.

INTRODUCTION

Healing of complicated bone fractures, fibrous non-unions and severe trauma require additional support material as scaffolds to aid the healing process¹. Selection of such scaffolds depends on organization behaviour and physico-mechanical properties of bone². Calcium phosphate (CaP) and functionalized biopolymer (FP) based hybrid composite scaffolds have become a promising approach for bone graft replacement. Therefore, development of three dimensional CaP based microstructures intermingled with functionalized polymer has been proposed as an attractive approach for rejuvenation of native tissues towards self-repairing and regeneration.

This hybrid composite mimicking the design from natural bone, as inorganic phase will provide toughness, strength and organic matrix will provide elasticity and resistance to stress, bending and fracture.

EXPERIMENTAL METHODS

Here we represent a method for fabrication of multiphasic highly interconnected multi-scalar porous CaP aligned fibres from natural sources (egg shell). Further, aligned CaP fibres coated with natural origin (chitosan) nano- fibrous patterned FP and intermingled with FP. Scaffolds were characterized for physico-chemical properties using SEM, TEM, EDS, XRD, FTIR, TG-DTA and stereo-zoom microscope. Cells metabolic, attachment, migration, proliferation, differentiation studies were carried out to evaluate its suitability for intended application.

In vivo studies at heterotopic site were conducted in rabbit animal model to assay the osteoinductivity³.

RESULTS AND DISCUSSION

Natural sources were successfully used for synthesis of multiphasic highly interconnected multi-scalar porous, fibrous CaP aligned fibres. Highly porous interconnected microstructure appeared on CaP fibrous scaffolds. CaP provide high mechanical support and interphase for bone tissue growth. Intermingled and integument FP enhance cell attachment and act as non-collagenase proteins during osteogenesis. Not only combination of two different phases, but also their

organization can also be varied with analogues to the bone in terms of microstructure and mechanical properties. CaP based composite scaffold with polymers have pH buffering effect which can control degradation and resorption rate of scaffold.

Preliminary cytotoxicity assay, hemocompatibility assay shown promising results. Mesenchymal stem cells survival percentage, growth rates and differentiation has been found enhanced with scaffolds. During ectopic site implantation, hybrid composite scaffold displayed increased RNA expression of collagen I and osteocalcin.

CONCLUSION

Micro fibrous CaP based hybrid scaffolds can be used as a bone graft replacement. Both the Calcium phosphate phase and functionalized polymer phase are originated from biological waste material, transformed in to biological active material in a cost effective way.

Bioactive and Highly Porous Nanofibres via Solution Blow Spinning

INTRODUCTION

We have developed a new combinational technique to rapidly produce porous nanofibres, as well as porous microspheres via solution blow spinning¹ (SBS) and thermally induced phase separation² (TIPS). SBS can produce nanofibres, analogous to those electrospun from polymers dissolved in suitable solvents, yet with a production rate (per head) circa 100 times faster, and without the need for electric fields¹. In this work we freeze the nanofibres shortly after their formation and ahead of excessive solvent evaporation, causing the solvent to freeze and hence phase separation. Subsequent freeze-drying of the fibres removes the solvent, yielding the highly porous nanofibres, and depending on polymer solution concentration, porous microspheres.

EXPERIMENTAL METHODS

Preparation of porous nanofibres and spheres via solution blow spinning

Amorphous polylactide (PLA) (used as a model polymer) was dissolved in dimethyl carbonate, at polymer concentrations (m/v%): 1, 2, 4, 6, 8, 10, 12, 15 and 20%, with respect to the solvent volume, providing a range of viscosities. SBS was conducted using pressures of 10-60 psi, and polymer solution injection rates of 100-200 $\mu\text{L}\cdot\text{min}^{-1}$ via a precision syringe driver. Polymer solutions were jetted directly into a cryogenic bath, which immediately resulted in TIPS of the polymer and solvent within the nanofibres/microspheres. Samples were then lyophilised to yield both porous nanofibres and microspheres, which were characterised by scanning electron microscopy and their diameters and pore dimensions assessed using image J. Nanofibres were rendered bioactive by inclusion of 5 and 10 wt.% bioactive glass nanoparticles (of the same composition as Bioglass45S5@; 20-30 nm in diameter), relative to the polymer, with ultrasonication ahead of SBS.

RESULTS AND DISCUSSION

Polymer solutions of > 6 m/v% formed nanofibres analogous to those spun via electrospinning. However, below concentration of 10 m/v% the presence of porous microspheres become increasingly prevalent, as well as the nanofibres becoming increasingly thinner ($< \sim 200$ nm). Fibres of 15 m/v% had diameters $399 \text{ nm} \pm 134$, and exhibited a highly porous structure consisting of elongated pores of ~ 50 nm by ~ 25 nm, as shown in Figure 1. Thermogravimetric analysis revealed the

bioactive glass content to be within $\pm 2\%$ of the intended filler volumes, indicating successful incorporation.

Figure 1. Porous bioactive nanofibres

To the Authors' knowledge this is the first time that SBS has been used to produce porous nanofibres, as well as bioactive porous nanofibres. Porous fibres have been produced using electrospinning yet with substantially lower rates³, our technique allows for the rapid production of open porous cotton-wool like structures.

CONCLUSION

This technique provides a simple and rapid route to produce nanofibres, as well as porous nanofibres, which can be rendered bioactive by bioactive nanoparticle inclusions. Using polymer concentrations lower than 6 m/v% it is also possible to produce highly porous microspheres, with dimensions as small as 500 nm.

INTRODUCTION

Gas foaming has been frequently used to prepare porous scaffolds. It includes 3 simple steps: Foaming, Casting, and Freezing¹. It was observed that in this method, decision about placing foaming before or after casting can be used to manipulate the scaffold pore size. Using such a feature, in this study two sets of scaffold pore sizes were prepared. Each set were crosslinked with a range of concentrations of glutaraldehyde (GTA) to investigate the reciprocal relationship that exists between pore size and GTA concentration and the effect that they collectively have on the scaffold tensile strength. It was shown that larger pore sizes cause lower tensile strength. However, this effect is more noticeable when the GTA concentration was increased.

EXPERIMENTAL METHODS

20% w/v gelatin aqueous solution was prepared by dissolving gelatin in 60°C de-ionised water. Two varieties of gas foaming method were performed:

- **Foaming BEFORE casting**
0.3g Sodium hydrogen carbonate and 360µl acetic acid were added to gelatin solution to initiate foaming. The foam was then cast in the mold.
- **Foaming AFTER casting**
The gelatin solution was cast in a mold. 0.8g Sodium hydrogen carbonate and 360µl acetic acid were added to the gelatin solution.

Each of these 2 groups of scaffolds were separately crosslinked using 5 different concentrations of GTA (0.00, 0.25, 0.50, 0.75, 1.00% v/v). Tensile tests were performed on each sample using a texture analyser (SMS, Surrey, UK). The obtained results formed triplet data points consisting of: pore size, GTA concentration, and tensile strength. The data points were plotted into a curve fitting software (Lab Fit, V.7.2., www.labfit.net) to find the best fitting binominal function.

RESULTS AND DISCUSSION

As a first result of this study, it was shown that undertaking foaming before casting led to smaller pores. This is due to release of the emitted gas before casting which led to smaller pores. This was independent of GTA concentrations. Fig. 1 shows side by side view of 2 separate SEM images taken from two sets of samples crosslinked at 1.00% GTA. It shows the effect of casting after foaming on the pore size.

Furthermore, the obtained results showed that the scaffolds with smaller pores had a higher tensile strength. This is due to function of pores as crack

initiation sites². Larger pores produce larger longitudinal cracks that lead to weaker scaffolds.

Finally obtained results showed that the effect of pore size on tensile strength is more noticeable when the concentration of GTA is higher. Higher concentration of GTA causes the structure to become more brittle. A more fragile construct is more susceptible to crack growth and fails at lower force³.

Figure 1: Side by side view of 2 SEM images taken from 2 separate scaffolds crosslinked at 1.00% GTA solution. Foaming after gelatin casting causes larger pores. This effect was independent of GTA concentration.

CONCLUSION

the Equation 1 can be proposed to show the relationship between the pore size, GTA concentration, and how they affect tensile strength. Equation 1 shows that value of GTA concentration exponentially raises the negative impact of pore size on the tensile strength.

$$\text{Tensile Strength} \propto \frac{1}{\text{Pore Size}^{\left(\frac{\text{GTA \%}}{0.03}\right)}} \quad (\text{Equation 1})$$

This study can help highlight the complexity that exists in the mechanical behaviour of porous structure. It illustrates the function of highly reactive crosslinkers like GTA as an element with dual effect. Whilst crosslinking using higher GTA concentration normally causes the mechanical strength to increase, in the case of a porous structure it can have a negative impact on the strength by turning the structure more brittle and enhancing the detrimental effect of pore size.

³Dept. of Pharmacology and Toxicology, University of Vienna, Austria

INTRODUCTION

The present work aims at the development of 3D scaffolds using both fused deposition modelling as well as a cryogenic treatment to create a fully interconnected pore network. Two material classes will be applied as starting compounds including polyesters (for their mechanical properties) and crosslinkable gelatin precursors (for their cell-interactive properties).

EXPERIMENTAL METHODS

In a first part, poly-L-lactic acid (PLA) was processed using fused deposition modelling (Ultimaker). Next, the porous PLA scaffolds were incubated in aqueous methacrylamide-modified gelatin (gel-MOD) solutions of varying concentrations (i.e. 2 – 10 w/v%) containing 2 mol% Irgacure 2959. The gelatin applied had a modification degree of 80%. Next, after vacuum application, the scaffolds were exposed to UV-light (365 nm) for 2 hours, placed in a cryo-unit and cooled from room temperature to -30°C during 5.5 hours while applying a temperature gradient of 30°C between top and bottom of the scaffolds. In a final step, the frozen hydrogel-PLA combination scaffolds were transferred to a freeze-dryer to remove the ice crystals. The scaffolds were characterized using micro-computed tomography (μ CT) and scanning electron microscopy (SEM). In addition, we assessed the *in vitro* swelling behaviour, the mechanical properties and the degradation behaviour. Furthermore, MC3T3 cells were seeded onto the scaffolds to determine cell interaction, attachment and proliferation.

In parallel, similar hydrogel precursor solutions containing MC3T3 cells were introduced into the 3D printed PLA scaffolds, followed by hydrogel crosslinking through UV irradiation. The scaffolds containing encapsulated cells were characterized using confocal laser scanning microscopy and Presto blue to determine cellular metabolic activity.

RESULTS AND DISCUSSION

First, the efficiency of the UV crosslinking of gel-MOD was assessed after its introduction in the porous PLA. Interestingly, the results indicated that relatively high gel fractions were obtained varying according to the polymer concentration applied which were comparable to the ones obtained in the absence of PLA. *In vitro* degradation tests indicated that the crosslinked gelatin was still prone to degradation in an enzyme containing solution, despite the presence of the surrounding PLA scaffold. Preliminary cell tests showed that upon exceeding a critical gelatin concentration (i.e. 10

w/v%), the presence of cryogels diminished cell migration throughout the PLA scaffolds. Currently, additional cell work is ongoing to optimize the balance between cryogel architecture and stability on the one hand and sufficient cellular infiltration on the other hand. However, the reference samples consisting of crosslinked hydrogel precursors encapsulating MC3T3 cells present in the PLA scaffolds were very promising as indicated in the figures below (scale bars equal 50 μ m). After 7 days, an increase in metabolic activity was observed, indicating the occurrence of cell proliferation in the scaffolds. In addition, live-dead stains only showed a limited number of dead cells due to UV crosslinking (see figure below). Moreover, positive ALP staining indicates the potential for these scaffolds to support osteogenesis.

CONCLUSIONS

The UV crosslinking of cell-interactive hydrogel precursors in the presence of suspended cells is a very valuable route to introduce cells throughout 3D PLA scaffolds. Alternatively, the combination of a gelatin cryogel and a PLA scaffold is a potential candidate for cell seeding purposes in the tissue engineering field. Taken together, these results indicate that the applied polymer-related and cryogenic parameters are crucial to determine the optimal cell seeding efficiency and the ultimate cellular infiltration in 3D PLA scaffolds.

Fine-Tuning Self-Assembling Peptide Hydrogels for Cell Culture Applications

Laura Szkolar^{1,2}, Alberto Saiani^{1,2}, Aline F Miller², Julie E Gough¹.

¹School of Materials, The University of Manchester, UK

²Manchester Institute of Biotechnology, The University of Manchester, UK Laura.Szkolar@Manchester.ac.uk

INTRODUCTION:

Degenerative diseases of cartilage affect a high proportion of the population. One of the main focuses of current research is to produce replacement cartilage *in-vitro* [1]. For this purpose the design of a suitable 3D scaffold for chondrocyte culture is essential.

Self-assembly has emerged as a powerful tool for the fabrication of novel functional biomaterials [2,3]. A variety of molecular building blocks can be used for this purpose. One such block that has attracted considerable attention in the last 20 years is *de-novo* designed peptides [4]. We have recently developed, in our group, a family of hydrogels that exploit the self-assembling properties of short peptides, typically 8 amino acids long [5,6]. The properties of these hydrogels can be tailored for use in a variety of biomedical application ranging of tissue engineering [7] to drug delivery [8].

In the present work we investigated the effect of peptide charge on the culture of primary bovine chondrocytes. The octapeptide FEFKFEFK (F-8) which is stable at pH 7.5 was shown in a recent work to be suitable for the culture of bovine chondrocytes [7]. The natural ECM exhibits a net positive charge due to the attraction of sodium ions by proteoglycans. For this reason a nonapeptide analog to F-8 comprising an additional positive charge (F-9) was chosen for comparison.

METHODS:

Cells were extracted [9] and cultured in 5 % CO₂ at 37 °C. BC's were maintained in DMEM supplemented with 10 % FBS 1 % antibiotic and 50µg/mL of ascorbic acid. Peptide solutions were prepared at concentrations of 10-30 mg mL⁻¹ and adjusted to pH 7.5 with 1M NaOH. Cells were suspended in media at 5x10⁵ cells per 300µL and cultured in 3D. Cell counting was performed using a haemocytometer by dissolving the gel in excess media.

RESULTS AND DISCUSSION

Fig.1) Cell numbers, 21 days on F-8[red] and F-9[pink]. Hydrogels had a G' of 10,000 Pa, 30mgmL⁻¹

Two peptide hydrogels with different net charges at pH 7.5 were produced: F-8 hydrogel neutral and F-9 hydrogel positively charged. The two hydrogel moduli were kept constant by changing the concentration of peptide used to ensure that the differences observed are due to overall hydrogel charge and not differing mechanical properties.

Primary Bovine chondrocytes were cultured in 3D for 21 days. It was observed cell numbers on F-9 showed a statistically significant increase over the 21 day culture period, when compared with F-8. This suggests that the net-positive charged gel provides a suitable scaffold for bovine chondrocyte proliferation. Between days 14 and 21 it is seen that cell numbers appear to be stable, suggesting the chondrocytes have adapted their non-proliferative state, seen in natural cartilage. Rheological data and antibody staining also supported this idea, with ECM production present.

CONCLUSIONS:

We have shown that the introduction of charge may allow a route by which the proliferation and growth of bovine chondrocytes may be influenced, without the use of growth factors. These primary bovine chondrocytes grown on hydrogels carrying a +1 charge allowed for higher cell numbers than those grown on the neutral charge peptide.

verdenelli@hotmail.it

INTRODUCTION

Protein adsorption and the ensuing cell adhesion, events that regulate host responses to materials, occur at the biomaterial-tissue interface, and the physicochemical properties of the material surface modulate these biological events¹. Therefore, in order to improve the biological, chemical and mechanical properties, surface modification is required in many cases². In this research surface modification by sol-gel techniques, one of the most promising solutions for attaching biomolecules onto biomaterial surfaces will be performed, using hyperbranched molecules called dendrons. These dendrons will be modified to promote the adhesion, proliferation and differentiation of specific cell types³ for the regeneration of new tissue i.e. in orthopedic applications for better integration of implants or vascular tissue as a treatment of ischemic injury.

EXPERIMENTAL METHODS

Different sols have been produced and sol-gel coating have been applied to titanium surfaces using a dip coater and samples have been immersed at different speeds. Dendrons branched up to three generations (G3) have been synthesized using solid-phase peptide synthesis. This synthesis process has been used to functionalize the generation 3 dendrons with three specific peptide sequences: -KRSR, to inhibit fibroblast adhesion, -FHRRIKA to facilitate osteoblast migration and -YIGSR to promote osteoblast adhesion. Dendron spray-coating has been applied to the sol-gel coating. Cytotoxicity and cell morphology were assessed *in vitro*, using two cell lines, primary mouse embryonic fibroblast derived cells (3T3) and primary human osteosarcoma derived cells (SAOS-2).

Sol-gel coating has been characterized by stereomicroscopy and scanning electron microscopy (SEM) to analyze the coating structure. Mass spectrometry (MS) has been used to characterize the produced dendrons. To determine if the dendron coating has been effectively applied, ninhydrin test, SEM analysis and preliminary *in vitro* cell studies have been performed.

RESULTS AND DISCUSSION

Macroscopic and SEM analyses have shown that samples immersed at low speeds (40 mm/min) led to a more stable and homogeneous sol-gel coating. SEM images (Fig.1) of the sol-gel coating and the dendron spray coated sol-gel also have shown topographical differences between the samples surfaces. *In vitro* results, in particular from the morphologic analyses, have proven that functionalized dendrimers induce different cellular responses depending. Indeed, -KRSR does not allow fibroblast attachment; -FHRRIKA

supports osteoblast migration and finally -YIGSR induces osteoblast adhesion (Fig.2).

Figure 1. Scanning electron micrographs of Sol-Gel 40% coating (A) and Dendron coating (B)

Figure 2. SAOS-2 morphology with Phalloidin staining after 48h. (A) sol+D+YIGSR; (B) sol+D+FHRRIKA; (C) sol+D+KRSR

CONCLUSION

The aim of this research was to produce and characterize a new method to modify biomaterial surfaces that included sol-gel technique and dendron synthesis. The principle was to match features of sol-gel coating with those of the dendrons, to obtain a functionalized biocompatible coating. The research has highlighted that this aim could be easily achieved: dendrons can be functionalized with any sort of moiety and can increase the surface to functionalize due to their hyperbranched structure. In addition, sol-gel was proven to provide a stable coating exhibiting functional groups on the surface. In this study it has been demonstrated that the different peptide sequences used truly induce a different cell response. Therefore this approach could be suitable for many regenerative medicine approaches e.g. regeneration of bone for better implant integration or for regeneration of tissue for the treatment of ischemic injury.

Characterization of Silicone-polycarbonate-urethane/PDMS based Material for Polymeric Heart Valves

Marianna Asaro¹, Tamer Al Kayal¹, Silvia Volpi¹, Paola Losi¹, Simona Celi², Mattia Glauber¹, Giorgio Soldani¹

¹National Council of Research, Institute of Clinical Physiology, Massa, Italy masaro@ifc.cnr.it

²Scuola Superiore S'Anna, Massa, Italy

INTRODUCTION

Worldwide the increasing number of deaths per year caused by heart valve diseases, made valve replacement the most common surgical therapy. The research for polymeric heart valves (PHV) has been proposed to overcome problems such as no physiological flow conditions, calcification and limited durability of the currently available heart valves prostheses (mechanical or biological). Segmented polyurethanes have been utilized in medical devices since years due to their established biocompatibility and excellent mechanical properties, but their tendency to degradation hampered their use in long-term implantation.

The aim of this work was to study a thermoplastic copolymer chain of polycarbonate-polyurethane and silicone [polydimethylsiloxane (PDMS)] modified with increasing percentages of extra-chain PDMS, for the development of a novel single-body polymeric tri-leaflet PHV made by a spray, phase-inversion technique.

EXPERIMENTAL METHODS

CarboSil® (CS) in grain form was dissolved in THF/DMAc 1:1 (v/v) to obtain a 2% (w/v) solution. CarboSil® solutions containing 10% (CS10) and 30% of PDMS (CS30) were obtained by a reaction under stirring and nitrogen flow for 6 h at 82 °C. For each materials planar patches were obtained by a spray, phase-inversion technique on a rotating cylindrical mandrel [1]. After materials deposition the patches were placed for 1 h in dH₂O to allow solvents removal, and then pressed (50 g/cm²) during an heat treatment at 100°C for 90 min.

In vitro tests were carried out to evaluate the biocompatibility, hemocompatibility, calcification [2], hydrolytic degradation (ISO 13781: Sorensen buffer, pH = 7.4), oxidative degradation [3], environmental stress cracking (ESC) degradation [4] and mechanical properties (ASTM D1708-02).

The material cytotoxicity was studied through extraction method according to ISO-10993-5 on L929 fibroblasts; the hemocompatibility was assessed after 2 h of static blood contact to evaluate platelet adhesion, activation and coagulation parameters.

After calcification and degradation tests, samples were investigated by infrared analysis and SEM.

Uniaxial static tensile tests were performed until failure on both longitudinal and transverse directions on a computer controlled tensile testing machine (100 N load cell). Ten samples were analysed for each materials. For each samples stress-strain data, ultimate tensile strength (UTS) and ultimate elongation (UE) were calculated.

A prototype of a tri-leaflet PHV, whose leaflets had the same thickness (300 µm) and characteristics of the tested patches, was obtained by the spray technique. A 3D mould housing a stent, made by rapid-prototyping

technique, was used to reproduce the morphology of a commercially available biological aortic valve and a 3D counter-mould was used to press/cure the valve prototype.

RESULTS AND DISCUSSION

All material extracts are devoid of any cytotoxic effects on mouse fibroblasts, since no decrease in cell viability (MTT test) and growth (BrdU proliferation test) was observed in comparison with untreated cells.

CS30 material induced a lower in vitro platelets adhesion than the CS one, while the coagulation times were similar for all the tested materials.

SEM analysis demonstrated that CS10 and CS30 presented significantly less formation of spots of calcification compared to CS. Infrared analysis demonstrated no significant differences among CS, CS10 e CS30 samples after the hydrolytic degradation test. CS30 samples exhibited less susceptibility to oxidative degradation and to ESC. Uniaxial tensile tests show a decrease of the UTS for the CS10 and CS30 with respect to the CS material of about 32%. No significant differences were found between all materials as far as the UE value.

A single-body PHV prototype (Fig.1), with a stent incorporated and kept in place without sutures along the peak of the crown, was successfully obtained by spray, phase-inversion technique with CS30.

Fig. 1. Example of CS30 valve.

CONCLUSION

This study demonstrated that the combination of the properties of the CarboSil®-PDMS with those of a controlled valve fabrication technique, such as the spray material deposition on a 3D mould, allowed the feasibility of a new low-cost and potentially long-term performing PHV.

INTRODUCTION

The Selective Laser Sintering (SLS) is an additive manufacturing process which reproduces, layer by layer, physical models using powder material and a laser beam [1]. This technique has been widely used in aerospace and automotive industry and also to develop scaffolds for tissue engineering. [2]. The visual quality and the mechanical properties of devices manufactured by SLS process are determined by the correct choice of manufacturing parameters and of materials' properties [3]. The poly (3-hydroxybutyrate) (PHB) is a natural polymer and has been widely studied as raw material for the production of scaffolds for tissue engineering. PHB is biocompatible and has no toxicity to several cells lines [4].

The goal of this study was to evaluate the effect of experimental parameter PLT of the SLS process on the morphology and mechanical properties of PHB scaffolds and to evaluate the behavior of cells growth on them.

EXPERIMENTAL METHODS

PHB scaffolds were produced by SLS 3D printer (Sinterstation® 2000, maker: 3D Systems), using digital model in a tetragonal shape (13 mm x 13 mm x 26 mm) with 3D orthogonal periodic porous architecture formed by a square (1mm x 1mm x 1mm) and struts of 1 mm. Three groups of samples were produced by variation of the layer thickness – PLT - (0.08, 0.18, 0.28mm). The laser power, scan spacing, part bed temperature, laser beam speed and part build orientation were kept in 15 W, 0.15 mm, 100 °C, 2000 mm/s and 45°, respectively. The images of the scaffolds external surfaces were analysed using a scanner (HP Deskjet F4580) and the Image-Pro Plus 6.0 software for pores dimensions measurement. Length, width and height were obtained using Matlab R2007b software. To determine the porosity of scaffolds of PHB, it follows the standard ASTM F250-10.

Mechanical characterization of the samples was carried out using a universal testing machine (compression mode, Instron 5567), 2 kN load, cross-head speed of 1.3 mm/min.

The cytotoxicity in vitro was assessed using neutral red incorporation in cells cultured for 24 hours in the materials extracts.

RESULTS AND DISCUSSION

The physical models showed dimensional deviations in the geometries of the external surfaces and in the pores compared to the digital model. All scaffolds showed reduction in the size of pores with respect to that established in the digital model. Printed scaffolds

showed pores area values of 0.34 mm², 0.50 mm², 0.58 mm² for PLT of 0.08mm, 0.18mm and 0.28mm, respectively, the increase of PLT reduced the size deviation. The porosity of samples increased with the increase of the PLT. These results can be attributed to the decrease in the amount of energy supplied each layer's volume with the increase of the PLT, as indicated by the volume energy density, that affects the degree of sintering.

The results of compression tests showed that, with the increase in PLT there was a decrease in the modulus values. The mechanical properties the scaffolds, as well as the morphology, were significantly influenced by the PLT. The scaffolds were considered non-cytotoxic.

"Table 1 shows the values of the mechanical tests"

(PLT) mm	Volume Energy Density (J/mm ³)	Compressive Modulus	Compressive Strength
0.08 mm	0.625 J/mm ³	(65.98 ± 13.33) MPa	(3.02 ± 0.17) MPa
0.18 mm	0.277 J/mm ³	(12.70 ± 0.82) MPa	(0.66 ± 0.02) MPa
0.28 mm	0.178 J/mm ³	(3.59 ± 0.19) MPa	(0.26 ± 0.01) MPa

CONCLUSION

Regarding layers thickness, increasing PLT led to an increase in the porosity, since for thicker layers, less energy laser beam is donated, interfering with the sintering process and leaving more voids. The scaffolds with thinner layer had high modulus, which can also be attributed to the better sintering. In addition, the framework with a thickness of 0.08mm presented modulus similar to that of human trabecular bone [5]. More tests are being conducted to evaluate the behavior of cells on scaffolds.

Assessment of the Corrosion Behaviour and Cytocompatibility of a Nano-fluorided Coating Obtained by Simple Chemical Conversion on AZ31 Biodegradable Mg Alloy

Emerson Alves Martins^{1,2}, Dorota Artymowicz¹, Kwangchul Shin², Andrey I. Shukalyuk², Roger C. Newman¹

¹ Department of Chemical Engineering and Applied Chemistry, University of Toronto, Canada

emerson.alvesmartins@utoronto.ca

INTRODUCTION

Magnesium based alloys have attracted great attention in recent years for possessing a natural ability to biodegrade due to corrosion when placed within aqueous substances. This is promising for orthopaedic and cardiovascular device applications. The natural tendency of this material to degrade is attributed to the high oxidative corrosion rates of Mg, however, this can limit the use for biomedical application^{1,2,3}. In order to improve corrosion resistance, a two-step treatment was prepared on AZ31 magnesium alloy by simple chemical conversion method. *In vitro* cytotoxicity tests were performed in order to evaluate if the metal ions released from the AZ31 alloy may cause biological responses.

EXPERIMENTAL METHODS

Preparation of the coating

Specimens with dimensions of 8 mm x 2 mm x 2 mm were cut from a rolled sheet of AZ31 Mg alloy. Each sample was abraded up to 2000 grid, cleaned in deionized water and ethanol, then dried. The surface treatment consisted of a two-step treatment process with immersion in 0.05 M $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ and 0.03 M $\text{NaH}_2\text{PO}_4 \cdot 2\text{H}_2\text{O}$ for 48 h at room temperature followed by immersion in 4g NaOH L⁻¹ and 5 g NaF L⁻¹ for 24 h. The morphology of the coating was observed by optical microscopy.

Electrochemical tests

The corrosion resistance was evaluated by electrochemical tests using simulated body fluid phosphate buffer solution (PBS). The PBS composition was NaCl 8.77g/L⁻¹, NaH_2PO_4 2.68 g/L⁻¹ and KH_2PO_4 2.72 g/L⁻¹, pH 7.4. A three-electrode cell was used with Ag/Ag/Cl as reference, a platinum electrode as the counter, and the sample as the work electrode. The electrochemical impedance spectroscopy (EIS) tests were performed at the open circuit potential with AC amplitude of 10 mV over the frequency range from 10⁵ Hz to 10⁻² Hz and potentiodynamic tests were carried out from -2.2 V to -1 V at a scan rate of 10 mV s⁻¹.

Cytotoxicity tests

Standard cell culture tests according to ISO 1993 using L929 fibroblast cells grown in Eagle's minimum essential medium (MEM) at 37° C for 10 days were used for obtaining a 100% test solution concentration. Extracts were prepared with the concentrations 100%, 50%, 25%, 12.5%, 0% and colorimetric analysis were used for assessing the cellular viability in these different concentrations. Negative and positive controls were used to establish an appropriate response.

RESULTS AND DISCUSSION

The two-step treatment resulted in a formation of a layer with needle-like morphology uniformly covering the specimen surface. The improvement of corrosion

resistance was confirmed by the electrochemical tests which showed that E_{corr} moved towards the active direction and that i_{corr} decreased due to the coating. EIS plots showed charge transfer resistance for the coated AZ31 Mg alloy compared with the uncoated one. The cytotoxicity tests indicated good cytocompatibility of L-929 cells with the first step treatment in the AZ31 alloy when cells were incubated 2 hours or 12 hours. However, the final step treatment had a positive trend after short-term cell exposure (2hrs) but was inconclusive after 12-hour exposure (see Figure 1).

Figure 1 L-929 cell viability in the different concentrations and exposure times.

CONCLUSION

The polarization curves and EIS plots indicated that the coating formed by simple chemical conversion on AZ31 improved the corrosion potential and polarization resistance. The cytotoxicity tests indicated good cytocompatibility of L-929 cells with the layer formed in the first step of the treatment. However, the cytotoxicity result of the second step of the treatment was inconclusive after 12-hour exposure suggesting that a series of optimizations need to be performed.

Mechanical Response of Calcium Phosphate Biocements

D.E. Mouzakis¹, S.P. Zaoutsos¹, S. Rokidi², N.Bouropoulos²

¹*Laboratory of Advanced Materials and Constructions, Department of Mechanical Engineering, Technological Educational Institute of Thessaly, GR 41110-Larissa, Hellas, mouzakis@teilar.gr

² Department of Materials Science, University of Patras, Rion 26500, Patras, Greece

INTRODUCTION

Calcium phosphate (CaP) cements are potential implanted materials for biomedical use due to the fact that they can be easily in-situ prepared by mixing a liquid with a powder phase composed of calcium phosphate salts. In spite the good biological properties of CaP based biocements they are usually plagued by low inherent mechanical properties [1]. The main objective of the current study as part of an overall project for the development of new CaP bone cements is the study of calcium phosphate cements with enhanced mechanical properties.

EXPERIMENTAL METHODS

For the preparation of α -TCP powder, equimolar quantities of calcium carbonate and calcium pyrophosphate ball milled and next the mixture was placed in alumina crucible, dried at 80 °C, placed in a furnace at 1300 °C for 12 hours and rapidly quenched on a metallic surface. The resulted material was crushed in the ball mill. The cement powder was mixed with 4 % w/v Na_2HPO_4 solution in an agate mortar at a powder/liquid ratio of 0.32 and the product in form of a paste, was moulded in 90 mm x 12.8 mm x 2.2 mm moulds. The specimens were remained in 100 % humidity for 12 hours and were then removed from the mould and placed at 37 °C in a polyethylene vial containing 60 ml of Ringer solution for 14 days for hardening [2]. Flexural properties of the materials were determined in three point bending mode. Moreover, DMA testing was conducted at three point bending loading for the CaP based biocements, in order to determine the dynamic properties of the material @ 25-200°C.

RESULTS AND DISCUSSION

It can be seen from the flexural properties presented in Table 1 below of the α -TCP based bone cements that their mechanical properties are comparable to those of the human bones (e.g. cortical bone), making them candidates for implants in bone deficiencies.

Property	E-modulus [MPa]	Flex. Strength [MPa]	Ultimate strain [%]
Mean	4879.8±972	3.39±0.28	0.07±0.01

Table 1. Typical Flexural properties of the bone cements studied.

Representative SEM images showing the morphological characteristics of the hardened cements are shown below in Figure 1. In the top-left is the α -TCP prior to the maturing procedure

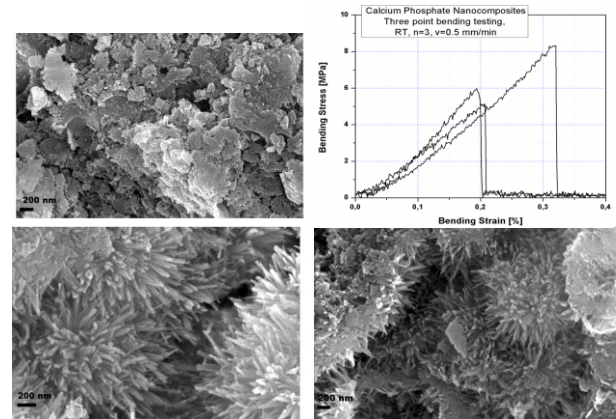

Figure 1. Flexural response and representative SEM pictures from the specimens tested.

An entangled network of nanoneedles is observed (bottom pics). These structures are composed of calcium deficient hydroxyapatite which is the result of the hydrolysis of α -TCP. Also, As seen in Figure 2, dynamic moduli of the CaP cements showed sensitivity to testing temperatures.

Figure 2. DMA scans, Storage moduli of Cap cements

CONCLUSION

Based on the analysis performed, it was shown that it is feasible to produce bone cements based on α -TCP, with an evolving nano-structure during the maturing-hardening phase with satisfactory biomechanical properties and dynamic behaviour.

Bacterial Cellulose Based Electrospun Scaffolds for Bone Tissue Engineering

Deniz Atila¹, Ayten Karataş², Dilek Keskin^{1,3}, Ayşen Tezcaner^{1,3}

¹Department of Engineering Sciences, Middle East Technical University, Turkey

²Department of Molecular Biology and Genetics, Istanbul Technical University, İstanbul, Turkey

³Center of Excellence in Biomaterials and Tissue Engineering, Turkey, atila.deniz@metu.edu.tr

INTRODUCTION

Success in tissue engineering studies highly depends on properties of materials used and parameters of the chosen method¹. Materials used specifically in bone tissue engineering, require high resistance to mechanical stress and biodegradability^{1,2}. We aim to prepare a nanofibrous three dimensional and porous electrospun scaffold for regeneration of bone tissue with modified bacterial cellulose (BC), produced by species of bacteria *Acetobacter xylinum* since BC is a crystalline biopolymer with good mechanical properties^{2,3}.

EXPERIMENTAL METHODS

BC was produced by culturing ATCC 10245 *Glucanoacetobacter xylinum* species and purified (Fig.1). After a sulphuric acid treatment⁴, BC was electrospun with another natural polymer pullulan (PULL) in order to make electrospinning easier⁵.

Fig 1. *G. xylinum* species seeded (a), BC produced on the culture (b), and BC purified (c).

Mixed BC/PULL (50/50 w/w %) dissolved in DMAc/DMSO/NMMO (Sigma-Aldrich) (1/1/2) were electrospun with 10-14 % of polymer concentrations. Wet electrospinning method was used with a collector bath filled with ethanol absolute (Merck). The applied voltage, tip-to-collector distance, and flow rate were fixed as 20 kV, 12 cm, and 1 ml/hr. Produced scaffolds were freeze-dried and analyzed.

RESULTS AND DISCUSSION

Macro-scale interpretations of the 3D carriers showed that the scaffolds become more compact after freeze-drying (Fig.2).

Fig 2. Electrospun BC/PULL carriers in ethanol before (a) and after freeze-drying step (b).

Dimensions of the carriers (either diameter or height) could be adjusted by changing the electrospinning time (i.e. the amount of electrospun meshes) according to intended application area.

SEM analysis was conducted to examine the morphological structure of 3D nanofibrous mesh (Fig.3). As the polymer concentration increases, fibre diameter decreases. In addition, huge beads within fibrous structures were scaled down.

Fig 3. SEM images of electrospun BC/PULL scaffolds with polymer concentrations 10 (a), 12 (b), and 14 % (c).

CONCLUSION

BC/PULL electrospun scaffolds were prepared for the first time. These scaffolds hold promise for bone tissue engineering applications.

The Influence of Porosity and Pore Shape of PCL Electro-spun Nano-fibrous Meshes on Macrophage Activation

Kieran P. Fuller^{1,2}, Colm O'Dowd², Abhay Pandit¹, and Dimitrios Zeugolis¹
dimitrios.zeugolis@nuigalway.ie

¹Network of Excellence for Functional Biomaterials, National University of Ireland Galway, Ireland

²Vornia Biomaterials, Galway, Ireland

INTRODUCTION

Clinical data in wound healing models indicate that current non-absorbable products are characterised by chronic inflammation, as a result of persistent foreign body reactions¹. It has been postulated that identification of modulatory effects of macrophage M1 and M2 activation will create clinically relevant meshes, which will minimise patient complications and improve recovery rates². Indeed, recent data indicate that topographical features preferentially modulate macrophage response³. Herein, it is hypothesised that macro-porous nano-fibrous constructs not only will have adequate mechanical properties, but will also minimise inflammatory response.

EXPERIMENTAL METHODS

Electro-spun meshes of 30, 50 and 70% porosity were created in rhomboid, circles, and square pore shape. Randomly orientated electro-spun fibres and solvent cast films acted as control. Morphological features were assessed with a stereo microscope and SEM. Mechanical properties were measured using uniaxial tensile testing. Human skin fibroblasts were used to assess cytotoxicity. Murine macrophages (Raw 264.7) were used to assess immunogenic response.

RESULTS

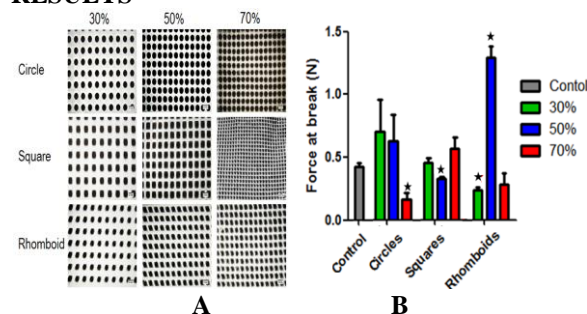

Figure 1: **A:** Optical analysis indicates that the produced meshes have clearly defined porosity. **B:** Uniaxial tensile testing analysis indicates that while the % porosity has a significant effect, the pore shape affects the mechanical properties to a higher degree as can be seen by the variation between samples, N=5.

Figure 3: The metabolic activity is equivalent or higher on the nanofibrous material compared to the film.

DISCUSSION AND CONCLUSION

The introduction of pores with a well-defined shape might improve mechanical properties over a random control but this is dependent on the porosity. The metabolic activity is not affected by any pore shape or porosity when compared to a film. Further analysis with macrophage response is in progress.

INTRODUCTION

Formation of bacteria biofilms on implanted titanium surfaces is a growing health issue. Biofilms are linked to infection of medical devices, jeopardizing their long-term service.

A chitosan coating of titanium doped with silver nanoparticles has been evaluated for conferring antibacterial properties to medical device surfaces [1]. A dip-coating method of deposition was chosen for its versatility and ease of application [2]. Both chitosan coating formation and silver nanoparticle incorporation in the coating have been evaluated to achieve an improved antibacterial response.

EXPERIMENTAL METHODS

Silver nanoparticles were created by a chemical precipitation reaction of silver nitrate in sodium citrate, with a concentration, temperature and time controlled process. The nanoparticles were characterized by SEM and TEM, and particle sizes were established by dynamic laser light scattering.

Chitosan films were manufactured from an acidic solution containing 1% chitosan of medium molecular weight. Grade 2 titanium polished surfaces were used as substrate. Chitosan coatings with and without silver nanoparticles were prepared by dip-coating titanium samples at 1mm/min. Samples were characterized by contact angle, surface roughness, mechanical resistance and chemical composition measurements.

Bacterial adhesion and proliferation assays were made *in vitro* with two strains present in oral biofilms, *Streptococcus sanguinis* and *Lactobacillus salivarius*. Cytotoxicity was evaluated with an LDH assay.

RESULTS AND DISCUSSION

Silver nanoparticles were produced with rounded geometry and diameter from 20 to 50nm, depending on processing conditions.

Figure 1. TEM image of silver nanoparticles dispersion in a chitosan coating.

A good dispersion of nanoparticles within the chitosan coating was achieved (Figure 1).

The layers formed on titanium chitosan showed a good adhesive strength, with detachment stresses over 3.8MPa.

The chitosan-nanoparticles combination showed an antibacterial effect in cell adhesion assays, producing the best results layers with smaller nanoparticles (figure 2).

Figure 2. In vitro antibacterial effect of chitosan (with and without silver nanoparticles) and titanium, used as a control.

The chitosan coatings, with and without silver nanoparticles, did not exhibit cytotoxicity *in vitro*.

CONCLUSION

A practical process for creating chitosan coatings doped with silver nanoparticles on titanium surfaces has been developed and characterized. The chitosan coatings doped with silver nanoparticles have a reasonable adhesive strength to the substrate and they present a noteworthy *in vitro* antibacterial activity.

Photo-crosslinkable and biopolymer-based inks for inkjet-bioprinting of artificial cartilage

Eva Hoch^{1*}, Achim Weber², Günter E.M. Tovar^{1,2} and Kirsten Borchers²

^{1*}Institute for Interfacial Process Engineering IGVP, University of Stuttgart, Germany, eva.hoch@igvp.uni-stuttgart.de

²Fraunhofer Institute for Interfacial Engineering and Biotechnology IGB, Stuttgart, Germany

INTRODUCTION

The future vision of implants comprises individually tailored prosthesis and the generation of artificial tissues and organs with sophisticated, biomimetic structure prepared from the patient's own cells. This challenging intention needs fabrication processes that do not set any limitations to the generation of various shapes. Thus, current research activities focus on the application of freeform fabrication methods, e.g. inkjet printing, for the deposition of cells and biomaterials into spatial orientations and geometries to reproduce the complexity of native tissues in a controllable and automated manner. This so called bioprinting requires biomaterials that are printable and, at the same time, hold appropriate physical, chemical, and biological properties. Thereby, biomolecules from the extracellular matrix of native tissues constitute very promising materials as they hold natural signaling motifs for the stimulation of cell adhesion, migration and function.

EXPERIMENTAL METHODS

For additive assembly of bioartificial tissue, photo-crosslinkable gelatin was prepared by derivatization with methacrylic anhydride.¹ In view of constituting bioartificial cartilage, chondroitin sulphate (CS) was also modified. Hydrogels were gained by photo-induced radical crosslinking in the presence of the water-soluble photoinitiator Irgacure 2959. The viscoelastic properties and long-term stability of the gels have been analyzed by swelling experiments and rheological measurements. Gels were investigated as encapsulation matrices for porcine articular chondrocytes to evaluate their applicability in respect to the generation of artificial cartilage. Processability by piezoelectric printing of the precursor solution was analyzed and printing of viable chondrocytes was performed (Nanoplotter NP2.1, GeSiM mbH, Germany).² Finally, cell-laden hydrogels were prepared by alternate printing and UV-induced crosslinking.

RESULTS AND DISCUSSION

We provide ECM-based hydrogels with tunable physico-chemical properties for use as biomimetic extracellular matrix for three-dimensional tissue substitutes. The developed precursor solutions hold low viscosities and show no gelling effects. Hence, the hydrogel system is suitable for processing in additive manufacturing, e.g. piezoelectric inkjet bioprinting. We

proved that the addition of CS to the bioartificial ECM substitute could promote the re-constitution of the chondrocyte-specific phenotyp after expansion in 2D cultivation.

Figure 1 shows photocrosslinked gelatin-based hydrogels with different mechanical properties (top), inkjet bioprinting of gelatin-based ink (bottom left) and viable printed chondrocytes (bottom right).

CONCLUSION

The developed biobased hydrogel system is suitable for processing by printing techniques and constitutes a biofunctional ECM substitute. Thus, it will contribute to the development of biological implants in the near future.

INTRODUCTION

Fibrin is a versatile biomaterial that has been used extensively in a variety of tissue engineering applications. We have developed a 3D *in vitro* culture system using a bioreactor (MagneTissue) which allows mechanical stimulation of myoblasts embedded in a ring shaped fibrin scaffold by application of strain. Using this system we sought to analyze the effects of mechanical strain on cell alignment and distribution, viability and expression of muscle markers.

EXPERIMENTAL METHODS

Fibrin rings were prepared by injection molding (TISSUCOL DUO 500 Fibrin Sealant Kit, Baxter) with following final concentrations: 4×10^6 C2C12 myoblasts embedded per ring, 20 mg/ml fibrinogen and 0.625 U/ml thrombin. The rings in the strain group were applied to the bioreactor system. At day 3, growth medium was changed to differentiation medium (both supplemented with 100 KIU/ml Aprotinin) for strain and control groups and 10% static strain was applied to the strain group daily for 1 hour for the rest of the culture period (until d9). All data are presented as mean \pm SD of at least three independent experiments. Statistical analysis was performed using the student's t-test and values of $p < 0.05$ were considered significant.

RESULTS AND DISCUSSION

We demonstrate that over a culture period of at least 9 days the cells remain viable and differentiate into myotubes. Application of static mechanical strain leads to parallel cell alignment (Fig.1A) and also seems to facilitate nutrient diffusion within the scaffold, demonstrated by improved cell distribution (Fig.1B).

Fig.1: Calcein-AM/PI co-stainings of cells embedded in a fibrin ring: (A) ring surface, (B) radial section.

Furthermore, RT-qPCR results reveal that expression of mid- and late-stage specific myogenic markers is significantly increased when static strain is applied, demonstrating the subtle involvement of mechanotransduction in myogenic differentiation (Fig.2).

Fig.2: Relative expression levels of Myogenin and TnT1 at indicated timepoints over the course of the culture period (* $p < 0.05$, *** $p < 0.001$).

Our findings demonstrate that static mechanical strain has the ability to not just improve cellular alignment, a prerequisite for myotube formation, but to also increase myogenic differentiation by upregulation of myogenic marker expression. More importantly, variation of strain application can serve as a way to provide differential developmental cues and therefore allows for partial guidance of cellular fate decisions.

CONCLUSION

The use of this 3D culture system may provide a powerful tool to study myogenic differentiation, mechanotransduction and muscle physiology or disease. In this respect, further optimization of different strain application patterns might increase the degree of myogenic differentiation and functionality, with the long-term goal of providing patients with fully functional engineered skeletal muscle transplants.

INTRODUCTION

The *in vitro* study of stem cell expansion and stemness maintenance has received growing attention in the last years, to possibly exploit the stem cell therapeutic use [1]. Finding a functional and transparent substrate for *in vitro* culture of stem cells, while preserving their stemness, is one of the challenging goals to be attained. Since not only the substrate type, but also its biofunctionalization represent a possible way to acquire the specific features during stem cell culture, the aim of our work was to prepare transparent 2D polyurethane (PU) substrates and functionalize them with bio-competent dendrons, so to provide the adequate surface for stem cells culture.

EXPERIMENTAL METHODS

The PU films were prepared using similar reagents as already set up for cytocompatible PU foams (MDI prepolymer, a polyether-polyol mixture with 1-1.5% water, and Fe AcetylAcetonate as catalyst) [2], but spreading a proper quantity of the reaction mixture on a glass plate (6, 4 or 3.5 g) and setting up the procedure. PU films (PU6, PU4 and PU3.5, according to the amount of reaction mixture spread) were characterized for morphology (optical and SEM observations), wettability (static contact angle), ATR-FTIR spectroscopy and mechanical tensile tests. Dendrons composed by an arginine root with a generation-three branched structure of lysine (RG3K) were synthesized and functionalized with betaine (RG3K(CB)₁₆) or with the amino acidic sequence YIGSR (RG3K(YIGSR)₁₆), as already described [3]. The surface of the most transparent and homogenous PU film (i.e. PU3.5) was activated by air plasma and NHS/EDC chemistry and subsequently biofunctionalized with dendrons or dip-coated with dendron-modified poly-L-Lysine (PLL). The effective PU film functionalization was assessed by contact angle and ATR-FTIR. Human Mesenchymal Stem Cells (hMSCs) were seeded (7000 cells/cm²) and cultured for 7 days on PU3.5 film ($\Phi=10$ mm) functionalized with dendrons or dip-coated with dendron-modified PLL, using not modified film and the culture plastic (TCP) as control. Cell morphology, in particular cell aggregates, was evaluated by SEM, CellTracker and DAPI staining [4].

RESULTS AND DISCUSSION

PU films produced by spreading 6g or 4g of the reaction mixture on the glass substrate proved to be thick, not homogenous and not completely transparent, mostly due to the presence of air bubbles. Instead, PU3.5 films were transparent and homogeneous (Fig. 1a), with lower thickness (~ 80 μ m, $p<0.05$) compared to PU6 and

PU4. No significant differences in elastic modulus ($p>0.05$) were observed for all the produced PU films.

Fig. 1: (a) Stereo image of PU3.5 film on a written paper (scale bar=2 mm); (b) hMSCs cultured on PU3.5 film dip-coated with RG3K(YIGSR)₁₆-modified PLL (scale bar=2 μ m). The synthesis and functionalization of the dendrons was demonstrated by mass spectrometry and ATR-FTIR. Surface wettability of the PU films functionalized with dendrons or dendron-modified PLL increased ($p<0.05$) compared to not modified films (Fig. 2), validating the efficacy of air plasma and NHS/EDC chemistry in activating the PU surface and of functionalization with dendrons and dendron-modified PLL.

Fig. 2: Contact angle of PU3.5 before and after the functionalization with dendron and dendron-modified PLL.

hMSCs cultured on dendron-modified PU films showed spherical morphology, in particular when in contact with RG3K(YIGSR)₁₆ dendron and RG3K(YIGSR)₁₆-modified PLL. On these modified substrates, a first formation of 3D cell aggregates, indicating cell viability and stemness maintenance, was noticed (Fig. 1b).

CONCLUSION

The possibility to produce transparent, homogeneous and reproducible PU 2D substrates, and then to surface modify and functionalize them was demonstrated. The encouraging results obtained with the hMSCs culture preliminarily indicate the suitability of the described biofunctionalized PU films as substrates for *in vitro* stem cell culture, not affecting their stem phenotype.

Quantification of Volume and Size Distribution of Internalised Calcium Phosphate Particles and Their Influence on Cell Fate

Richard Williams¹, Midhat Salimi¹, Gary Leeke¹, Paula Mendes¹, Liam Grover¹
¹ School of Chemical Engineering, University of Birmingham, Birmingham, UK.
rxw946@bham.ac.uk

INTRODUCTION

Calcium phosphates (CaPs) have been used extensively as bone replacement materials, substrates for drug release and transfection agents because of their non-cytotoxic nature and chemical similarity to the mineral component of human bone [1]. However, the fate of CaPs upon cellular internalisation is not fully understood, which has implications as a consequence of the effects of CaP wear debris from bone implants on surrounding tissues. Through surface modification and fluorescent tagging of CaPs, we were able to track particle internalisation within cells. We report observations from cell studies showing that the size distribution of internalised material – not just total volume – affects cell fate.

EXPERIMENTAL METHODS

Surface modification and fluorescent tagging of Silicon-substituted hydroxyapatite (SiHA) was based on a previously developed [2]. Briefly, 230mg of SiHA was added to a 3%(v/v) solution of 3-mercaptopropyltrimethoxysilane and 3%(v/v) DI water in methanol (10mL total volume, pH 5, left for 3 hours). pH then adjusted to 10, left overnight and washed. **Live cell imaging:** As described in [2]. Briefly, SiHA was mixed with a 1mL 100µM solution of Fluorescein-5-Maleimide in PBS. MC3T3 cells plated into live cell imaging dishes were exposed to the labeled SiHA for 24 hours with 50 µM LysoTracker Red added 30mins prior to confocal imaging. **Image analysis:** fluorescent SiHA and lysosomes were segmented by grey-level thresholding. Particle size and volume was estimated by computing the area of a bounding box, computing major/minor axis values and calibrating the voxel scale from the data file.

RESULTS AND DISCUSSION

Structures up to 1µm were most prevalent within the cells, but sizes up to 3-4µm were also observed. Lysosomes were generally found to contain structures up to 2-3µm (Figure 1), leaving any larger structures within the overall cell. No clear relationship was found between the volume of material transferred to lysosomes and the total material internalised by the cell as a whole. All particles ranging from 0.2-3µm in lysosomes correlated to cell morphology change from elongated to round shape. When particles larger than 2µm were not encapsulated within lysosomes, a dramatic increase in number of lysosomes and their convergence around the structures was observed. Cells appeared to detach from the plate when structures larger than 1µm were left exposed within the cell. This suggests that cell fate may not be dictated by the volume of material internalised alone. The location of any particulates >1µm within the cell (regardless of the total

volume of material) appears to have a strong influence on cell response.

Figure 1: Confocal images of labelled SiHA structures (green), partially (left) and fully (right) encapsulated by lysosomes (red).

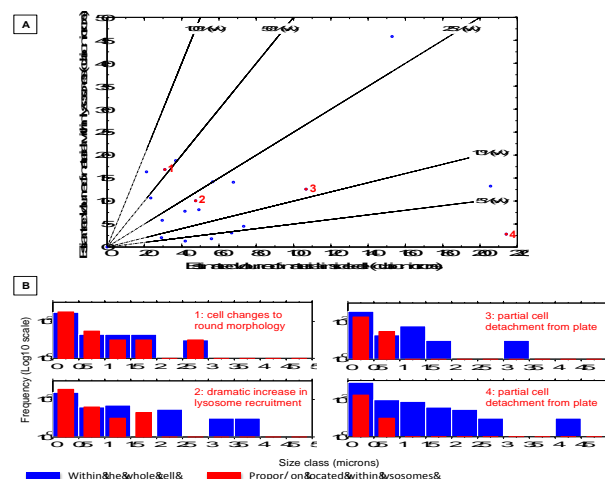

Figure 2: Volume of material in lysosomes (A) and size distribution of material in 4 example cases of changes of cell behaviour (B).

CONCLUSION

This study has revealed that CaP particles of >1µm in size can enter MC3T3 cells, but cannot be internalised in lysosomes. The results presented here demonstrate a correlation between the presence of particles of this size range and cell death. This result may have wider implications for the understanding of how particles eroded from the surface of implants may influence biological response.

INTRODUCTION

The high incidence of lesions in articular cartilage, associated to the soaring rise of life expectancy of the western population, has stressed the urgent need for medical solutions for osteoarthritis. Current clinical treatment of diseased or injured cartilage does not sufficiently restore long-term function and relieve joint pain.¹ This brings new opportunities for scalable regenerative solutions that involve the combination of biomaterials and chondrogenic inductive agents that can reliably induce the formation of functionally acceptable neocartilage and resolve challenges such as neo-tissue integration at the donor site.² In this work we synthesize cryogels of poly [2-ethyl-(2-pyrrolidone) methacrylate] (PEPM) and functionalized hyaluronic acid with aldehyde groups (A-HA), incorporating transforming growth factor- β_3 (TGF- β_3) and study their properties and potential for cartilage repair strategies.

EXPERIMENTAL METHODS

Porous semi-interpenetrating networks (sIPN) were prepared by the cryopolymerization of EPM (0.725M) using triethyleneglycol dimethacrylate (1.7% molar fraction) as crosslinker and potassium persulfate (2×10^{-2} M), as radical initiator activated with TEMED (0.27% v/v), in the presence of aqueous solutions of pure A-HA (5% w/v) or A-HA previously functionalized with TGF- β_3 . Reacting mixtures were first cooled to 0°C, deoxygenated during 30 minutes and progressively reduced to -15°C, at a cooling rate of 0.5 °C/min, within a cryostat. After 12 hours of reaction, both PEPM-A-HA cryogels were demolded, cut into discs (6 x 2.5 mm) and freeze-dried, until constant weight. Physicochemical characterization of the cryogels was performed (nuclear magnetic resonance - NMR, morphology and swelling). TGF- β_3 in vitro release profile was followed during 21 days and quantified using an ELISA kit. The chondrogenic differentiation of human bone marrow-derived MSCs on PEPM-A-HA cryogels with or without TGF β_3 was studied over 4 weeks. Thereafter the expression of cartilage interest genes and the quality of the synthesized extracellular matrix were analyzed, respectively, by using real-time PCR and histological staining.

RESULTS AND DISCUSSION

HA polysaccharide backbone was oxidized with sodium periodate to form aldehyde groups with an efficiency of 39% as confirmed by NMR. The aldehyde functionality of the A-HA conjugates with amines present at TGF- β_3 via Schiff-base reaction (confirmed by ELISA). The

morphology of PEPM-A-HA cryogels was characterized by scanning electron microscopy (SEM) micrographs that revealed an interconnected and highly porous network structure, uniformly distributed, with a pore size in the range of 15-50 μ m. Cryogels were able to swell up to 600% of their initial dry weight. PEPM-TGF- β_3 -A-HA cryogels presented a total cumulative amount of nearly 70% (ELISA). BM-MSCs were metabolically active when seeded in the synthesized cryogels and the pore configuration allowed cell penetration. Moreover from the alamar blue assay (Figure 1) it is clear a significant positive influence of the release of TGF- β_3 in cell's proliferation over 14 days ($p < 0.05$, using one-way ANOVA) regarding both TCPS control as well as PEPM-A-HA. MSCs were able to undergo chondrogenic differentiation in the presence of both produced systems.

Fig 1. Alamar blue dye reduction assay after 7 and 14 days for tissue culture plastic polystyrene (TCPS) as positive control, PEPM-A-HA and PEPM-TGF- β_3 -A-HA cryogels (n=5).

CONCLUSION

The incorporation of TGF- β_3 into PEPM-A-HA cryogels enhanced BM-MSC proliferation and chondrogenic differentiation presenting potential use in cartilage repair.

Biaxial stretching of poly(L-lactide) tubes for improvement of mechanical properties

A. Løvda¹, J. Wenzel Andreassen², L. Pilgaard Mikkelsen³, K. Agersted², K. Almdal¹

¹Department of Micro- and Nanotechnology, Technical University of Denmark, Denmark

³Department of Wind Energy, Technical University of Denmark, Denmark

alvlo@nanotech.dtu.dk

INTRODUCTION

Poly(L-lactide) (PLLA) is a semi-crystalline bioabsorbable polymer, which has been widely investigated for medical devices despite its inferior stiffness and strength compared with conventional materials such as metal alloys¹. Due to the semi-crystallinity behaviour of the polymer, strain-induced crystallinity is expected to improve such mechanical properties by orientation of the crystals as seen in biaxial films^{2,3}. The objective was to investigate improvement of mechanical properties and the changes in crystallinity, crystal size and orientation in simultaneous biaxial strained PLLA tubes.

EXPERIMENTAL METHODS

PLLA (2003D) was extruded into tubes (OD 3.4mm). The tubes were heated to 74°C and longitudinally strained while applying internal pressure, initiating a tube expansion in the heated zone, resulting in a simultaneous biaxial strain.

The degree of strain in each direction is noted as the ratio between the longitudinal and radial strain (LxR). Mechanical testing was conducted to evaluate material properties and the effect of orientation. Orientation and crystal size was determined by X-ray diffraction (XRD), while total crystallinity (X_c) was determined by differential scanning calorimetry (DSC).

RESULTS AND DISCUSSION

Tensile testing of specimens in the circumferential direction show the typical strain hardening behaviour of

Fig1: Elastic modulus and yield stress for PLLA tubes with different LxR ratio obtained from tensile testing in the circumferential and longitudinal direction.

a semi crystalline polymer, but this is not seen for specimens tested in the longitudinal direction.

The elastic moduli (Fig.1) in the circumferential direction were superior to the modulus in the longitudinal direction at all times, due to the higher degree of strain in the given direction. Also the modulus is improved with degree of total area expansion, whereas the LxR ratio does not determine the

properties. The yield stress is less affected by the total area expansion (T_{area}).

XRD images in Fig 2 show that crystal orientation is predominant longitudinal when only strained in the longitudinal direction (LxR =1.0x0). The intensity plot in Fig. 2 show that once the tube is expanded, the peak in the 110/200 plane is no longer at perpendicular orientation to the longitudinal direction, but parallel. Despite a larger degree of T_{area} or LxR ratio, the orientation did not change.

X_c does not increase with the degree of T_{area} or LxR ratio, and the improved stiffness of the tubes is therefore not explained by neither crystal orientation nor an increase in strain-induced crystal formation.

XRD measurement also showed that crystals initially formed during uniaxial strain have a large crystal size circumferentially (183Å) and smaller axially (62Å), but this relation is flipped if radial expansion occurs simultaneously with 65Å radially and 134Å axially. The crystal size does not change significantly in the circumferential direction (65-70Å) with expansion or as function of LxR ratio, whereas the crystal size in the longitudinal direction decrease from 160Å to 137Å.

Fig 2: Intensity plot obtained from XRD of tubes with a different L/R ratio.

CONCLUSION

By biaxial stretching PLLA tubes improvement of stiffness and strength was obtained in both directions. Longitudinal stretching leads to crystal orientation in that given direction. Crystal orientation gained from this strain is reduced by degree of radial strain and altering the crystal alignment longitudinally. X_c does not increase with degree of radial strain and the improved properties are therefore not related to the crystal orientation nor a higher degree of crystallinity, but possibly stretching of the amorphous regions.

Controlled IL-2 Delivery from Novel Photocured Biodegradable Poly (decane-co-tricarballylate) Elastomers

Husam M. Younes* and Mohammad Shaker

Pharmaceutics and Polymeric Drug Delivery Research laboratory, College of Pharmacy, Qatar University, PO Box 2713, Doha, Qatar. husamy@qu.edu.qa

INTRODUCTION

One of the main challenges in interleukin-2 (IL-2) cancer immunotherapy is achieving localized and efficient delivery over a sustained period of time with proper maintenance of its stability and bioactivity¹. New biodegradable elastomeric poly (decane-co-tricarballylate) [PDET] matrices which utilize the osmotic-driven controlled release mechanism were designed in an attempt to overcome stability and bioactivity challenges facing IL-2 delivery²⁻⁴.

EXPERIMENTAL METHODS

Elastomer synthesis was achieved by polycondensation reaction between tricarballylic acid and alkylene diols, followed by acrylation and photocuring. IL-2 loaded matrices were prepared by intimately mixing lyophilized IL-2 powder with the acrylated prepolymer prior to crosslinking. Protein release was analyzed using ELISA and the in vitro bioactivity of released IL-2 was assessed using C57BL/6 mouse cytotoxic T lymphocytes. The influence of various parameters such as the elastomers' crosslinking density, the volumetric loading percentage and the incorporation of osmotic excipients on the release kinetics of the drug was also studied.

RESULTS AND DISCUSSION

Disk-shaped loaded matrices showed faster controlled IL-2 release patterns than microcylinders, with drug release proceeding via typical zero-order release kinetics. The increase in the device's surface area and the incorporation of trehalose in the loaded lyophilized mix increased the IL-2 release rate. As well, it was shown that the decrease in the degree of prepolymer acrylation of the prepared devices increased the IL-2 release rate. The cell based bioactivity assay for IL-2 over a release period of 28 days showed that the released IL-2 retained more than 94% of its initial activity.

CONCLUSION

A new protein delivery matrices composed of biodegradable PDET elastomers demonstrated to be promising and effective for linear, constant and sustained osmotic-driven release of IL-2 and other similar cytokines.

Incorporation of Elastin Enhancement Agents on Nano-scale Fibers

F.Damanik¹, C. van Blitterswijk¹, J. Rotmans², and L. Moroni^{1*}

¹ Department of Tissue Regeneration, MIRA Institute for Biomedical Technology and Technical Medicine, University of Twente, The Netherlands; E-mail: f.damanik@utwente.nl

²Department of Nephrology, Eindhoven Laboratory, LUMC, The Netherlands

INTRODUCTION

Over the past years, electrospinning has been the preferred technique for fabrication of nano-scale fibres due to its simplicity, tunability and versatility to spin a wide range of polymers. Owing to its adaptability on porosity, broad selection of material and architecture, electrospun fibres have been developed as biocompatible scaffolds or drug delivery systems for tissue engineering¹. Elastin has been the missing link in vascular tissue engineering². Therapeutic agents such as minoxidil, retinoic acid and aldosterone have been studied to enhance elastin synthesis. However, side effects may develop if the release of these agents is not localised and controlled. In this study, we developed a drug delivery system by incorporating these elastin enhancement agents into electrospun scaffolds to provide a local and controlled release.

EXPERIMENTAL METHODS

Electrospinning. Poly (ϵ -caprolactone) (PCL) solutions (15, 20, and 30% w/v) were prepared by dissolving the polymer in a 8:2 chloroform:methanol mixture under gentle stirring overnight. A stock solution of 3mg/ml in methanol for each elastin enhancing agent was added to the PCL solution to obtain different concentrations (0.01-0.5%) and stirred overnight. Solutions were electrospun by tuning flow rate (0.5-2ml/hr), working distance (15-20cm) and voltage applied (15-30kV) to modulate the controlled release of agents and minimize burst release. SEM was done to analyse the structure of loaded electrospun scaffold.

In vitro release and loading efficacy. Electrospun scaffolds were incubated at 37°C in PBS and supernatant collected at day 1, 4, 7, 10, and 14 for release measurements. For loading efficacy, loaded scaffolds were dissolved in chloroform:methanol mixture and vortexed. The absorbance of the samples and standard were read at each respective wavelength of the agent by a spectrometer.

In vitro cell culture. Human dermal fibroblast and mesenchymal stem cells were seeded onto loaded electrospun scaffolds with a cell density of 50,000 cells/scaffold. Analysis of cell metabolic activity, proliferation and morphology was done with presto blue, DNA assay and immunostaining.

RESULTS AND DISCUSSION

SEM analysis shows capability to obtain nano-scale fibers of $128 \text{ nm} \pm 62 \text{ nm}$ through electrospinning and maintenance of fibre morphology with loaded agents.

Figure 1. SEM images of (a) PCL, (b) PCL-retinoic acid and (c) PCL-minoxidil electrospun sheets. Scale bar: 2µm

By modulating the parameters, loading efficacy increased from 30% to 75%. Preliminary study on release showed minimized burst release in comparison to dip-coated samples. Metabolic activity of cells seeded on loaded PCL scaffold increased compared to unloaded PCL scaffolds. Immunostaining showed strong cell attachment and formation of multiple focal adhesion on the loaded scaffolds.

Figure 2. Immunostaining of vinculin-FITC and phalloidin-Texas red on PCL loaded scaffolds. Scale bar: (a) 50µm, (b) 10µm.

By tuning different parameters, one could electrospin PCL loaded fibers to obtain similar fibre morphology of PCL unloaded scaffold, and deliver the targeted agents in a controlled manner. Loaded scaffolds did not show any adverse reaction, but instead increase metabolic activity of cells, possibly enhancing elastin synthesis. Further quantification of elastin will be performed to confirm this.

CONCLUSION

In conclusion, elastin therapeutic agents were successfully incorporated into electrospun scaffolds while maintaining desired nano-scale fibre architecture, and were delivered in a controlled manner.

Mineralized Porous Pullulan Microcarriers for Bone Tissue Engineering

Hazal Aydoğdu¹, Dilek Keskin^{1,2,3}, Ayşen Tezcaner^{1,2,3}, Erkan Türker Baran³

¹ Biomedical Engineering, Middle East Technical University, Turkey, e-mail: ahazal@metu.edu.tr

INTRODUCTION

Because of ageing population there is increased clinical need for tissue engineered bone substitutes that incorporate autologous bone cells and osteogenic materials. Previously apatite precipitations on polymeric scaffolds showed a suitable microenvironment for osteogenic cells¹. Therefore, we developed a three-dimensional pullulan hydrogel based microcarrier by using porogen leaching and *in vitro* apatite formation for efficient osteogenesis. We aim to create mineralized macroscopic tissue constructs carrying osteoblasts that can be injected into the defect site for bone tissue regeneration.

EXPERIMENTAL METHODS

Porous pullulan microspheres were prepared through water-in-oil emulsion crosslinking of stirred micro droplets of polymer with sodium trimetaphosphate and calcium carbonate granules (about 20 µm in size). Calcium carbonate was then removed by hydrochloric acid leaching leaving pores behind. Morphologies and average diameters of cross-linked microspheres were assessed with microscopic techniques. Microspheres were incubated in simulated body fluid (SBF) to create bonelike apatite by biomimetic mineralization. For cell culture the mineralized microspheres are seeded with Saos-2 cells and incubated in growth medium. Saos-2 cells were seeded onto SBF incubated (7 day) pullulan microspheres for 1 day and were analysed by fluorescence microscopy to see the effect of mineralization on cell-material interactions.

RESULTS AND DISCUSSION

Pullulan microspheres, fabricated by emulsion at 500 rpm, had spherical shape and porous structure with an average diameter of 115 µm with 30% porogen calcium carbonate. The porogens were found to be homogeneously distributed (Fig 1). The incubation of the microcarriers in SBF led to the nucleation and growth of apatite improving the osteoconductive character of the microspheres.

Figure 1. µCT of upper (A) and frontal section view of CaCO₃ incorporating packed pullulan microspheres.

The cell culture study showed that SBF incubated microspheres had better surface properties cell attachment (Fig. 2). The cells had more tendency to interact with the SBF incubated and biomimetically mineralized microspheres than untreated microspheres with SBF.

Figure 2. Phase contrast and fluorescence microscope images of SaOs-2 seeded on native (A, B) and SBF incubated pullulan microspheres (B, C), respectively. Green illuminance shows Nile red stained SaOs-2 cells.

CONCLUSION

We introduce data to demonstrate that biomimetically mineralized porous pullulan microspheres serve as a suitable cell carrier system. The apatite obtained through biomimetic process can be similar to the natural bone mineral and thus may provide a more preferential environment for bone formation. Thus mineralization of the cell-seeded microspheres can enhance cell adhesion and generates an injectable system that can be applied to bone defect sites for an improved response by accelerating regeneration of the bone.

INTRODUCTION

The use of biofunctionalised nanoparticles, in which the specificity for recognising and the capacity for releasing effective drugs to targeted cells are combined, has become a promising tool in theranostics. In this context, Silica nanoparticles (SiNPs) turned out to be a good approach for *in vivo* applications [1]. However, available data on basic interaction studies between biofunctionalised SiNPs and their target cells are limited.

The present study was aimed at investigation of fluorescent anti-EpCAM-modified SiNPs (70 nm) fabricated to specifically detect malignant Colon Carcinoma cells (Caco2) so as to be used, in the future, as a drug-delivery carrier. Cytotoxicity, association and internalisation of plain-, dendrimer- and EpCAM-SiNPs were assessed on Caco2 cells using different techniques such as MTT assay (dehydrogenase enzymes activity), Flow Cytometry (FC), Confocal Laser Scanning Microscopy (CLSM) and Scanning Electron Microscopy (SEM). HeLa cells were used as non-targeted control cells.

EXPERIMENTAL METHODS

Association study by FC and SEM

Caco2 and HeLa cells (1×10^5) cultured in a 6-well plate were incubated with 50 $\mu\text{g/mL}$ SiNPs during different times (20 min and 24 h) then cells were either trypsinised or fixed with 2% glutaraldehyde to carry out FC or SEM analysis, respectively.

Internalisation evaluation by CLSM

Internalisation rates were evaluated using the same concentration of SiNPs and the same incubation times as for association studies. After removing SiNPs, cell plasma membranes and nuclei were further labelled with Cell Mask and Hoechst respectively. Analysis by CLSM was carried out acquiring xyz stacks of images in order to have a 3D reconstruction of the cells.

Cytotoxicity assessment by MTT assay

Cells were incubated with SiNPs for 1 h and a standard MTT assay was performed at different post-incubation times (0h, 6h, 24h, 72h, 7 days).

RESULTS AND DISCUSSION

Cell-NP association was detected by FC 20 min after SiNPs incubation (Fig. 1a). The percentage of cells associated to fluorescent SiNPs reached its maximum at 24 h (Fig. 1b). FC charts show the increment of cell population with green fluorescence over time (Fig 1a, b). SEM analysis showed that SiNPs could still be seen adhered to the plasma membrane of Caco2 cells at 20

min. However, the number of SiNPs decreased over time disappearing completely at 24 h.

Data obtained by CLSM analysis (Fig 1c) are in agreement with that obtained by FC and SEM. SiNPs seem to be entrapped in endosome or lysosome compartments at 24 h (Fig 1c).

Finally, MTT assays demonstrate that SiNPs are not toxic for Caco2 cells in the concentration used (50 $\mu\text{g/mL}$ SiNPs). Cells have been cultured in presence of this SiNPs up to 7 days (data not shown). The production of insoluble formazan indicates that cells are metabolically active and that SiNPs do not hamper cell proliferation.

Fig.1. Caco2 cells incubated with NPs (plain, dendrimer- or EpCAM-SiNPs). In the analysis by FC performed at 20 min (a) and 24 h (b) an increase of the percentage of positive association over time can be seen. CLSM image shows SiNPs internalization.

CONCLUSION

SiNPs designed and fabricated to be used as drug delivery platforms demonstrated to be non-toxic for Caco2 cells. NPs can be internalized and probably they are entrapped in endosomes or lisosomes.

Expression of Bone Markers in Pre-Osteoblastic Cells Grown on Titanium Surface with Nanotopography

L. M. S. de Castro-Raucci¹, L. N. Teixeira², P.T. de Oliveira¹, A. L. Rosa¹, M.M. Beloti¹

¹Cell Culture Laboratory, School of Dentistry of Ribeirão Preto, University of São Paulo, Brazil

²Department of Oral Pathology, School of Dentistry of Piracicaba, State University of Campinas, Brazil
larissa_spinola@yahoo.com.br

INTRODUCTION

The biocompatibility of dental and orthopaedic metal implants is strongly associated with osteoblastic responses to the surface of the biomaterial. Nanostructured titanium (Ti) surfaces can be obtained by a simple method, based on deoxidation and reoxidation controlled by means of chemical etching with solution H_2SO_4/H_2O_2 ¹. Previous studies have shown that the nanotopography accelerates and/or increases the extracellular matrix mineralization compared with untreated surface in cell cultures derived from newborn rat calvaria², indicating an enhanced osteoblast differentiation. The mechanisms by which nanotopography surfaces act on cells promoting osteoblastic differentiation and mineralization of the extracellular matrix are not fully understood. Considering that BMPs, including BMP-2/4, regulate osteoblastic differentiation and bone formation, the aim of this study was to evaluate the effect of Ti with nanotopography on the expression of key osteoblastic markers and BMP-2/4.

EXPERIMENTAL METHODS

Commercially pure Ti discs were polished with silicon carbide abrasive papers (320 and 600 grit) and treated with a mixture of H_2SO_4/H_2O_2 during four hours to generate nanotopography (Nano). Polished Ti discs were used as Control. Murine pre-osteoblastic cell line MC3T3-E1 (subclone 14) were plated on both Ti surfaces, i.e. Nano and Control, at 20,000 cells/well and cultured under osteogenic conditions for 3 days. Osteoblastic differentiation was evaluated by real-time PCR to detect the gene expression of runt-related transcription factor 2 (Runx2), alkaline phosphatase (ALP) and osteocalcin (OC). Quantitative gene expression data were normalized to the expression of the housekeeping gene GAPDH and calibrated by the expression of Control group. At the same time point, ELISA was performed to detect protein content of BMP-2 and -4. The quantitative data were submitted to Mann-Whitney test ($p < 0.05$).

RESULTS AND DISCUSSION

Gene expression assay revealed that Ti with nanotopography increased mRNA levels of Runx-2,

ALP and OC in MC3T3-E1 cell line (Table 1). On the other hand, protein content of BMP-2 and -4 was not altered by the treatment of Ti surface (Table 2). However, the role of BMP-2 and 4 on the osteogenic potential of Ti with nanotopography should not be neglected since other proteins related to BMP signalling pathway, as SMADs, may be affected by nanotopography.

Table 1. Gene expression of Runx-2, ALP and OC in MC3T3-E1 cells grown on Control and Ti with nanotopography surfaces.

Experimental groups	Gene expression		
	Runx-2	ALP	OC
Control	1.1±0.16	1.0±0.04	1.0±0.09
Nano	3.5±0.59	5.8±0.32	5.29±1.17
<i>p</i> value	0.029	0.029	0.029

Table 2. Protein syntheses of BMP-2 and -4 in MC3T3-E1 cells grown on Control and Ti with nanotopography surfaces.

Experimental groups	Protein content	
	BMP-2	BMP-4
Control	441.5±15.67	119.4±37.61
Nano	168.1±18.40	132.7±7.35
<i>p</i> value	0.7	0.1

CONCLUSION

The results showed that the nanotopography generated by treatment of Ti surfaces with mixture of H_2SO_4/H_2O_2 increases gene expression of bone markers without interfering with BMP-2 and -4 protein syntheses.

A novel method to measure the primary stability of dental implants and orthodontic screws

Fabrizio Barberis¹, Alberto Lagazzo¹, Stefano Benedicenti², Marco Migliorati², Marco Capurro¹

¹Department of Civil, Chemical and Environmental Engineering (DICC), University of Genoa, Italy

²Department of Integrated Surgical and Diagnostic Sciences (DiSC), University of Genoa, Italy

alberto.lagazzo@unige.it

INTRODUCTION

In dentistry and orthodontics there is an increasing tendency towards short-term loading of respectively implants and temporally anchorage devices (TADs)¹. This means that only the so-called primary stability (PS), namely the mechanically locking of prosthetic tools inside bone, previous to osseointegration, is called into play². Many indirect methods have been applied to evaluate PS in ex-vivo tests in view of a comparison of different devices and application techniques^{3,4}, but none of them is based on the measurement of the response of the implants to forces transversal to their axis. This way of loading is an important fraction of the load experienced by the implant in service.

In the present work we describe a specific apparatus developed to measure PS of dental implants or TADs through their compliance to a dynamically applied transversal point force. Some results obtained on different types of orthodontic mini-screws implanting on porcine bone samples are discussed. The same apparatus could be also employed in long-term experiments or fatigue tests.

EXPERIMENTAL METHODS

An instrumentation currently adopted for Dynamic Mechanical Analysis (DMA) of materials has been used to measure the dynamic compliance to transversal load. The implant is inserted following a related clinical protocol in a segment of medio-thoracic porcine rib encased in a plaster block. This block is bolted to the fixed head of the testing machine. The implant abutment is fixed to the moving head by means of an adjustable grip. The grip is designed as a hinge, preventing any displacement relative to the abutment, but allowing for rotation. The load line was vertical and perpendicular to the implant axis with a fixed lever arm with respect to the bone surface. The displacement of the abutment in the load direction was measured by a laser vibrometer with a resolution of 0.1 μm , which focused on the grip head. A piezoelectric force sensor is also assembled on the moving head of the apparatus.

The test consists in loading cyclically the sample at frequencies which can be automatically swept in any selected range between 0.5–1000 Hz. The amplitude of the applied oscillating force can be varied in the range between 0.1–1 N. The DMA device processed the time records of force and displacement via a Frequency Response Function (FRF), which provided a complex compliance spectrum of the sample. The real part of the spectrum corresponds to the elastic compliance, while the ratio of imaginary to real part (loss factor) provides an estimate of the energy dissipated in a cycle. The execution of tests is completely automatic being controlled by a dedicated software.

The apparatus was used to test the complex compliance of 12 samples prepared with 4 different types of mini-

screws for orthodontic applications. In this case a very narrow frequency interval was scanned (2–2.5 Hz), so the spectrum practically is reduced to a single value of compliance and a single value of loss factor for each test. The applied transversal forces were about 0.35 N. These tests were repeated in 5 consecutive days after the implantation. The specimens were stored during tests in physiological saline solution (NaCl 0.9%, pH 5.5), with the addition of antibiotic powder.

RESULTS AND DISCUSSION

In Fig. 1 complex compliance measurements (real part) of four types of mini-screw implants, measured with the method described above, are reported in their time evolution within 5 days from the insertion.

Fig. 1. Comparison of compliance of different types of mini-screws inserted in porcine bone.

Three types of behaviour can be easily observed: stable through all tests, gradually increasing or abruptly increasing.

The same apparatus can be also controlled for fatigue tests.

CONCLUSION

In this work a novel method of investigating the PS of dental implants or orthodontics mini-screws, based on the dynamic compliance with respect to a transversal point force, is illustrated. This method applied to a set of orthodontic mini-screws permitted to discriminate the performance allowing for clinical decisions.

Development of novel tamponades to treat retinal detachments

Victoria Kearns^{1*}, Robert Poole², Albert Caramoy³ and Rachel Williams¹

¹Department of Eye and Vision Science, University of Liverpool, UK

² Centre for Engineering Dynamics, University of Liverpool, UK

³Department of Ophthalmology, University of Cologne, Germany, *vkearns@liv.ac.uk

INTRODUCTION

Silicone oils are frequently used as long-term ocular tamponades in the treatment of complex retinal detachments. Although they have some properties that are advantageous for this application, such as the ability to exclude aqueous from the wound site and provide long term physical support, there are several aspects that could be improved:

1. Standard silicone oil is lighter than water, meaning that it can only support the superior retina. Oils heavier than water are required to treat tears in the inferior retina¹.
2. In clinical practice, lower viscosity oils are easier to inject into the eye, but are also less emulsification resistant. Emulsification is known to cause complications such as secondary glaucoma, macrophage activation, and pigment epithelium proliferation.
3. Formation of scar tissue within the retina or vitreous can occur. The tamponade agent could be used to deliver a pharmacological adjunct to treat this.

Modifications to address any of these may change other properties of the oil, so a detailed characterisation of the rheological, emulsification and biocompatibility behaviour must be conducted. In this study we exploited the ability of very high molecular weight polymers to increase viscoelasticity and potentially resist emulsification. Results of the rheological examination of these novel heavy tamponade formulations are presented.

EXPERIMENTAL METHODS

Polydimethylsiloxane (PDMS) oils with shear viscosity of 1000 mPa.s or 5000 mPa.s, a high molecular weight additive and perfluorohexyloctane (F6H8) (Fluoron GmbH, Germany) were blended in various ratios. Densiron 68 (Fluoron), a commercially-available heavy tamponade, was used as a control.

Rheological measurements were carried out using a TA Instruments Rheolyst AR 1000 N controlled-stress rheometer (TA Instruments, Elstree, United Kingdom) using a 60 mm diameter, 2° acrylic cone geometry. Measurements of the shear viscosity (μ) in steady shear and of the storage (G') and loss moduli (G'') in small amplitude oscillatory shear (SAOS) were conducted.

RESULTS AND DISCUSSION

The shear viscosity of the blends increased with the addition of the high molecular weight polymer (HMW) (data not shown). Further investigation suggested that there was a power-law relationship between the amount of additive and the increase in shear viscosity above that of the base solvent (μ_s) (Figure 1). This empirical

relationship allows prediction of the shear viscosity for any amount of HMW additive falling within the tested range. For every blend of oil through the frequency range, G'' was significantly greater than G' , confirming that these fluids are only weakly elastic. As the amount of HMW additive increased, the relaxation time increased, demonstrating that the addition of the HMW polymer increased the viscoelasticity of the oil blends. For blends based on 1000 mPa.s oil, relaxation times were 1.5-10.0 ms. For blends based on 5000 mPa.s oil, relaxation times were 1.5-4.4 ms. Using these data it is possible to choose a particular blend to achieve the desired shear and viscoelastic properties.

Figure 1: Difference in shear viscosity of blend (μ) compared to base solvent (μ_s) for different concentrations of high molecular weight polymer addition for both 1000 mPa.s and 5000 mPa.s based oils including power-law fits to the data.

CONCLUSION

Modifications to standard silicone oil tamponade formulations can be made to improve various aspects of the tamponade performance, including the ability to support the inferior retina while maintaining clinically useful injection properties. A full characterisation of physical properties and the biological response to novel tamponades must be conducted before using these oils clinically.

Ambient Temperature Patterning of Bioactive Deposits on Curved Metallic Substrates For Orthopaedic Implants

A. Nithyanandan* and M. Edirisinghe

UCL Mechanical Engineering, University College London, United Kingdom *anouska.nithyanandan.11@ucl.ac.uk

INTRODUCTION

Modifying the surface of load-bearing orthopaedic implants with patterned deposits of bioactive materials, can support cell proliferation and orientation, improving direct biological fixation. Practically this results in increased functional service life of implants, and fewer revisions surgeries for patients. Template assisted electrohydrodynamic atomisation (TAEA) spraying is novel ambient temperature process that can be employed to apply deposits in a wide range of materials, including biopolymers¹ and potentially biological agents and drugs during manufacture. The topography can be controlled via template choice, and the biological benefit of such patterns over continuous coatings has been established². The development of TAEA for application on curved substrates is a natural progression of research, which has been exclusively on flat surfaces to-date³, and is a key milestone towards commercial viability. This work aims to further develop TAEA for the applications of bioceramic patterns onto curved titanium substrates for the first time. The resultant pattern microstructure and topographical geometry were analysed to establish whether the process could be controlled to create patterns closely resembling the initial template.

EXPERIMENTAL METHODS

Appropriate quantities of TiO₂ (titanium dioxide) were mixed in ethanol. The weight ratios of TiO₂ to ethanol were as follows: (TiO₂:ethanol) 2:98, 4:96, 6:94 i.e. 2, 4 and 6wt% TiO₂ in ethanol respectively. Copper templates with parallel patterned mesh with a strut thickness of 50µm and spacing of 100µm were used in all experiments. The controlled flow rate was varied (5, 10, 15, 20 and 25µlmin⁻¹), and TAEA spraying was carried out to fully coat the titanium substrate and copper template (schematic of TAEA process shown in Figure 1), then it was left for the solvent to evaporate away before removing the template, leaving the bioactive pattern in the shape of the inverted template.

All experiments were carried out at ambient temperature (~20°C), and collection distance was kept at 60mm, collection time at 300s. The morphology and structure of the coatings were determined using optical and scanning electron microscopy. The width of deposits were measured via image analysis with n=50.

Figure 1: Schematic diagram of the TAEA process

RESULTS AND DISCUSSION

Figure 2: (a) optical micrographs of copper template, strut thickness 50µm, spacing of 100µm (b) TiO₂ pattern on curved substrate (c) scanning electron micrograph of TiO₂ pattern microstructure on curved substrate. Coating is 4wt% TiO₂ with flow rate, applied voltage and collection time, 20µl.min⁻¹, 10kV and 300s respectively. Substrate is 25.4mm diameter convex Ti surface.

Figure 2 shows that TiO₂ patterns have been applied onto curved titanium substrates with uniform and ordered topography, and there was a clear correlation between the template shape and size and the achieved pattern was established. Results for the parallel template (with strut thickness 50µm, spacing of 100µm) show that the mean distance between patterned lines is 54µm and the mean strut thickness is 97µm (standard deviation 6µm and 12µm respectively). This was achieved for the samples shown above. Figure 2(c) shows that the coatings exhibit a microporous surface, with pore less than 1µm in diameter. This is beneficial for cell attachment and enhances bioactivity²².

CONCLUSION

For the first time, ambient temperature TAEA has produced bioceramic TiO₂ patterns on curved titanium substrates (d=25.4mm) with a high degree of control over the pattern geometry. TiO₂ patterns with parallel line microstructures (mean strut thickness is 97µm, standard deviation 12µm) have been successfully produced. A clear correlation between the template shape and size and the achieved pattern was established, therefore the template can chosen to reflect the specific clinical needs of the coating. This work is ongoing, but results to-date show that the TAEA process is highly controllable and compatible on a range of substrate geometries, including flat and curved substrates. Due to the versatile nature of the process, TAEA could provide increased capabilities regarding the coating of orthopaedic implants.

Effect of Substrate Geometry on Mineralization and Cell Proliferation of Calcium Phosphate Ceramics

E.R. Urquia Edreira¹, Astghik.Hayrapetyan¹, J.G.C. Wolke¹, J.A. Jansen¹, J.J.J.P. van den Beucken¹

¹Department of Biomaterials, Radboud University Nijmegen Medical Center, The Netherlands,
EvaRaquel.UrquiaEdreira@radboudumc.nl

INTRODUCTION

Calcium phosphate ceramics in combination with implant surface geometry have been shown to influence biological performance. Ripamonti et al. have extensively investigated the osteogenic effect of repetitive surface concavities on bulk ceramics and calcium phosphate coated titanium implants¹⁻³. These studies have shown that the presence of concavities affects osteoinductive capacity without application of osteogenic soluble factors.

In our previous study we tried to rationalize the mineralization process through an *in vitro* test in SBF⁴. Bianchi et al. showed that the mineralization process started preferentially within the concavities in hydroxyapatite (HA) disks sintered at 1200 °C and concavity size controlled the extent of mineralization.

It is also known that micro- and nano-scale morphology of the calcium phosphate surface can strongly influence osteoblast and stem cell adhesion, proliferation, and differentiation⁵⁻⁷. In our current study we aimed to investigate how cells populate concavities and to what extent concavity size influences mineralization when cells are present. We hypothesized that surface concavities facilitate cell proliferation and mineralization and that these effects are increased in the smaller concavity.

EXPERIMENTAL METHODS

Cavity sizes of 400, 800 and 1600 µm were created on the surface of HA disks sintered at 1200°C and cultured with adipose tissue mesenchymal stem cells (AT-MSCs) in osteogenic medium for up to 28 days at 37°C. At selected time points (3, 7, 14, 21, and 28 days), samples were removed and after fixation cells were fluorescently labelled with phalloidin-Alexa 568 (1:250; molecular probes) for filamentous (F-) actin and DAPI (1:2500) for nuclear staining. Cells were imaged and examined with a confocal laser scanning microscopy (CLSM) Olympus FV1000.

RESULTS AND DISCUSSION

Immunofluorescence three-dimensional (3D) image analysis showed differences in cell number between concavities at early culture time points (3 days). The highest number of cell nuclei was found in the 400 µm cavity (Figure 1) and the lowest number in the 1600 µm. Firstly, cells were able to migrate towards the concavities and adhere to their edges and walls. Preferential mineralization was observed inside the concavities. Cells spread over and to the bottom of

concavities covering all their volume and creating multilayers on their surfaces.

Figure 1. Immunofluorescence images at three days showing nuclei of cells on the 400 µm concavity.

CONCLUSION

High resolution 3D images gave qualitative and quantitative data on concavity volumes. CaP ceramics with surface concavities induced cell (AT-MSCs) adhesion and migration towards the concavities and were able to create multilayers. Results from this study suggest a correlation between mineralization and cell proliferation within concavities.

Bone mineralization in Zebrafish embryos treated with Silicon ions

M.Montazerolghaem¹, L.Nyström¹, H.Engqvist¹ and M. Karlsson Ott¹

¹Materials in Medicine, Division of Applied Materials Science, Department of Engineering Sciences, Uppsala University, Sweden, maryam.montazerolghaem@angstrom.uu.se

INTRODUCTION

Silicon (Si) is a mineral that has an important role in bone formation. Studies have shown that Si supplementation accelerates the rate of bone mineralization¹. Because of this Si has been incorporated into different biomaterials to improve their osteogenic properties.

Zebrafish are used as a model system for investigating bone development and bone formation².

In this study our aim was to assess whether zebrafish could be used to evaluate the effect of Si ions on bone formation. For this purpose we supplemented fish media with Si ions and investigated the effect of bone mineralization. We also studied mineralization *in vitro* by using the murine osteoblastic cell line, MC3T3-E1.

EXPERIMENTAL METHODS

Mineralization in zebrafish

Zebrafish embryos were reared in embryonic medium E1. 3 days post fertilization the medium was supplemented with sodium metasilicate (625 μ M or 125 μ M). The embryos were kept in the supplemented medium for an additional 6 days and then stained with alizarin red. The embryos were then anesthetized and pictures were taken. The amount of mineralized bone was measured using the image analysis software Image J and statistical analysis was made using students t-test.

Mineralization in cell culture

MC3T3-E1 (subclone 14) was cultured in α -MEM medium, supplemented with sodium metasilicate (625 μ M and 125 μ M). After three days in culture, ascorbic acid and β -glycerophosphate was added. After an additional 10 days the mineralization was visualized with alizarin red stain.

RESULTS AND DISCUSSION

The results showed a dose dependent response to the Si ion concentration for both the zebrafish embryos (fig. 1) and MC3T3 cells (fig. 2). The mineralized area in the zebrafish embryos supplemented with 625 μ M Si was significantly higher as compared to the control and the lower concentration of Si. Interestingly the results show that the same concentration range increased the mineralization for both zebrafish and osteoblasts. Moreover these results indicate that zebrafish embryos can be used as a model system for evaluating osteogenic effects of Si ions.

Figure 1. The amount of mineralized bone area in zebrafish embryos treated with sodium metasilicate, after 9 days post fertilization. * indicate statistical significant difference from control group, (n = 5).

Figure 2. A dose dependent increase in mineralization of MC3T3 cells supplemented with sodium metasilicate.

CONCLUSION

In this study we have proven that mineralization in zebrafish embryos show a dose dependent response to Si ion supplementation. Since zebrafish have the complete bone remodelling system it could potentially be a useful *in vivo* model for evaluating Si doped biomaterials, in contrast to using only osteoblastic cells or osteoblastic cell lines.

PolyHIPE-based porous microparticles for bone tissue engineering
T. Paterson¹, C. Sherborne¹, R. Owen¹, S. Puwunun¹, G. Reilly¹, F. Claeysens¹

¹Kroto Research Institute, Department of Materials Science and Engineering, University of Sheffield, Sheffield, S Yorkshire, United Kingdom, mta08tp@sheffield.ac.uk

INTRODUCTION

Particle-based systems have great potential as scaffolds for tissue engineering, since they are injectable, avoiding the need for open surgery. In this study we are investigating how the osteogenic human cell line (hESMP) responds to monodisperse microporous particles. Particles with different size averages and Young's Moduli (YM) will be investigated. The microporous material is constructed from a HIPE (High Internal Phase Emulsion[1]) via photocuring. The YM of the polyHIPE can be controlled by varying the ratios of its monomers. It has been demonstrated that the YM of the surface affects the behavior of hESMP cells. We have used microfluidics for production of microparticles with highly controlled size and shapes. Engineering the shape of these particles allows tuning of the overall porosity to enhance angiogenesis within these scaffolds, as well as the ability to incorporate regions of specific functionality such as stem cell niches.

EXPERIMENTAL METHODS

Porous polyHIPE particles were created by a T-junction set-up in which a small internal diameter (100 μm) syringe needle injects the photocurable polyHIPE into a 6 mm diameter silicone tube containing a continuous stream of H_2O (sustained via a peristaltic pump) and subsequently curing the spherical particles with a UV lamp. By changing the flow of the liquids and the size of the needle tip dispensing the polyHIPE, it is possible to finely control the size of the resulting particles. Particles were produced in three different size ranges: 100, 200, and 300 μm . The polyHIPE was formed in three formulations* to produce particles of 200 μm in size with three different YM. To improve cell adhesion, particles are coated with acrylic acid in a plasma deposition chamber. hESMP cells are cultured under both continuous and static conditions to simulate the future processes required to produce injectable bone tissue engineering scaffolds. Cell growth was investigated using MTT and cell number per particle for proliferation data. Sectioning, confocal imaging and SEM were used to gather information on hESMP cell behaviour.

RESULTS AND DISCUSSION

Spherical particles have been produced with the microfluidic method at 80, 200, and 320 μm in size. All particles have a size variance of less than 30 μm . Bulk material of the different polyHIPE formulations was also formed into testing specimens and tested on a Bose mechanical testing machine (ELF3200) to determine the YM. MTT data on primary human fibroblast growth on thin films of the polyHIPE material will be presented. This data reveals that the porosity of the HIPEs increases cell proliferation as compared to a non-porous equivalent of the material. The data also showed that acrylic acid coating increases cell growth on both porous and non-porous material, as is reported in literature.[2] Exploiting both surface chemistry and porosity of the scaffolds greatly increases the cell adhesion and proliferation on these surfaces. Cell proliferation on the porous particles will also be reported upon.

PolyHIPE particles. Left: optical microscope image of 320 μm particles. Right: SEM image of 200 μm particle

CONCLUSION

Microporous particles have been produced in sizes between 100 μm and 1 mm with a controlled and narrow size distribution. Different polyHIPE materials have been formulated with a spread of YM as determined by mechanically testing. Human fibroblasts have been successfully cultured on the polyHIPE materials and these experiments demonstrated that both porosity and acrylic acid coating increases cell survivability. Work is ongoing to determine hESMP response to both particle size and YM.

Retrieval Analysis of Titanium – Nitride Coated Femoral Heads Articulating Against Polyethylene

Łukasz Łapaj¹, Justyna Wendland², Adrian Mróz², Jacek Markuszewski², Tomasz Wiśniewski²

¹Department of General Orthopaedics, Musculoskeletal Oncology and Trauma Surgery, Poznan University of Medical Sciences, Poland, esperal@tlen.pl

^{2*}Metal Forming Institute, Poznan, Poland

INTRODUCTION

Titanium nitride (TiN) coatings are used in total hip arthroplasty to reduce friction of bearing couples or to decrease the allergic potential of orthopaedic alloys. Little is known about performance of these implants, since only few retrieval studies were performed, furthermore they included a small number of implants manufactured over 15 years ago [1,2].

That is why we decided to perform a retrieval analysis of modern TiN coated femoral heads articulating against ultra-high molecular weight polyethylene (UHMWPE)

EXPERIMENTAL METHODS

This study included six 28 mm femoral heads with a made of TiAl6V4 alloy and coated with TiN using Physical Vapour Deposition (PVD). All heads were retrieved after at least 12 months of use (mean 31,2 range 14-52). The reason for revision was aseptic loosening in 5 cases and recurrent dislocations of one uncemented hip replacement (five episodes).

All implants were evaluated with light microscopy, Scanning Electron Microscopy (SEM) with Energy-Dispersive X-ray Spectroscopy (EDS). 30 SEM images from each implant were digitally analysed using ImageJ software to compare surface topography in loaded and non weight-bearing parts of the heads.

RESULTS AND DISCUSSION

Studies with light microscopy revealed severe damage to the dislocated femoral head, with multiple metallic scratches. Slight discoloration of the bearing surfaces were observed in other implants.

SEM studies indicated presence of multiple scratches as well as pinholes with a diameter of 1-10 µm. (Fig. 1a) Their number and surface area evaluated using digital image analysis differed between implants, however we found no statistical difference between weight-bearing part of the head and other segments within each head.

In all implants we found irregular areas (diam. 20-50 µm) where the coating was delaminated from the substrate metal (Fig. 1b). Some of these debonded fragments were embedded into the PVD layer in weight-bearing parts of all heads (Fig. 1c). In one head, (which was dislocated) we observed deposits of titanium alloy from the acetabular shell. The deposits were accompanied by large patches of delaminated coating as well as multiple cracks (Fig. 1 d). Small fragments of the acetabular titanium alloy damaged the coating in third body mechanism.

Residue from the manufacturing process was present in all implants in form of pure Ti droplets found

in round voids (Fig 1e). Surprisingly in three implants we EDS analysis revealed similar structures containing Niobium (Nb) particles (bright spots, Fig 1f)

Fig. 1 SEM findings in retrieved TiN coated femoral heads

Similarly as in previous reports [1,2] our findings indicate that TiN coating degrades during in vivo use predominantly due to delamination. Contrary to previous papers we also observed wear in third body mechanism, especially in the dislocated head. Microscopic findings suggest, that mechanical failure of the coating results from its high stiffness, compared to the substrate material, similarly as observed in laboratory studies [3]. Another previously unreported finding is the presence of Nb residues in some implants, which, as we believe were formed during the manufacturing process. We hypothesize that different types of coatings were applied in the same vacuum chamber and residues from some batches could have contaminated other implants.

CONCLUSION

Our study indicates, that the TiN coating degrades during in vivo use, and underline the need for further development of the manufacturing process in order to avoid contamination of the coating.

Investigation of Ion Exchange between Silicate-substituted Bone Graft Substitutes and Cell Culture Media and the effect on Osteoblast-like Cell Response

N. K. Chana^{1*}, S. C.F. Rawlinson² and K. A. Hing¹

INTRODUCTION

Ionic dissolution from bone graft substitutes (BGS) to the surrounding medium has an effect on the cell response around implants due to the changes in ionic concentrations¹⁻². The aim of this study was to investigate the effect of varying reservoir volumes of media (PCM) circulating through silicate substituted hydroxyapatite (SA) granules on ion exchange and the subsequent impact this had on cell response under static conditions.

EXPERIMENTAL METHODS

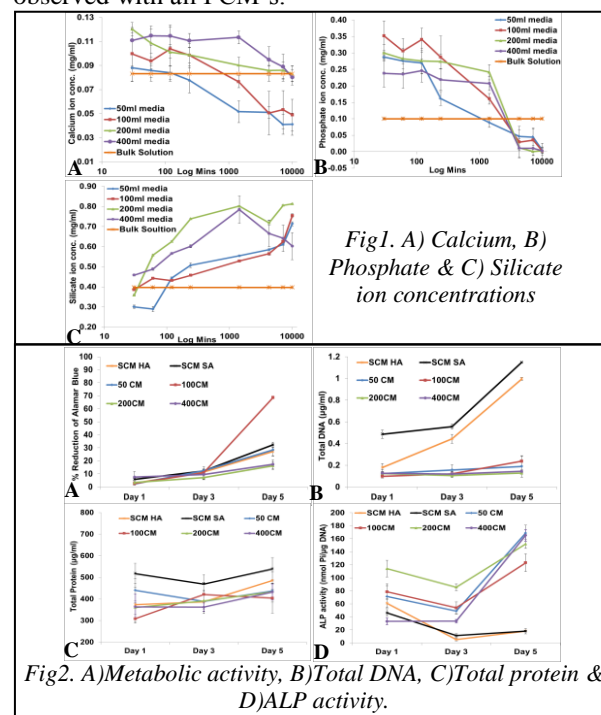

PCM was obtained by circulating known volumes of media (50ml, 100ml, 200ml and 400ml) at a flow rate of 0.7ml/min through 0.45g of 0.8wt% SA granules (20% strut porosity), packed in an 8 mm diameter tube. The media comprised Dulbecco's Modified Eagle Medium containing 1% Penicillin-Streptomycin (DMEM). 5ml of solution was extracted at time intervals of 0.5, 1, 2, 4, 24, 72, 120 and 168 hours and replaced with 5ml fresh DMEM. Calcium, phosphate and silicate ion concentrations of the extracted solutions were analysed using colorimetric assays¹. At 168 hours (7 days) the four volumes of DMEM were collected, individually sterile filtered and supplemented with 10% Fetal Bovine Serum (FBS) and stored as PCM.

MG63 osteoblast-like cells (passage 4) were seeded on 0.45g of stoichiometric hydroxyapatite granules in 24 well plates at a density of 4×10^4 cells/ml in serum containing media (SCM) composed of DMEM supplemented with 10% FBS and allowed to attach at 37°C and 5% CO₂. After 2 hours the SCM was replaced with either one of the four PCM or fresh SCM as a control. SA granules with SCM were also used as a second control. The cells were incubated for periods of 1, 3 and 5 days. The media was refreshed at 24 hours then 48 hours thereafter. DNA quantification, ALP specific activity and total protein release was monitored at each time point. Cell metabolism was also monitored using the Alamar Blue assay.

RESULTS

From Fig 1 it can be seen that a variation in ion concentration occurred throughout the entire length of the conditioning experiment. At 24 hours a depletion of Ca from the media in the two low volume media (50, 100ml) was observed in contrast to an initial elevation in for the two higher volumes of media (200, 400ml), Fig 1A. All media demonstrated a depletion in Ca from 0.5-168 hours, however the level of depletion was reduced for the two higher volumes of media in comparison to the lower volumes. All media volumes showed an initial increase in PO₄ ion concentration over the first 24 hours, Fig 1B, after which there was a depletion of PO₄ ions from all media to levels nearing

zero. SiO₄ ion release was observed in all media volumes however, sustained release was only observed for the two lower media volumes. Cell response to incubation on HA granules in conditioned media clearly demonstrated sensitivity to ion levels, Fig2. Cell metabolic activity was elevated with 100PCM but proliferation was suppressed with all PCM in comparison to the controls. At day 5 lower protein productions but significantly elevated ALP activity was observed with all PCM's.

DISCUSSIONS AND CONCLUSIONS

The circulating study demonstrated that there is a fluctuation in ion concentration with not only time but also volume of circulating media. The cell study demonstrated that variation in Ca, PO₄ and SiO₄ ion concentrations has a clear impact on osteoblast-like cell response. After 7 days circulation 100PCM provided the most supportive environment for cell proliferation on HA granules as compared to the other PCM despite the significantly depleted levels of Ca and PO₄ ions to SCM and a similar level of SiO₄ ion enrichment to 50PCM. The depletion of PO₄ ions from all PCM seemed to affect cell proliferation. To overcome this we can suggest that the 3D perfusion experiments should be partially or continuously refreshed in order to reflect more closely the *in vivo* environment if the mechanisms behind osteoinductivity are to be investigated *in vitro*.

INTRODUCTION

Combining man-made three-dimensional (3D) construct with cells to regenerate damaged tissue is considered as promising approach to replace the current techniques in use. However, effective regeneration of a bone tissue requires scaffolds mimicking natural conditions. In this case, replacing bone tissue, which is a complex structure of more than one material, with polymer-glass/ceramic composite, is an obvious choice. Recently, a novel gellan gum (GG) hydrogel reinforced with bioactive glass (BAG) nanoparticles was proposed as a promising material for biomedical bone applications¹. Although the addition of BAG particles improved the mechanical properties of the GG, the properties were still far from those characteristic for the natural bone. Therefore, to further improve the properties of the composites, another set of experiments was performed with a high fraction of BAG particles embedded in GG. In addition, to better understand the effect of the BAG on gelation of GG, in situ rheology studies were performed. As the BAG-GG composite is proposed as a temporary scaffold for tissue regeneration, mechanical properties of the hydrogels during immersion in simulated body fluid were also investigated.

EXPERIMENTAL METHODS

Particulate nano-sized BAG², in composition of 70 mol. % SiO₂ and 30 mol. % CaO, was obtained by modified sol-gel process. The bioactive particles were afterwards added to GG as reinforcement (0 to 90 wt. % of BAG) to obtain composite hydrogels. GG hydrogels were formed by ionic cross-linker and change of temperature. Exploiting phase separation process, porous scaffold were obtained by lyophilisation of the as prepared hydrogels for 72 h. In scaffold with higher percentage of reinforcement the porosity was introduced by addition of reactive chemical, which forms oxygen - forming connected porosity when heated. Mechanical properties of lyophilized hydrogels were studied by compression test. To understand the temperature dependent gelation process and the effect of the BAG concentration on the GG material, rheology studies were performed. The microstructure of highly reinforced GG lyophilized scaffolds was examined by scanning electron microscopy (SEM) and ability to form hydroxyapatite (HA) by immersion in simulated body fluid (SBF). Compression properties of samples during the SBF immersion were evaluated at different time points.

RESULTS AND DISCUSSION

With increasing percentage of the BAG particles, the porosity of the lyophilized hydrogels decreased as well as the average pore size. Mean pore size decreased from over 500 µm for GG to 100 µm for the composite with 50 wt. % BAG and to even much lower pores, down to 10 µm, for the highly reinforced composites. Accordingly, the mechanical properties of the material increased from 0.5 MPa for GG to ~2 MPa for moderately reinforced composites, however, obtained mechanical properties were still insufficient to apply the material for the load bearing regeneration.

Due to the insufficient porosity of the BAG-GG composites with high BAG content, hydrogen peroxide was implemented into the system to obtain pores in range of 100 µm. Incorporation of the hydrogen peroxide and adjustment of the process reaction resulted in anisotropic porosity.

One of the important contributions of the incorporated BAG is formation of hydroxyapatite in body fluid that gives the material a potential to retain the mechanical properties during the degradation. This was verified by measuring mechanical properties after the materials were soaked into a simulated body fluid. As it was expected, the presence of BAG, which promoted rather fast HA formation resulted in less pronounced decrease in the mechanical properties of the scaffold.

CONCLUSION

With the focus on material processing, 3-dimensional BAG-GG composites with high porosity were prepared. Highly reinforced composites containing up to 90 wt. % BAG exhibited properties that promise the use in bone tissue engineering. During dissolution of both components in simulated body fluid, hydroxyapatite induced by BAG dissolution products is formed within the 3D structure that enables the material to partly retain its mechanical properties.

***In vitro* testing of osteoinductivity and osteoconductivity of titanium alloys with nanostructured surface for orthopaedic applications**

E. Jablonská^{1*}, J. Lipov¹, J. Fojt², L. Joska², T. Ruml¹

¹Department of Biochemistry and Microbiology, Institute of Chemical Technology, Prague, Czech Republic, eva.jablonska@vscht.cz

²Department of Metallic materials and Corrosion Engineering, Institute of Chemical Technology, Prague, Czech Republic

INTRODUCTION

Titanium and its alloys have been considered as a gold standard among biomaterials for permanent implants. Moreover, their mechanical properties (especially elastic modulus) and also biocompatibility can be improved. Osteoinductivity and osteoconductivity of the material are achieved by creating nanostructured surface via anodic oxidation in appropriate electrolytes¹. These nanotubes formed *in situ* enhance preferential adhesion of osteoblasts, and thus support osteointegration and prevent development of fibrous layer on the material-bone interface². Specific parameters of the nanotubes and their influence on the cell growth have been extensively studied recently. Here, we present data on titanium alloys with different nanotube diameter and their ability to enhance adhesion and growth of osteoblast-like cell line.

EXPERIMENTAL METHODS

U-2 OS cells were seeded onto the surface of the tested metal discs placed in 12-well plate in the density of 7,000 cells·cm⁻². After 1, 2 and 5 days, the cells were fixed with 4% formaldehyde, permeabilized (0.1% Tween-20) and stained with TRITC-phalloidin (1 µg·ml⁻¹) and DAPI (0.5 µg·ml⁻¹). From each sample, 20 fields of view were recorded using wide-field fluorescence microscope (100-fold magnification). Morphology of the cells was evaluated and the cell number (via number of nuclei) was determined using ImageJ 1.43.

RESULTS AND DISCUSSION

Fig. 1 U-2 OS cells grown on Ti-alloy samples with nanotubes (A – 50 nm, B - 100 nm in diameter) after 5 days of inoculation. Scale bar equals to 100 µm.

After 5 days of cultivation, the cells showed improved proliferation on nanotubes with larger diameter (100 nm) compared to smaller diameter (50 nm). On the contrary, Park *et al.*³ reported enhanced cell growth on nanotubes with smaller diameter (15 nm) when using different cell model. Interestingly, cells grown on 50nm nanotubes were strongly elongated in comparison to the control cells grown on glass coverslips. Similar phenomenon was also observed by Brammer *et al.*⁴.

CONCLUSION

These preliminary results indicate that the nanotubes with greater diameter possess better osteoinductive and osteoconductive properties. Nevertheless, for further studies, we would like to use more appropriate model (MC3T3-E1 or SaOs cells) and also evaluate parameters such as ability of extracellular matrix formation and mineralisation, which can be studied via monitoring of type I collagen and osteocalcin expression using qPCR. In the next step, newly developed beta-titanium alloys with elastic modulus closer to bone will be studied.

Influence of collagen cross-linking on fibroblast and macrophage response

Luis M. Delgado¹, Abhay Pandit¹, Dimitrios I. Zeugolis^{1*}

^{1*}Network of Excellence for Functional Biomaterials, National University of Ireland, Galway, Ireland, dimitrios.zeugolis@nuigalway.ie

INTRODUCTION

Given that the native lysyl-oxidase cross-linking of collagen does not occur *in vitro*, exogenous cross-linking methods are under investigation to increase the mechanical and enzymatic stability of collagen-based devices¹. However, chemical methods based on aldehydes, epoxides and carbodiimide are often associated with cytotoxicity, macrophage activation and foreign body reaction². Alternative cross-linking methods, based on plant extracts and polyethylene glycol (PEG) have attracted great scientific attention the recent years, due to their low cytotoxicity^{3,4}. Herein, it is hypothesised that collagen films can be optimally cross-linked with PEG and plant extracts to induce adequate stability, whilst avoiding toxicity and macrophage activation. The specific objective is to optimise collagen films stability modulating macrophage response without compromising cell toxicity.

EXPERIMENTAL METHODS

Collagen films were cross-linked with 0.625% glutaraldehyde (GTA), 50 mM 1-Ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC), 1 mM 4-arm PEG succinimidyl glutarate MW 10,000 (4SP), 0.625% Genipin (GEN) or 0.1% Oleuropein (OLE). As control, non-cross-linked films (NCL) were used. Films were assessed by SEM, mechanical testing, DSC, swelling and collagenase assay. Cytotoxicity was assessed using WS1 fibroblast, and subsequent cell morphology, metabolic activity (alamarBlue™) and cell proliferation (PicoGreen®) analysis. *In vitro* response was assessed using human monocyte-derived THP-1 macrophages and subsequently by morphology, alamarBlue™, PicoGreen and multiplex assay for the main inflammatory cytokines. As control, macrophages seeded on TCPS were activated by lipopolysaccharide (LPS). Statistical significance was set at $p < 0.05$.

RESULTS AND DISCUSSION

Fibroblast seeded on all cross-linked films showed over 90% cell metabolic activity and similar proliferation rate at day 3; only GEN increased fibroblast proliferation (Fig. 1).

Fig. 1. Fibroblast metabolic activity and proliferation for cross-linked collagen films after 3 days in culture. * indicates statistical significance compared to TCP.

Moreover, GEN increased macrophages metabolic activity as LPS treated macrophages. Other cross-linked films maintained similar activity as non-treated macrophages (Fig. 2). Also, some preliminary data showed that cross-linking can affect macrophage morphology (Fig. 3).

Fig. 2. Macrophage metabolic activity for different cross-linked collagen films after 1 day in culture. * indicates statistical significance compared to LPS-.

Fig. 3. Macrophage morphology for different cross-linked collagen films after 1 day in culture. OLE maintained morphology while 4SP induced macrophage aggregation.

CONCLUSION

PEG and plant extract cross-linkers have shown to increase stability and none of them had an effect on fibroblast viability and metabolic activity. Although preliminary macrophage culture shows that some of these cross-linking methods may activate macrophages as the positive LPS control.

INTRODUCTION

Sudden heavy bleeding in a surgery or from a wound always leads to severe damage or life-threatening effect for a patient. Commercial products mainly including powders and sponges are made of cellulose, alginate, collagen, chitosan, zeolite, and so on. Frequently-used sponge-like patches supply fast hemostatic effect on covered wound; however, do not cover the whole area of a wound with irregular shape. Powdered hemostatic materials provide large contact area with wounds and high exudate adsorption. However, difficult quantity control for sprinkling a powder on a wound surface and possible overdose of powder are frequently happened in hemostasis process. Hemostatic spray might be a better design which could display excellent thrombogenicity using a small amount and form a thin film to cover irregular-shape wound. Furthermore, chitosan with positive abundance ammonium pendent groups in its structure when it is dissolved in a weak acid solution, the positive charges can absorb and activate negatively-charged platelets. These activated platelets aggregate to form a platelet plug, release agonists which recruit more platelets to the growing thrombus, and form a clot mass to stop bleeding in a short time. In order to rapidly induce thrombus and fibrin formation, chitosan nanowire suspensions were synthesized to constitute network-like structure to improve particle-like powder to provide a potential hemostatic spray material.

EXPERIMENTAL METHODS

1. Preparation of chitosan nanowires. Chitosan (MW= 35000) was dissolved in 90 wt.% acetic acid to prepare a 10 wt.% chitosan solution after heating at 50 °C for an hour with gentle stir and then constantly stirring for 24 hr. The chitosan solution was then poured into a 5 ml syringe fitted with a 23G needle (inside diameter 0.34 mm) and connected to a microsyringe pump. The high-voltage power supply was then connected to the needle tip and the other electrode, stainless steel mesh with a 0.6 x 0.6 mm² grid, was grounded with a 7 cm distance to the needle. The metal mesh was supported with a beaker containing 1 wt.% NaOH aqueous solution to solidify and collect those forming chitosan nanowires. The injection rate was controlled at 0.1 ml/hr. The schematic of apparatus is shown in Fig. 1. The other composition, chitosan mixed with polyvinyl alcohol (PVA) in a ratio of 2:1 was used to prepare CS-PVA nanowires for a reference. The dried nanowires were then crosslinked using 2 ml 0.25 wt.% alginate solution (or 1 mg/ml triphosphate solution) to react for one hr.

2. Characterization and physical property measurement. The dimension analysis of nanowires was carried out using SEM and STEM.

3. Clotting test and blood cell adherence measurement. Replace collection liquid to an aluminium disc to prepare a chitosan nanowire-coated surface with electro-spraying for 5 min. Then the sample discs were used to contact whole blood sample for 3 min. The cells adhered on the discs were rinsed, fixed, and observed for their surface morphologies via SEM. As for the clotting time measurement, the 20 mg nanowires were located into a glass tube and 2 ml blood sample was then poured into in a 37 °C water bath. The other portion 200 µl 0.2 M calcium chloride solution was added into the vertically-standing test tube which was then turn to horizontally-lying every 30 sec to check the blood flow until it stop flowing.

RESULTS AND DISCUSSION

We improved the traditional electro-spinning process to fabricate short nanowires using high-boiling-pointed acetic acid and low-molecular-weighted chitosan. Due to low evaporating property of the solution and less entanglement between polymer chains, the shortened chitosan nanowires could be obtained via collecting nanowires passing through a grounded metal mesh in a basic alcoholic solution. The diameters of nanowires could be controlled via some parameters: precipitating agents, operation voltages, and working distances, and so on. Higher operation voltage generated relatively narrow nanowires. the precipitating agents using different NaOH/ethanol ratios could dominate the morphology of nanowires, affect the precipitation, and change diameters of nanowires. In blood coagulation tests, TPP could enhance fibrin formation but take more time; while alginate-crosslinked chitosan might exhibit high water adsorption to intercept more blood and cells. However, surface-crosslinked chitosan might be neutralized on those positive ammonium groups, decreasing the positive charges on surfaces and also the adsorption and activation of platelets.

Fig.1. Schematic of electrospray apparatus and SEM image of RBS tied with nanowire networks.

CONCLUSION

We used chitosan nanowires as hemostatic materials in this research according to the hemostasis property of chitosan, which can also absorb and activate platelets and enhance the formation of fibrin.

Mobilization of Mesenchymal Progenitor Cells to Improve Bone Healing

P.S. Lienemann¹, A.S. Kivelioe¹, S. Metzger¹, S. Höhnel², A. Roch², O. Naveiras², A. Sala¹, V. Milleret¹, F. E. Weber³, W. Weber⁴, M.P. Lütolf², M. Ehrbar¹

² Laboratory of Stem Cell Bioengineering, EPF Lausanne, Switzerland

³ Craniofacial Surgery, University Hospital Zürich, Switzerland

⁴ Faculty of Biology and BIOS Centre for Biological Signalling Studies, University of Freiburg, Germany

INTRODUCTION

Bone morphogenic proteins have shown unexpectedly low bone healing capacity in clinical situations and thus are need in doses, exceeding the physiological ones by several orders of magnitude. By use of adequate delivery systems which provide a continuous low level of osteogenic growth factors and the appropriate co-signaling with integrins bone formation could be enhanced, while adverse off-site effects are kept minimal. On the on the hand, optimizing early stages of bone healing could likely provide improve the mobilization of mesenchymal progenitor cell (MPC) ¹. As MPCs have both a great proliferation potential and the capacity to form bone they could have a major impact on bone healing efficiency.

Materials and Methods

Transglutaminase factor XIII cross-linked PEG-based hydrogels (TG-PEG) ^{2,3} of 5mm diameter and 1mm thickness were formed at low cross-link density (1.7%) and placed in 5mm critical sized calvarial defects of GFP-mice. After 1, 2, and 3 week of implantation hydrogels were harvested and mobilized cells and tissues were characterized by FACS or immunohistochemistry. Prospectively isolated non-endothelial (CD31⁻) and non-hematopoietic (CD45⁻/Ter119⁻) cells were selected based on their expression of the cell surface markers Sca1 and Alcam ⁴. The obtained cell fractions were tested for their ability to form colony forming units fibroblast (CFU-F) at a seeding density of 10³ cells per cm². Additionally they were allowed to form microtissues (over night, as a hanging drop) which were embedded in a TG-PEG hydrogel (1.5%) and cultured in presence of a series of 20 factors known to be involved in mesenchymal cell migration at concentrations of 50ng per mL of culture medium. Best growth factor candidates were admixed to forming hydrogels and implanted in critical sized murine calvarial defects. The healing of defects is characterized by longitudinal evaluation of bone formation using micro computed tomography as well as

by histological (haematoxylin & eosin) and immunohistochemical (CD31, Sca1, CD45) stains.

Results and Discussion

Trapped cells could be readily obtained from the healing bone defect by digestion of the provisional TG-PEG hydrogels using collagenase. By prospective isolation of non-hematopoietic and non-endothelial cells, three mesenchymal populations of ca. 10⁴ cells per defect were obtained which were Alcam⁺/Sca1⁻, Alcam⁻/Sca1⁻ or Alcam⁻/Sca1⁺. Although all three mesenchymal cell populations could be expanded in vitro most of the CFU-Fs were formed by Alcam⁻/Sca1⁺ fraction. Additionally this cell fraction could be differentiated towards the osteogenic, chondrogenic and adipogenic lineages, indicating that it contains cells with characteristics compatible with the definition of MPCs. When entrapped in TG-PEG hydrogels, microtissues consisting of Alcam⁻/Sca1⁺ cells, they were promoted to migrate out of the microtissue by a number of factors described to be involved in mesenchymal cell recruitment. Currently, selected growth factors are being tested for their ability to promote the recruitment of mesenchymal progenitor cells and the formation of novel bone in the murine critical size defect.

Conclusion

Cells trapped at the site of bone defect healing contain MPCs, which can be prospectively isolated and are promising candidates for the screening of factors involved at different stages of bone regeneration.

INTRODUCTION

Formation of surface brush layers based on deposition of amphiphilic block copolymers composed of polylactide (PLA) and poly(ethylene oxide) (PEO) from selective solvents is studied as a method of surface modification of PLA-based biomaterials for tissue engineering.¹ Nano-colloid printing of functional PLA-*b*-PEO is under investigation for preparation of specific surface pattern of biomimetic groups that would influence cell adhesion, growth and differentiation.² The crucial factor of this approach, i.e. to provide specific cues for cells through the synthetic oligopeptides present on the biomaterial surface, is the resistance of such surface to nonspecific protein adsorption, otherwise the proteins from the cell culture medium or body fluids will cover present bioactive groups. In this study, we investigate the effect of the deposition of PLA-*b*-PEO copolymer nano-colloids on PLA surface and the efficiency of resistance of such surfaces to proteins, e.g. albumin and fibrinogen, with respect to the molecular parameters of used copolymers.

EXPERIMENTAL METHODS

PLA-*b*-PEO block copolymers with matching PLA block (7 kDa) and different PEO block length (5, 10 and 15 kDa) were synthesized by ring opening polymerization of L-lactide in toluene using α -hydroxy- ω -methoxy-PEO as a macroinitiator and Sn(Oct)₂ as a co-initiator. PLA-*b*-PEO copolymers were deposited on PLA surface on poly(dopamine) (PDA) coated Au SPR chips and characterized by spectroscopic ellipsometry, infrared reflection adsorption spectroscopy (IRRAS), contact angle measurement (CA), atomic force microscopy (AFM) and surface plasmon resonance measurement (SPR) to determine the optical thickness of polymer films, composition of top layer, wettability, topography and protein resistivity of prepared surfaces.

RESULTS AND DISCUSSION

Amphiphilic block copolymers such as PLA-*b*-PEO in selective solvents can associate to self-assemblies and/or with surface compatible with PLA block.

Three PLA-*b*-PEO copolymers with increasing PEO block length were spin coated from the selective solvent (acetone/methanol 1/9 v/v) on the top of PLA film providing layers with optical thickness about 20 nm without any significant difference with respect to PEO block length. The presence of PLA-*b*-PEO top layer was confirmed by IRRAS where the spectral contributions of PEO rise with increasing molecular weight of PEO block. Further, the length of PEO block, and the PLA/PEO ration in copolymer affected the surface topography (Figure 1). The lamellar structure of PLA/PEO-15kDa top layer can be attributed to the ability of PEO to crystallize (Figure 1A).

Figure 1: AFM topography images of PLA/PEO-15kDa (A), PLA/PEO-10kDa (B) and PLA/PEO-5kDa (C) layer deposited on PLA surface. Scan size: 5x5 μ m, Z-scale: 50 nm.

The deposition of PLA-*b*-PEO nano-colloids resulted in surfaces with highly hydrophilic character (PLA/PEO-15kDa and PLA/PEO-10kDa) and moderately hydrophilic character (PLA/PEO-5kDa) compared to pure hydrophobic PLA. The wettability corresponds well with the fouling properties where the adsorption of albumin and fibrinogen decreases with increasing hydrophilicity of the surface. For example, the adsorption of fibrinogen to PLA-*b*-PEO-5kDa was determined to be more than ten times lower compared to pure PLA, and furthermore, the adsorption to PLA-*b*-PEO-15kDa was lower about 200 times.

The results demonstrate that the character of deposited copolymer layer, and hence, the formation of PEO brush were affected by the molecular parameters of used copolymer. The copolymer with longer PEO block provide hydrophilic layer with PEO exposed on the surface when the surface is in contact with water. The PEO chains can be hydrated and expanded, thus providing an efficient shield against protein adsorption.

CONCLUSION

Poly lactide biomaterials can be effectively modified by deposition of amphiphilic PLA-*b*-PEO copolymers. The efficiency of modification and the non-fouling character depends on molecular parameters of used copolymers. The most efficient surface modification was achieved with PLA-*b*-PEO copolymer with longer PEO block, particularly 15kDa, providing hydrophilic surface with significantly suppressed adsorption of albumin and fibrinogen in comparison to pure PLA.

INTRODUCTION

Patients suffering from osteoporosis or other osteopenic conditions are in higher risk of revision surgeries of skeletal devices. An improved primary implant fixation is possible if implant surface is employed as a drug reservoir from which drugs can be delivered site of healing. This also brings about higher drug efficacy and mitigation of side effects. In the present work, Ti implants were coated with 200 nm thick mesoporous (MP) TiO₂ [1-3] loaded with alendronate (ALN), a N-bisphosphonate, and evaluated *in vivo* in terms drug efficacy, distribution and bone anchorage in healthy or osteoporotic rat models.

METHODS

Mesoporous TiO₂ coatings were synthesized on machined Ti implants by Evaporation Induced Self-Assembly (EISA), achieving an ordered structure and a narrow pore size distribution ($\Phi=6$ nm). Approx 500 ng/cm² of ALN was deposited from solution (0.8 mg/ml) into the coatings, and the implants inserted in the tibia of mature male- or ovariectomized female rats. As reference, ALN was given systemically. Bone anchorage in terms of bone area (BA), bone-implant-contact (BIC) and removal torque (RTQ) were determined after 4 weeks of healing. In addition, expression of bone remodelling markers were analysed in qPCR and the distribution of locally given ALN was assessed after 8 weeks by ¹⁴C-ALN analysis in autoradiography and Liquid Scintillation Counting (LSC).

RESULTS AND DISCUSSION

MP coatings were proven successful for local delivery of ALN in healthy and osteoporotic bone. Significantly higher BIC and RTQ values were observed for locally delivered ALN than systemically delivered ditto (see Table 1). BIC was 48% higher and RTQ 45% higher (local vs. systemic, $p<0.05$, $n=8$). BA showed a similar same trend, but not with a significant difference between the groups. The implant close distribution of ALN declined slowly thru 8 weeks, confirming its long residence time and high affinity to bone. Autoradiographic data were analysed with respect to imaginary profiles cross the implant, which revealed the release of ALN in relation to distance from tibial cortex vs. intermedullary space. When overlapped with backscattered SEM, the high affinity of ALN to apatite was clearly depicted (see Fig.1). LSC revealed a release of ALN in the range of 3-500 ng in peri-implant tissue when using MP TiO₂ thin films as a drug reservoir.

Table 1 Summary of μ CT data showing BIC and RTQ data showing bone-anchorage after local or systemic ALN delivery. Implantation time 4 weeks in rat tibia. (* $p<0.05$, $n=8$)

	BIC (% \pm SD)	RTQ (Ncm \pm SD)
Implant w/ALN	41.8 \pm 4.6*	5.06 \pm 0.71*
No drug	34.3 \pm 6.8	3.59 \pm 0.86
Systemic ALN	31.8 \pm 4.3	3.48 \pm 0.78
Saline	32.2 \pm 4.4	3.35 \pm 0.81

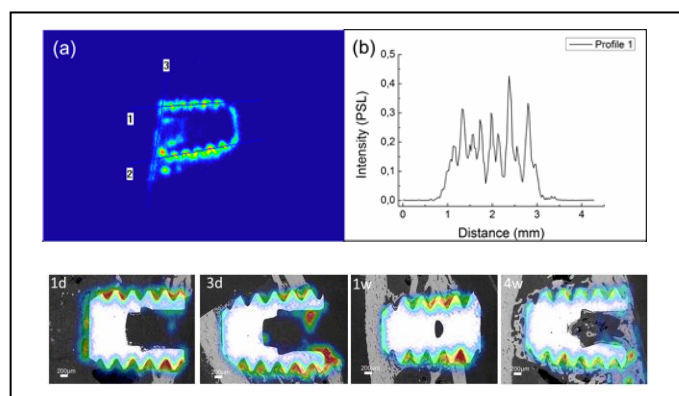

Fig. 1: (upper) Profile analysis in autoradiography after 4 weeks of healing. (lower) Overlap of the autoradiographic and backscattered SEM images thru 4 weeks of implantation in rat tibia.

CONCLUSION

When early implant fixation is impaired in compromised patient groups, ALN can be delivered locally from implant surfaces. With high affinity to bone, the high drug efficacy improves bone-anchorage and mitigate systemic effects that may be otherwise related to systemic administration of bisphosphonates.

INTRODUCTION

Mimicking the extracellular matrix (ECM) by binding growth factors (GFs) and cell-instructive cues inside naturally occurring or synthetic scaffolds in vitro allows the study of biological processes taking place between cells and the ECM in living tissue. This work presents a strategy for the local immobilization of GFs inside polyethylene glycol (PEG) hydrogels [1] using a streptavidin linker that is enzymatically cross-linked to PEG hydrogels by the transglutaminase FXIII. We hereby demonstrate a way to efficiently immobilize and display recombinant human bone morphogenetic protein-2 (rhBMP2). Scaffolds with spatially defined rhBMP-2 areas were generated and promoted the localized differentiation of a myoblastic cell line and of mesenchymal stem cells (MSCs) towards the osteogenic lineage, characterized by the expression of alkaline phosphatase (ALP).

EXPERIMENTAL METHODS

A peptide linker composed of the streptavidin sequence and the substrate sequence of FXIII was produced. Its functionality was assessed by Western blotting to show its incorporation into PEG hydrogels. Its ability to capture biotinylated ALP (ALP-biotin) was showed using the SEAP assay. Biotinylation of rhBMP-2 was carried with NHS-PEG₄-biotin and detected by Western blotting. The functionality of biotinylated rhBMP-2 (rhBMP-2-biotin) was assessed with the ALP activity assay on C2C12 cells. Binding of rhBMP-2-biotin to PEG hydrogels with the linker was determined by incubating the hydrogels in a solution of rhBMP-2-biotin and measuring the rhBMP-2-biotin left in the solution via ELISA. The release of immobilized rhBMP-2-biotin from the hydrogels was also determined by ELISA by incubating the hydrogels in cell culture medium for 5 days and quantifying the amount of rhBMP-2-biotin released into the buffer at day 1, 2 and 5. Localized differentiation of C2C12 cells and bone marrow-derived MSCs (BM-MSCs) in PEG hydrogels was demonstrated by colorimetric staining of ALP and immunostaining against bone ALP.

RESULTS AND DISCUSSION

The streptavidin linker was reacted with PEG components and FXIII and incorporation was shown by the increased molecular weight of the linker due to cross-linking. Hydrogels containing the linker were incubated in a solution of ALP-biotin and the amount of ALP-biotin left in the solution was measured with the SEAP assay. Hydrogels containing 50 μ M and 125 μ M of linker were able to bind almost 50% and 80% of the ALP-biotin in solution after 24 hrs respectively.

Following experiments were carried with 100 μ M of streptavidin linker. After biotinylation, the biological activity of rhBMP-2-biotin was compared to rhBMP-2. The ALP activity assay showed that almost 98% of the biological activity was retained. The binding study showed that over 80% of rhBMP-2-biotin was captured by the hydrogels after 16 hrs incubation, out of which approximately 25% were slowly released after 2 days of incubation in cell culture medium (compared to 90% release without linker), showing improved retention of the GF. Finally PEG hydrogel constructs with locally immobilized rhBMP-2-biotin and seeded with C2C12 cells (Fig. 1A) or BM-MSCs (Fig. 1B) were prepared. After 9 days in culture, the cells growing in the rhBMP-2-biotin area expressed ALP, whereas the cells surrounding this area did not.

Figure 1. PEG constructs with locally immobilized rhBMP-2-biotin or soluble rhBMP-2 and seeded with C2C12 cells (A) or BM-MSCs (B) showing localized ALP expression (top: colorimetric staining, scale bar = 2mm; bottom: immunostaining, scale bar = 200 μ m).

CONCLUSION

The streptavidin linker was successfully used to immobilize rhBMP-2-biotin into PEG hydrogels and to obtain local differentiation of cells. This linker could be potentially used in conjunction with other types of linker compatible with the enzymatically cross-linked PEG hydrogel system [2] in order to achieve controlled immobilization of GFs in precise patterns.

Plasma Spraying of Zinc Substituted Hydroxyapatite

David Shepherd¹, Roger Brooks² and Serena Best¹

¹CCMM, Department of Materials Science and Metallurgy, University of Cambridge, United Kingdom

²Orthopaedic Research, Addenbrooke's Hospital, University of Cambridge, United Kingdom

INTRODUCTION

With an ageing population there is an ever-increasing demand for implants. Current implants have a finite life that could be extended by improving the implant-bone interface. This could be achieved by improved coatings; reducing the amount of resorption taking place at the bone implant interface but also increasing bone apposition around the implant.

Zinc has a proven effect on bone cells, by increasing the activity of osteoblasts but also inhibiting the activity of osteoclasts, and may thus lead to an overall increase in bone deposition.

Work previously carried out by the authors showed that it is possible to substitute zinc into hydroxyapatite and that it has an inhibitory effect on osteoclast number and subsequent activity^{1,2}.

The aim of this work was to investigate if it is possible to plasma spray zinc substituted hydroxyapatite and examine the coatings.

EXPERIMENTAL METHODS

Zinc substituted hydroxyapatite (ZnHA) of 0.65wt% and pure HA (0wt% zinc) were produced using a method described previously¹. These powders were then prepared for plasma spraying according to a previously described procedure². From previous studies applying hydroxyapatite coatings by plasma spraying it was decided to investigate the coatings produced from operating voltages of 25, 30 and 35 kV.

The coatings were physically characterised by XRD, to identify the phases present and SEM to study the morphology of the coatings and splats produced through the plasma spraying technique

RESULTS AND DISCUSSION

Through XRD analysis of the coatings (Figure 1) it could be observed that there were other phases present. These included calcium oxide (CaO) and tri-calcium phosphate (TCP). These phases are formed through the decomposition of HA. As these are not normally observed using plasma spraying of hydroxyapatite it can be hypothesised that the zinc substituted into the HA lattice leads to a lowering of the thermal stability of the apatite. The reduction of the CaO phase with lower operating voltages and thus lower plasma temperature tends to agree with this hypothesis.

SEM images (Figure 2) shows that there were splats produced at all operating voltages. The best coating was unsurprisingly produced with the highest operating voltage. The coatings produced at 30 kV and 25 kV were similar in appearance. Any further reduction in

operating voltage would have led to incomplete melting of the particles and hence, a poor coating.

Figure 1: XRD Patterns for Plasma Sprayed 0.65 wt% ZnHA at the three operating voltages 35 kV, 30 kV and 25 kV

Figure 2: SEM images of the plasma coatings; a + b 35 kV; c + d 30 kV and e + f 25 kV

Results from the 2 physical characterisation techniques showed that the coating produced at 35 kV, whilst producing the optimum splat morphology, has high levels of CaO and so has to be discounted. The morphology of the splats for the operating voltages of 30 and 25 kV were very similar but XRD analysis of the coating at 30 kV also has a high level of CaO and so also has to be ruled out as a coating parameter.

CONCLUSION

The work found that it is possible to produce a plasma sprayed coating of ZnHA and the optimum operating voltage is 25 kV. Further studies are required to determine if this coating is suitable for consideration for use on orthopaedic implants.

***Candida glabrata* in mouthwash -coated endotracheal tubes: antibiofilm activity by electronically scanning microscopy**

Danielle Bezerra Cabral¹, Evandro Watanabe² and Denise de Andrade¹

¹Fundamental Nursing/ University of São Paulo at Ribeirão Preto/ College of Nursing, Brazil

²Restorative Dentistry/ Faculty of Dentistry/University of São Paulo at Ribeirão Preto, Brazil
dannyebezerra@usp.br

INTRODUCTION

Candida glabrata has emerged as a notable pathogen oral mucosa and may promote concomitant infection with *C. albicans*. It is known for its pathogenicity in the oropharynx with difficult treatment and relevance in global casuists¹. The oral microbiome is major factors to health and disease process and its rupture indicate or influence the course of oral diseases². Furthermore, the fungi can colonize substrates polymeric compounds, ceramics, wood and glass, and this is due to not having antimicrobial activity³. This study aimed to evaluate antibiofilm activity of endotracheal tubes (ETT) coated alcohol-free mouthwash containing 0.12% chlorhexidine gluconate, 0.075% cetylpyridinium chloride (CPC) and Listerine® as well as tea tree oil (TTO) by quantification of colony forming units (CFU/ml) and visualization of biofilm by scanning electron microscopy.

EXPERIMENTAL METHODS

Of the total 20 oral clinical isolates of *C. glabrata* available in the database ambulatory of dentistry from the University of Sao Paulo, we used 4 strains to form biofilm, in triplicate and *in vitro*. Each mouthwash was injected 10 ml inside segments (2cm) of TETs at 45° and homogenized for 10sec in orbital shaker solutions AP -59 (Phoenix Luferco®, Brazil). There was masking by the principal investigator to use the technique of coating ETT with mouthwash. The cuts were kept in the wells plates for 24 hours at room temperature. For the formation of biofilm was transferred 100 µl standard microbial inoculum for the test-tube containing Sabourand dextrose broth, 2g glucose and 4g sucrose (V=10 ml) and then homogenized for 1 min. 50µl each culture was serially diluted and transferred to petri plates, generating five replicated plates for each isolate and then incubated at 37°C and visualized after 48 h. Following incubation, these plates were assessed for counting colony forming units per millilitre (CFU/ml) and also by scanning electron microscopy (SEM, JSM 6610LV, JEOL, Tokyo, Japan). The statistical analysis of biofilm formation will be performed using the software R version 3.0.2⁴, applying the likelihood ratio test, considering a significance level of $\alpha = 0.05$. To investigate the efficacy of mouthwashes on biofilms formation will be analyzed data by the distribution free Kolmogorov-Smirnov test.

RESULTS AND DISCUSSION

Preliminaries data showed the mean counts of total viable *Candida glabrata* had a range from 10^2 to 10^5 CFU/mL. The media and standard desviation of each mouthwash tested were: A= $4,8 \times 10^5$ (MD) \pm $2,2 \times 10^5$ CFU/ ETT (SD); B = $4,6 \times 10^5$ (MD) \pm $2,6 \times 10^5$

CFU/ ETT (SD); C = $3,1 \times 10^5$ (MD) \pm $2,6 \times 10^5$ CFU/ ETT (SD); D = $5,8 \times 10^5$ (MD) \pm $2,9 \times 10^5$ CFU/ETT (SD); E = $2,3 \times 10^5$ (MD) \pm $2,7 \times 10^5$ CFU/ ETT. The PC (Fig. 1a) showed inhibition of colony formation, in duplicate, but a clinical isolate (2 strains) had microbial count of 7.7×10^4 CFU/ETT. An important virulence factor of *Candida* species is their ability to form biofilms and these can be formed on abiotic surfaces such as medical devices⁵. *Candida glabrata* has ability to form oral biofilms and present a high tolerance to antifungal agents used in fungal infection treatment. Thus, biofilms this study were visualized in other mouthwashes (Fig 1b).

Fig. 1 Representative scanning electron microscope images of clinical isolates of *C. glabrata*. **A** - Antibiofilm activity of 0.075% CPC against clinical isolate of *C. glabrata* at 1,000 \times magnification, 25kV. **B** - *C. glabrata* biofilm growth in ETT coated tea tree oil at 5,000 \times magnification, 25kV.

Our findings also show that the planktonic isolates of *C. glabrata* tested were susceptible to TTO with average of 8.3×10^5 CFU/ETT and all other mouthwashes tested showed relatively poor activity biofilm against the isolates tested.

CONCLUSION

It is speculated that the 0.075% cetylpyridinium chloride had antibiofilm activity against clinical isolates of *Candida glabrata* on the preliminary results.

Simple Silver Deposition Strategy for Antibacterial Titanium Implants

Kennedy Omoniala, David Armitage, Susannah Walsh
Leicester School of Pharmacy, De Montfort University, Leicester, England
kennedy.omoniala@email.dmu.ac.uk

INTRODUCTION

Support tissue replacement has become a mainstay of modern medical practice. With this evolution has emerged titanium as the replacement material of choice because of its numerous advantages over other materials hitherto in use. Two of the common factors influencing in situ longevity of implants are the strength of the bond between the implant material and the surrounding mechanical (bone) tissue, and bacterial colonisation of the now poorly vascularised tissue-implant interface¹. In this study, a simple strategy for modifying the titanium implant surface to improve osteo-integration and also confer anti-bacterial properties is evaluated.

EXPERIMENTAL METHODS

Surface Modification: Titanium discs were water-jet cut from 1mm sheet (Goodfellow, Cambridge). Polishing was carried out by grinding with silicon carbide paper followed by final polishing with colloidal silica and hydrogen peroxide. The mirror finished surfaces were then sonically cleaned with acetone. Polished surfaces were then subjected to a thermo-chemical treatment involving a pre-treatment with 10M NaOH for 24hrs, brief washing in deionised water and treated with 1M AgNO₃ for 24hrs. All treatments were performed in a shaker water-bath maintained at 80°C and 60rpm. All treated surfaces were characterised for surface energy, composition, and morphology by means of goniometry, SEM/EDX, and AFM².

Biofilm Formation: 18 Ti discs in groups of 6 unpolished, mirror-finished and Ag-treated, together with 6 polycarbonate discs were exposed to biofilm formation on their surfaces, in a CDC-Biofilm reactor, using *Staphylococcus aureus*. Biofilms formed on the surfaces were aseptically removed, suspended in sterile distilled water and serially plated on 90cm nutrient agar using a spiral plater. The plates were incubated at 37°C for 24hrs and bacteria colony forming units counted. The procedure was repeated for 3 more batches of 18 Ti disc and 6 polycarbonate discs, making a total of 24 discs in each group. Inhibition zones for the different surfaces were also determined. The normality of distribution of data and the significance in variations between the various groups were tested using SPSS.

RESULTS AND DISCUSSION

Figure 1: SEM of polished/ mirror-finished and Ag treated Ti surfaces

Figure 2: Log reduction of bacteria over time for Ag treated and polished surfaces

Figure 3: number of cfu from biofilms on Ag and control surfaces for 9 repeats

Figure 4: Mean number of bacteria cfu from biofilms on Ag and control surfaces in 24hrs

Fig 5: Inhibition zones around various from surface after 24hrs: 1-Ag,5-Polished,6-Coupon

The experimental data indicated the surface modification technique used here, involving polishing the commercially pure titanium (cpTi) surface to a mirror finish allowed for a significantly higher amounts of ionic Ag to be deposited on the modified surface ($7.51.3\% \pm 2.08$), than on the unmodified surface ($2.48\% \pm 0.19$), with a paired sample test sig. <0.05 . The incorporation of Ag⁺ onto the Ti surface as opposed to simple drying out of AgNO₃ on the surface is evident in the negligible amount (nil in some cases), of nitrogen on the SEM/EDX. A *staph. aureus* suspension assay indicated a steady stationary phase over 60min for the mirror finished surface. For the same period, the silver treated surface showed a 32% reduction in bacteria cfu after 30min, and 43% reduction after 60min. Bacteria biofilm formation assays appear to indicate that the deposited Ag significantly inhibits the survival and growth of the bacterial, (sig. <0.05 , 95%). This was 3.3, 2.93 and 2.7 folds respective reduction in biofilm formed for the Ag treated surface compares to the control coupon, unpolished and polished surfaces.

CONCLUSION

The chemical surface modification strategy described above, applied to pure titanium surfaces, can lead to the deposition of significant amounts of Ag⁺ on a titanium implant surface. The deposited Ag⁺ is available in sufficient amounts to provide a significant reduction in bacterial biofilm load. This has the potential to reduce the incidence of peri- and post-surgery related incidence of implanted associated infections.

INTRODUCTION

Generation of safe, multifunctional and biocompatible materials is an enormous challenge in nano-chemistry. Metals nanoparticles especially gold (Au) can be used as efficient materials for protein immobilization and have already been widely used in biosensor fabrication. Gold and silver nanoparticles were used as a template for the growth of HA crystals when immersed in simulated body fluid^{1,2}. The uptake kinetics of Ca and P onto hydroxyapatite/polyvinyl alcohol (HAV) doped with silver NPs were experimentally investigated and theoretically modelled and high uptake capacities were obtained in the presence of silver NPs³. This work investigates the effect of adding gold NPs in ppm on the bioactivity of nanocomposites prepared from HAV using a kinetic approach.

EXPERIMENTAL METHODS

HAV prepared by an in situ biomimetic approach was doped with different concentrations of gold NPs (HAV-Au) named U1.5, U5 and U16, and the formed powder samples were characterized by different physicochemical techniques such as ICP-OES and DTA. Bioactivity was evaluated in simulated body fluid (SBF) through studying the kinetics of Ca and P uptake onto the different nanocomposite samples.

RESULTS AND DISCUSSION

Table 1 shows the concentrations in (ppm) of Ca, P and Au elements in the composite powders of HAV and the different compositions doped with Au composites along with the corresponding Ca/P molar ratios.

Sample	Ca	P	Au	Molar
symbol	(ppm)	(ppm)	(ppm)	Ca/P
HAV	29.51	12.80	—	1.78
U1.5	36.57	15.41	ND	1.83
U5	29.26	11.83	0.045	1.90
U16	25.09	9.80	0.144	1.97

Figure 1 shows the TGA and DTA of the prepared samples where the total weight loss was apparently increased by the addition of the gold nanoparticles from -20% up to -70% after heating up to 1200 °C. A peak around 450 °C appears as shoulder in U1.5 and is transformed to a significant peak by increasing the amount of gold NPs. Uptake kinetics for Ca and P onto the different composite samples was well described by a pseudo-second-order model (Eq 1) that correlates

uptake (q) to time (t), parameters thereof are compiled in Table 2.

Figure 1. DTA results for HAV and HAV-Au samples.

$$\frac{t}{q} = \frac{1}{k_2 q_e^2} + \frac{t}{q_e} \quad (1)$$

Table 2. Values of the pseudo second-order (k_2) kinetic rate constants and maximum uptake (q_e) for Ca onto HAV and different HAV-Au composites.

	k_2	q_e	R^2	χ^2
	(g/mg.h)*10 ⁸	(mg/g)		
HAV	193.88	12.89	0.987	0.32
U1.5	2.10	87.72	0.939	0.11
U5	7.97	47.17	0.959	0.60
U16	10.60	29.50	0.956	0.40

It can be deduced that adding Au NPs to HAV enhances the uptake of both Ca and P (not shown). The lowest added concentration of Au NPs (U1.5) gave the highest uptake for both Ca and P. Even though increasing the concentration of Au NPs in the HAV-Au samples decreases the uptake amount, it however substantially increases the rate of uptake as clear from the k_2 values.

CONCLUSION

Gold NPs significantly enhanced the bioactivity of HAV nanocomposites where high uptake capacities of Ca and P were obtained. The developed nanocomposites promise to be excellent biomaterials for bone and reconstructive surgery applications.

INTRODUCTION

Gold nanoparticles (AuNPs) have received global attention in applications ranging from therapeutics to diagnostics and use in advanced imaging systems.¹⁻² Their unique physicochemical properties such as adsorption of near infrared light to release thermal energy offers new opportunities in the treatment of disease. Their size range similar to many important biomolecules gives rise to unique reactivity, and strategies tailored towards chemical modification offers enhanced bioactivity and targeted delivery. The aim of this study was to evaluate the effects of size using citrate stabilised AuNPs as a simple model system to study their interactions in whole blood and influence on blood coagulation.

EXPERIMENTAL METHODS

Citrate stabilised AuNPs were produced through chemical reduction of Au (III) chloride (HAuCl₄) following the method of Frens.³ Each Au dispersion was standardised by calculating the mean number of Au atoms per particle to determine the molar concentration. Transmission electron microscopy (TEM) evaluated the size of AuNPs via random sampling of multiple fields of view (n=20). Differential centrifugal sedimentation (DCS, Analytik Ltd, UK) was used to determine particle size and distribution. Fresh whole blood was collected from healthy consenting volunteers using collection tubes containing 0.5ml buffered sodium citrate. 255µl of whole blood was added to 85µl of AuNPs (0.66nM). The solution was transferred in to polystyrene TEG[®] cups, and 20µl CaCl₂ (0.2M) was added to initiate blood coagulation, and measured immediately using a TEG[®] 5000 haemostasis analyser (Medicell Ltd, UK).

RESULTS AND DISCUSSION

A range of stable Au dispersions was obtained using the citrate reduction method to yield different sized NPs identifiable by their unique colour (Figure 1, A-B).

Figure 1. Digital image of Au dispersions (A), and a schematic image (B) highlighting charge stabilisation via negatively charged citrate ions (C₃H₅O(COO₃³⁻)).

TEM and DCS confirmed the particle size/distribution, which revealed spherical NPs ranging from 15, 21, 35, 50, and 60 nm in diameter (samples I-V). Elemental analysis using energy dispersive X-ray (EDX) confirmed the composition of AuNPs. TEG[®] was used as a simple laboratory screening tool to monitor the effects of citrate stabilised AuNPs on blood coagulation. TEG[®] analysis of whole blood found that 35 nm particles (sample III) were the most prothrombogenic with the highest clot rate and stability (Figure 2, A-D).

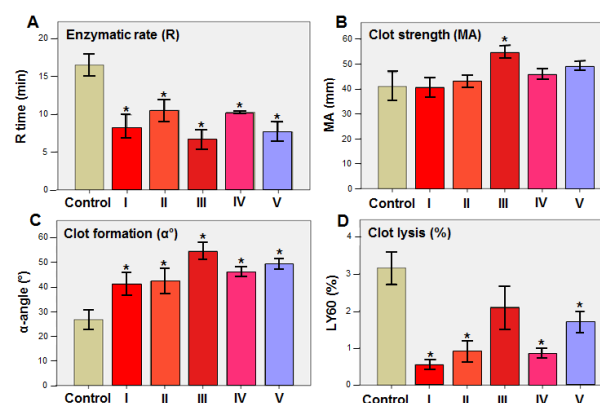

Figure 2. TEG[®] analysis of Au dispersions in (A) highlighting the contribution of enzymes (R time), (B) fibrinogen and platelets (MA), (C) clot formation (α-angle°), and (D) clot lysis (LY60). * = P < 0.05 when compared with citrated whole blood (n = 4).

CONCLUSION

It can be seen that TEG[®] is well suited to evaluate blood compatibility of AuNPs, and offers a better selection of test candidates for *in vitro* and *in vivo* testing based on size, shape and chemistry. Much effort is needed to determine the role of serum proteins, enzymes, platelets and cells with AuNPs in the blood for site specificity and targeted delivery. However, before such tools become available, in-depth studies in the basic science of NP interactions are essential steps in their evolution.

INTRODUCTION

The challenge for creating new synthetic materials able to serve as biologically active scaffolds that support key aspects of tissue regeneration has driven multidisciplinary efforts for the identification of cell-free routes able to recapitulate the properties of extracellular matrices. Cells within tissues are in fact surrounded by fibrillar matrices that support and regulate cell adhesion, migration, proliferation and differentiation. Within this perspective, the development of artificial biologically active fibronectin (FN) networks through cell-free routes gains a distinct bioengineering interest, because it is a way to enhance the biocompatibility of materials. In our group, we have identified specific surface chemistries that promote the cell-free formation of biologically active physiological-like fibronectin fibrils.¹ In this work, we address the role of another multi-functional adhesive glycoprotein, vitronectin (VN), in the regulation of the biological activity of the material-driven fibrillogenesis of FN, following previous indications that VN confers higher mobility to the protein matrix.²

EXPERIMENTAL METHODS

Polymer sheets were obtained by radical polymerization of ethyl acrylate. Thin films of polymer (PEA) were prepared by spin coating a 2.5% polymer solution in toluene on 12 mm glass coverslips at 2000 rpm for 30 s. FN and VN from human plasma were adsorbed onto the surfaces at a total concentration of 10 µg/ml in different weight ratios (100/0, 70/30, 50/50, 30/70, 0/100). Protein distribution and conformation were evaluated by AFM in tapping mode, while the amount of FN adsorbed onto the substrates was quantified by western blot.

Murine C2C12 myoblasts cells were cultured on protein-coated materials at a density of 20000 cells/cm² for 4 days under differentiation conditions, immunostained for sarcomeric myosin, and differentiation levels were quantified through image analysis. For protein blocking experiments, the RGD domain on FN and on VN were blocked using HFN7.1 and Mab1945 monoclonal antibodies, respectively. To follow the evolution of cell differentiation over time, cells were fixed at 5 time points (3h, 24h, 48h, 72h and 4 days) and the actin cytoskeleton was stained.

RESULTS AND DISCUSSION

AFM shows that FN adsorbed on PEA assembles into a fibrillar network that resembles its physiological cell-mediated assembly. The presence of VN during the adsorption results in the incorporation of VN molecules into the protein network, facilitating the mobility of the protein at the material interface and resulting in higher

adsorption of FN and faster dynamics of network formation at certain FN/VN ratios (70/30, 50/50).

When C2C12 cells are cultured on these surfaces, the presence of VN non-monotonically tunes myogenic differentiation, as the degree of differentiation reaches a minimum for a 50/50 protein ratio, whilst cell density is increased (Figure 1). Moreover, the presence of VN triggers higher levels of cell fusion with the formation of bigger multi-nucleated myotubes compared to sole FN (Figure 1).

Figure 1. Myogenic differentiation as determined by the percentage of sarcomeric myosin-positive cells and fluorescence staining images. Bar is 200 µm.

Myotube formation was followed over time to better elucidate the dynamics of cell fusion in the presence of VN. The role of the mobility conferred by VN to the protein layer was also addressed by blocking cell adhesion to VN via monoclonal antibodies.

CONCLUSION

VN tunes material-driven FN fibrillogenesis and modulates myogenic differentiation, both in terms of differentiation levels and dynamics of cell fusion.

Investigation on Mechanical Loading of Hydrogels for Cartilage Tissue Engineering

Stefanie Biechler^{1*}, Sandy Williams¹, and Ruochong Fei¹

¹Bose Corporation, ElectroForce Systems Group, Eden Prairie, MN, USA, stefanie_biechler@bose.com

INTRODUCTION

Degeneration of joint cartilage can result from primary osteoarthritis, injury or disease. Unfortunately, adult cartilage has very limited tendency to self-heal, and it possibly leading to further degeneration, increased pain, and reduced quality of life. Currently, donor site morbidity and limited availability of autologous osteochondral plugs hinder the possibility of mosaicplasty and autologous chondrocyte implantation. Therefore, there is a pervasive need for effective clinical treatments to repair cartilage injuries. In recent years, regenerative medicine has been looked at to replace damaged cartilage with tissue-engineered cartilage constructs. Specifically, hydrogels have been used in many of these efforts because they not only provide a boundary for retention of cells, but also act as a substrate to which anchorage-dependent chondrocytes can adhere.

It is known that mechanical stimulation has a significant impact on cell differentiation and proliferation during three-dimensional cell culture. Sinusoidal waveforms are typically used when studying the relationships between cell growth and dynamic mechanical stimulation. However, it would be more relevant to study these relationships under physiological mechanical loading because such “in vivo”-like loading protocols are directly applicable to cell stimulation during culture. Thus, applying accurate and efficient mechanical stimuli is crucial in quality control of the final tissue engineered construct. In this study, the mechanical response of polyethylene glycol (PEG) hydrogels was observed in response to physiologically relevant loading conditions and an irregular waveform to mimic the dynamic compressive strain on knee cartilage during a walking gait cycle was applied to stacks of hydrogel sheets.

EXPERIMENTAL METHODS

A waveform model (Figure 1) of strain vs. gait cycle based on simulation of human walking was used in this study [1]. This waveform was extracted using Matlab. According to normal human walking speed of 5 km/h, a one gait cycle time of 1.1 sec was used. An ASCII file was constructed and the percent strain was scaled according to specimen thickness. The final point-by-point file was directly imported into the control software for application to the hydrogels.

Polyethylene glycol (PEG) hydrogel sheets (4" × 4") were purchased from Medline Industries and specimens were punched from the hydrogel sheet (12 mm in diameter and 6 mm in height). The samples were soaked in 37C saline for two hours prior to placement on the mechanical loading frame. A preloading force of 0.1 N was applied initially to ensure that the entire

scaffold surface was in contact with the compression platens prior to application of the walking gait waveform. In addition to individual sample loading, simultaneous loading of 24 hydrogel samples was performed in a multi-specimen compression bioreactor to assess the loading accuracy when stimulating multiple samples with the same actuator.

RESULTS AND DISCUSSION

Initially, three specimens were tested with the custom waveform to record the corresponding loads and determine the statistical repeatability of the loading waveform (Figure 1). Similar testing results of three specimens were achieved, and reliable repeatability of this testing method was demonstrated (displacement difference between samples: < 2.5%; load difference between samples: < 13.9%). Compared to the original extracted waveform in the ASCII file, the majority of the waveform details were retained accurately, including micron-level changes in strain. Similarly, when applying the load to 24 samples simultaneously, the sample stage was found to synchronously and evenly distribute the load to all 24 specimens.

Figure 1: Representative walking gait waveform and load response on a single hydrogel sample.

CONCLUSION

In this study, a physiologically relevant walking gait waveform was used to dynamically compress hydrogels for the application of cartilage tissue engineering. The load response of the hydrogels was observed and the waveform was determined to be applicable to future cell culture studies. The next steps will be to repeat the loading protocol for an extended period of time on a cell-seeded construct to investigate the biological response of chondrocytes to mechanical loading.

INTRODUCTION

Tissue-engineered hydrogels hold great potential as nucleus pulposus substitutes (NP) since it can mimic the native 3D environment¹. Methacrylated gellan gum (GG-MA) hydrogels have been reported as suitable matrices for NP regeneration², due to their remarkable biological and biomechanical properties. In this study, the biological performance and mechanical properties of cell-laden GG-MA hydrogels were evaluated *in vitro*.

EXPERIMENTAL METHODS

Human intervertebral disc (hIVD) cells were isolated from herniated patients submitted to surgery, following an enzymatic digestion-based method and expanded using standard culture conditions. Prior to cell encapsulation, hIVD cells were characterized by flow cytometry regarding the expression of markers specific for: NP (CD24 and HIF-1), adipose-derived stem cells or mesenchymal stem cells (CD29, CD73, CD90, CD105) and hematopoietic and endothelial lineages (CD34, CD45). The hIVD cells were then encapsulated at a cell density of 2×10^6 cells/mL and cultured within ionic- (iGG-MA) and photo-crosslinked (phGG-MA) hydrogel discs, up to 21 d. Cell behaviour was studied in terms of viability (Live/dead assay) and morphology (DAPI/Texas red-Phalloidin staining), production of a cartilage-like tissue by histological staining and expression of typical chondrogenic markers and specific NP-markers through immunocytochemistry from 2 h until 21 d of culturing. The cell-laden constructs were also analyzed by dynamic mechanical analysis (DMA) after each culturing time.

RESULTS AND DISCUSSION

Different populations of hIVD cells, which were isolated from male/female patients (25-57 years) at different passages, were characterized by flow cytometry. Generally, hIVD cell populations were positive for CD29, CD73, CD90 and CD105 and negative for hematopoietic markers such as CD45 and CD34. Differences were found in the expression of NP-specific markers between the populations/passages analyzed. A population obtained from a 51-year old female patient, with an expression of 13% and 0.5% for CD24 or HIF-1alpha respectively, was selected for the subsequent assays.

Cell viability was evaluated in both cell-laden iGG-MA and phGG-MA constructs (Figure 1). It is possible to conclude from the microscopy images that both hydrogels enable cellular encapsulation, allowing for a good distribution of cells and support cell viability until 21 d of culturing. The effect of encapsulating hIVD cells on the mechanical performance of the hydrogels was evaluated by DMA. The incorporation of cells seems to have an immediate negative effect (not statistically significant) on the mechanical properties of

the hydrogels, which is recovered after 1 d of culturing (data not shown). An increase in E' value (in relation to acellular hydrogels) was observed only after longer culturing times (*i.e.*, 21 d; Figure 2), which is consistent with the viability and production of extracellular matrix by hIVD cells, as demonstrated by the evaluation of biological performance.

Figure 1. Fluorescence microscopy images of hIVD cells encapsulated within iGG-MA and phGG-MA hydrogels, after 3, 14 and 21 d of culturing (green color – Calcein AM – corresponds to live cells and red color – PI – to dead cells).

Figure 2. Dynamic mechanical analysis of acellular and cell-laden iGG-MA and phGG-MA hydrogel discs after culturing for 21 d, showing the storage (E') modulus and loss factor ($\tan \delta$) measured in PBS at 37°C. Statistical analysis was performed based on the values at 1 Hz and using a two-way ANOVA followed by Bonferroni's post test ($n=6$; * $p < 0.05$).

CONCLUSION

This study showed that the iGG-MA and phGG-MA hydrogels are stable and non-cytotoxic *in vitro* and present adequate mechanical properties. The hydrogels supported hIVD cells encapsulation and viability, thus possessing promising properties for being tested in cellular-based tissue engineering strategies aimed to restore the functionality of NP.

INTRODUCTION

Melt electrospinning has been recently utilised to control fibre deposition in a manner in-line with conventional 3D printing technologies, producing fibres in the range of 1 to 30 microns with a high degree of order, a size range which has been deemed highly suitable for biofabrication^{1,2}. Recently our lab has produced melt electrospun fibres with a high degree of order up to 2 mm in thickness, 10× greater than previously presented data.

Many polymers can be melt spun, however the most commonly used one is Polycaprolactone (PCL). PCL has many features which makes it suitable for electrospinning and biofabrication, including good viscoelastic properties for fabrication and low melting point (~65°C)³. While PCL is bioresorbable, by itself it is not bioactive. This functionality can be added to PCL scaffolds by combining them with bioactive molecules, such as the osteogenic bioactive glasses (BGs)^{4,5}. Previous work has shown that BG particles can be intergrated into molten PCL and melt spun, although aligned fibres were not achieved⁴.

The combination of PCL and bioactive glasses with melt electrospinning present the possibility to develop pro-osteogenic scaffolds whose structures have a high degree of order and thinner fibers than conventional 3D printing technology.

EXPERIMENTAL METHODS

45S5 Bioglass® and Strontium substituted bioactive glass (supplied by Prof Molly Stevens' Group, Imperial College London) were used for this experiment. Particle size distribution was determined by a Master Sorter 3000 (Marlvern). BGs were then ground via a Micronizing mill (McCrone) for 2 hours 30 min, and size distribution resampled.

PCL (*Capa 6400*; Perstorp UK Limited) was mixed with the BG (ground or unground) particles (10% wt) chloroform (10 ml per gram of PCL) at room temperature, followed by ethanol precipitation and air drying, prior to loading into a syringe for melt electrospinning.

A bespoke melt electrospinning device with dual voltage control and an X-Y-Z stage was used for the scaffold manufacture. Electrospinning conditions were: +7.5 kV tip charge, -3.5 kV collector charge, feed rate 40 µl hour, G19 needle, 90°C melt temperature and 10 mm tip to collector distance.

Fibre size, alignment and particle distribution were assessed by light microscopy (Zeiss Axio Imager M2).

Scaffolds were etched NaOH for 1 hour before being cultured with MC3T3 preosteoblastic cell line (~5000 cells per 30 mm²). Confocal microscopy of DAPI/Alexa Fluor® 488 phalloidin + Alizarin red staining of BG particles was used to assess cell attachment.

RESULTS AND DISCUSSION

PCL/BG (unground 13 – 110 µm) composite scaffolds could be spun with average fibre size higher than PCL alone. Obtaining alignment was impossible due to instability in the jet causing random deposition of fibres (Fig 1A). PCL/BG (ground 1 – 7 µm) composite scaffolds exhibited superior jet stability, and they were successfully spun in straight lines (Fig 1B). MC3T3s preferentially attached to areas of scaffold where BG particles were exposed (Fig 1C).

Fig. 1. Light microscopy of unground (A) and ground (B) PCL/BG composite scaffolds, and MC3T3 cellular attachment to the composite (C). Scale bars as shown.

CONCLUSION

By reducing the particle size of the BGs, superior spinning characteristics were achieved, and melt spun composites were able to be directly written as a straight line. These results further the potential for using melt electrospinning as an effective 3D additive manufacturing technique for biomaterial fabrication.

INTRODUCTION

Fibronectin (FN) is a ubiquitous extracellular matrix (ECM) protein that is organised into fibrillar networks by cells through an integrin-mediated process that involves contractile forces. This assembly allows for the unfolding of the FN molecule, exposing cryptic domains that are not available in the native globular FN structure and activating intracellular signalling complexes. We have demonstrated cell-free, material-induced FN fibrillogenesis into a biological matrix with enhanced cellular activities upon simple FN adsorption onto poly(ethyl acrylate) (PEA) surfaces (material-driven fibronectin fibrillogenesis).¹ Engineering cellular environments to promote tissue healing involves the design of complex systems that combine materials, ECM proteins and growth factors (GFs). We have engineered biomimetic fibronectin fibrillar networks to enhance the presentation and activity of growth factors (using the promiscuity of the FNIII₁₂₋₁₄ domain present in FN to bind GF) during tissue healing making use of the material-driven fibronectin fibrillogenesis.

EXPERIMENTAL METHODS

Glass coverslips were coated with PEA, poly(methyl acrylate) (PMA) or P(EA-co-MA) (50/50) in toluene. FN from human plasma was used to coat the samples at 20 µg/ml, followed by 1% BSA coating and BMP-2 (25 ng/ml) when required. AFM (tapping mode) experiments were performed using a NanoScope IIIa instrument on samples coated with FN (3 µg/ml), BMP-2 (1 µg/ml) and FN followed by BMP-2 (20 µg/ml and 25 ng/ml respectively); also, in this last condition immunogold was used to label BMP-2 adsorbed on FN-coated samples. BMP-2 adsorption was quantified by sandwich ELISA. The availability of FNIII₁₂₋₁₄ domain was measured by ELISA. Early signalling in human mesenchymal stem cells was studied after 40 min by sandwich ELISA for ERK1/2 phosphorylation. SMADs signalling was studied after 40 min (pSMAD1, 1/5, and 1/5/8 using western blot). Osteogenic differentiation was studied after 14 days using immunofluorescence and qRT-PCR for osteocalcin (OCN) and osteonectin (ON).

RESULTS AND DISCUSSION

FN adsorption from a solution of concentration 20 µg/ml on material substrates, as shown by AFM, results in globular aggregates on PMA, organisation into (nano)network on PEA and a less interconnected network on P(EA-co-MA). FNIII₁₂₋₁₄ domain (heparin II domain) was more exposed on PEA than on PMA (Figure 1a). AFM images of FN and BMP-2 showed that BMP-2 interacts with FNIII₁₂₋₁₄, the promiscuous

GF binding domain in FN, as confirmed by immunogold (Figure 1b). Presentation of BMP-2 to MSCs via FN networks enhanced phosphorylation of ERK1/2. Osteogenic differentiation by qRT-PCR for OCN and ON was higher on PEA coated with BMP-2 after FN adsorption compared with PEA where the BMP-2 was only present in the medium (Figure 1c).

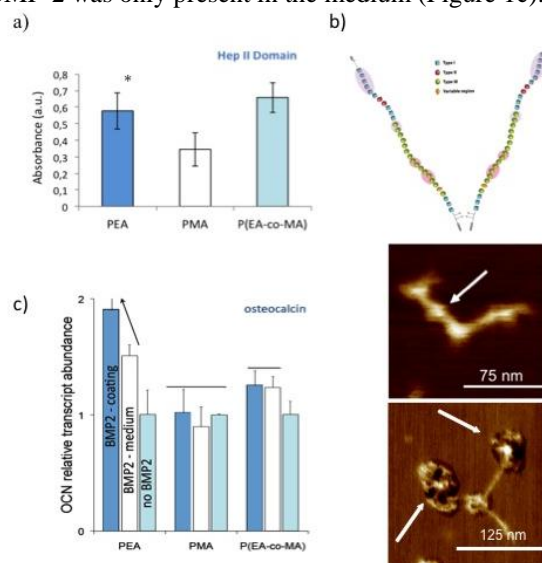

Figure 1. a) ELISA for Hep II domain availability on the different materials. b) FN molecule with indication of the different domains and two AFM images of a single FN molecule on PEA. Arrows show the BMP-2 on the Hep II region. In the second image BMP-2 is detected using immunogold labelling. c) OCN mRNA abundance on the different materials after 14 days.

CONCLUSION

We made use of the ability of some material surfaces to direct the physiological organization of FN into fibrillar networks in absence of cells (material-driven fibronectin fibrillogenesis) to engineer advanced micro-environments for cell culture. These surfaces trigger the organization of FN upon simple adsorption from solution and provide a functional biomimetic interface with the ability to bind growth factors. BMP-2, presented to MSCs through synergistic interaction between integrins and GF receptors, enhanced their osteogenic differentiation.

INTRODUCTION

The importance of the extracellular matrix (ECM) in regulating stem cell differentiation is now well-recognized¹. Apart from influencing cell behaviour through specific cell-matrix interactions, the physico-chemical properties of the ECM are also important (e.g., hydrophobicity, elasticity and nanoscale topography²). We have previously shown that biomaterials that mimic aspects of ECM proteins can regulate the differentiation of mesenchymal stem cells³. This study aims to design biomaterials that are able to control the differentiation of mouse kidney-derived stem cells (mKSCs) into either proximal tubule cells (PTCs) or podocytes, two cell types that are commonly involved in kidney disease. We have developed polyacrylate polymers (ESP03, ESP04, ESP07, BTL15) with various functional groups, such as amine, hydroxyl and carboxylic acid groups, as well as integrated hydrophobic spacer chains, to mimic aspects of key ECM proteins normally found in the kidney. Using various types of physicochemical analyses, we have investigated the effects of the chemical modifications on the physical properties of the substrates, including surface wettability and topography. So far we found that two of our polymers, referred to as ESP07 and BTL15, were able to direct the differentiation of mouse KSCs into PTCs. These two polyacrylates differ in topography and wettability, but, interestingly, show very similar surface chemistry.

EXPERIMENTAL METHODS

Glass cover slips (Fisher Scientific) were coated with a solution of 3% polymer in DMF; 22mm² discs for Dynamic Contact Angle (DCA) analyses and 13mm discs for all other analyses. Atomic Force Microscopy (AFM) was conducted using a Multimode 8 system (Bruker) equipped with silicon nitride probes and operated in Peak Force Tapping mode. X-ray Photoelectron Spectroscopy (XPS) analyses were performed using an NCESS ESCA300 XPS spectrometer (VG Scienta). Survey, C1s, O1s and N1s spectra were analysed at 150 eV, 0.8 mm slit, 1.8 kW. DCA was recorded using the Willhelmy method with a Cahn DCA322 microbalance. Advancing and receding contact angles were calculated for each sample in distilled water (72.6 dyne cm⁻¹). Samples were sterilized under UV light prior to cell culture. mKSCs⁴ were cultured on tissue culture dishes (Corning) and fed every other day. Cells were passaged once per week. For differentiation studies, 1000 cells were seeded on polymer coated coverslips, left for 4 days and subsequently analysed.

RESULTS AND DISCUSSION

Surface analyses showed that the polymers show only small differences in surface elemental composition (carbon, nitrogen, oxygen). However, there were relative differences in the COOH, OH and NH₂ content between the polyacrylates (Table 1).

Table 1: Functional groups within polyacrylates.

Functional group	Trend within range of polymers
C-COOH	ESP04<ESP7<BTL15<ESP03
C-NH ₂	ESP04<BTL15<ESP03=ESP07
C-OH	ESP07<BTL15

Surface wettability confirms the XPS results showing higher contact angles for polymers with higher carbon content and vice versa. The trend for advancing/receding contact angle is as follows:

BTL15=ESP03<ESP07<ESP04. Surface topography analyses showed that the polymers appear to have very different characteristics with hill-like features differing strongly in height between polymers. ESP07 was the smoothest with maximum peak to trough height of 100 nm, for ESP03 and ESP04 this varied between 300 and 600 nm and for BTL15 it was in the order of 1µm. Preliminary results have shown that, following a 4 day culture period of mKSCs on polyacrylates ESP07 and BTL15 (the substrates with hydroxyl and amine functionality) the cells differentiate towards PTCs as these cells express higher amounts of megalin and alkaline phosphatase.

CONCLUSION

Polyacrylate substrates ESP07 and BTL15 have high potential to direct the differentiation of mKSPCs into specialized renal cells. These findings could provide a significant contribution to stem cell research by providing materials with specific surface properties that promote directed cell differentiation.

INTRODUCTION

In the cases where medical devices contact with physiological media such as blood, saliva or living tissue, the first biological reactions occur on the surface interface. Therefore, surface of medical materials are extremely important for biocompatibility of the device. If the surface has some affinity for bacteria adhesion, the presence of bacteria can cause pathogenic biofilm formation and subsequent infectious complications. There are some techniques used to modify the surfaces and chemical modification with antibacterial agents is still the most preferable and reliable strategy for the prevention of biofilm formation. In this study, it was aimed to prepare surface functionalized medical grade polyurethane (PU) having stable antibacterial activity. For this purpose, PU films were synthesized in medical purity and surfaces were covalently modified by chitosan (CH) which is a multifunctional natural biopolymer since it has high biocompatibility, biodegradability and antibacterial activity. Surface properties of the modified films, such as chemistry, functionality, topography, hydrophilicity, surface free energy and antibacterial efficiencies against *P. aeruginosa* and *S. aureus* were investigated.

EXPERIMENTAL METHODS

Polyurethane films (PUh) were synthesized in medical purity by using hexamethylene diisocyanate and polypropylene ethylene glycol without addition of any other ingredients such as catalyst, chain extender, solvent¹. PUh surfaces were activated by oxygen plasma (100W, 10 min) and modified by CH via covalent immobilization in two different concentrations (0.5 mg/mL and 2.0 mg/mL) (Figure 1).

Figure 1. Surface modification steps of PUh films with CH.

PUh and CH immobilized PUh surfaces (PUh-CH-0.5 and PUh-CH-2.0) were characterized by FTIR-ATR, ESCA and goniometer. Surface topographies were examined by AFM. Antibacterial activity and bacterial anti-adhesion properties were examined by viable count method and SEM against Gram negative *P. aeruginosa* and Gram positive *S. aureus*.

RESULTS AND DISCUSSION

ESCA results showed variations in the composition after CH immobilization on film surfaces. Presence of CH caused an increase in nitrogen content from 0.4% (PUh) to 4.4% and 4.5% for PUh-CH-0.5 and PUh-CH-2.0 samples, respectively (Table1). PUh-CH films had an extra peak due to O-C-O of saccharide units of CH.

Table 1. ESCA C-1s binding energy and relative contents (%)

Samples	C-C/C-H 285 eV	C-O/C-N 286.6 eV	O-C-O 288.1 eV	N-C=O 289.2 eV
PUh	38.2	58.7	-	3.1
PUh-CH-0.5	41.6	48.1	8.1	2.2
PUh-CH-2.0	41.9	47.0	8.9	2.2

Modified films were more hydrophilic than PU ones and water contact angles of pristine films decreased from 86° to 78° and 76° for PUh-CH-0.5 and PUh-CH-2.0, respectively. Plasma application caused some roughness on the surface but this roughness decreased by immobilization of CH. Bacterial adhesion of *P. aeruginosa* and *S. aureus* on both modified surfaces decreased compared to PUh films. Figure 2 show that both PUh-CH-0.5 and PUh-CH-2.0 demonstrated strong antibacterial activity for both bacteria types.

Figure 2. Antibacterial activities of control and modified films.

CONCLUSION

The surface chemistry and topography of the film samples changed after CH immobilization and modified films demonstrated strong antibacterial activities. The results shows surface modification with CH is an effective technique to control the antibacterial or anti-adhesive properties of biomaterials.

Catechol-Chitosan/Genipin Hydrogel as Mucoadhesive Buccal Drug Delivery System

J. Xu¹, S. Strandman², J. Zhu², J. Barralet³ and M. Cerruti^{*1,3}

¹Department of Mining and Materials Engineering, McGill University, Montreal, Quebec, H3A 0C5, Canada; ²Department of Chemistry, Université de Montréal, Montreal, Quebec, H3C 3J7, Canada; ³Faculty of Dentistry, McGill University, Montreal, Quebec, H3A 07C, Canada. marta.cerruti@mcgill.ca

We developed a hydrogel made in catechol-modified chitosan (Cat-CS) crosslinked by genipin (GP) as a mucoadhesive drug delivery system through buccal mucosa. We show enhanced mucoadhesion and controlled release of a model drug, lidocaine (LD) both in-vitro and in-vivo in rabbit models. This hydrogel is especially promising for the delivery of sensitive proteins and nutraceuticals that cannot be delivered using dry pellets currently used in buccal delivery.

INTRODUCTION

Oral transmucosal delivery is a non-invasive way of drug administration that prevents presystemic clearance at gastrointestinal tract and avoids the first-pass elimination in the liver during systemic circulation¹. To sustain drug release, materials for buccal delivery should adhere tightly to the buccal mucosa. Currently dry tablets are used for this purpose. The drawback of this approach is that bioactive compounds needing to stay hydrated cannot be delivered. Chitosan (CS) is a mildly mucoadhesive, biocompatible natural polysaccharide. A catechol-containing compound is responsible for the outstanding underwater adhesion of marine mussels². We previously showed that adding catechol-containing compounds to CS gels can increase their adhesion to intestinal membranes³. Here, we covalently bond catechol groups to CS (i.e. Cat-CS), and crosslink the resulting polymers using a non-toxic natural compound, genipin (GP), to form Cat-CS/GP hydrogels. We test the hydrogel mucoadhesion in-vitro to porcine buccal tissue, and both in-vitro and in-vivo in rabbit models for the delivery of LD, a local anesthetic commonly used in dental procedures.

EXPERIMENTAL METHODS

Catechol functional groups were covalently bonded to chitosan by EDC coupling, preparing Cat-CS with catechol contents of 9% and 19%. Hydrogels were prepared by crosslinking Cat-CS with GP. Rheological behavior was tested by both time and stress sweeps using cone/plate steel geometry (Φ 40 mm, 2°). Lidocaine (LD) as model drug was loaded into the hydrogels. Drug release was quantified in vitro by liquid chromatography. Mucoadhesion was evaluated by measuring detachment time from pig buccal mucosa surface in PBS (pH6.8), at 300 rpm continuous stirring. Drug-loaded hydrogel patches were attached to the buccal mucosa of rabbits for the in-vivo tests. Blood samples were collected, followed by HPLC quantification of drug concentration in the serum. CS crosslinked by GP hydrogels (CS/GP) were used as controls. Histology was performed on the tissue in contact with the hydrogel patches.

RESULTS AND DISCUSSION

Both NMR and FTIR confirmed the successful synthesis of Cat9-CS and Cat19-CS. Cat-CS hydrogels were denser than control CS hydrogels. The gelation of both CS/GP and Cat-CS/GP hydrogels reached equilibrium after 12 h at 37 °C. Cat-CS/GP showed higher ultimate shear strength than CS/GP, indicating Cat-CS/GP hydrogels are stronger than CS/GP. Cat-CS/GP significantly enhanced the adhesion time at pig buccal mucosa in PBS (Fig.1A). Sustained release of LD was achieved in both Cat-CS and CS hydrogels in-vitro, and a slower release was observed for the Cat-CS hydrogels. In-vivo tests in rabbits showed that LD could be detected in the rabbit serum after 3 hours only if it was released from Cat-CS/GP hydrogel patches. Only very low LD values were measured after release from CS/GP hydrogels (Figure 1B). Histology showed that Cat-CS/GP hydrogels did not cause any adverse reaction on the tissue in contact.

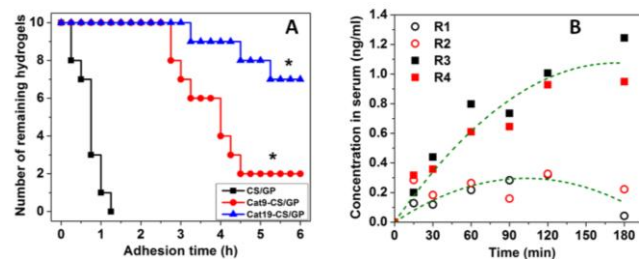

Figure 1. (A) Adhesion of CS/GP and Cat-CS/GP hydrogels on porcine buccal mucosa in PBS. (B) LD concentration measured in the serum of rabbits R1-R4 after application of drug-loaded Cat19-CS/GP (R3 and R4) and control CS/GP hydrogels (R1 and R2) on the buccal mucosa

CONCLUSION

Cat-CS/GP hydrogels are promising candidates as buccal drug delivery systems, showing excellent mucoadhesion in-vitro and sustained LD delivery both in-vitro and in-vivo. The improved in-vivo behavior is to be related to the intimate contact between the Cat-CS hydrogels and buccal mucosa due to their strong mucoadhesion.

Inflammatory Response to Magnesium Based Biodegradable Implant Materials

Maria Costantino¹, Bérengère Luthringer¹, Regine Willumeit^{1*}

¹ Helmholtz-Zentrum Geesthacht, Zentrum für Material- und Küstenforschung, Germany

^{1*} Helmholtz-Zentrum Geesthacht, Zentrum für Material- und Küstenforschung, Germany, regine.willumeit@hzg.de

INTRODUCTION

The biodegradability and the mechanical properties of magnesium alloys make them a suitable material for orthopaedic implant applications. Several papers are studying the interaction of bone cells with these materials [1, 2]. Still during implantation a variety of cells is interacting. Among them are cells of the immune system which are responsible for the inflammatory reaction of the organisms. Macrophages play a central role in the inflammatory process and their interaction with the degrading material is consequently the target of this study.

EXPERIMENTAL METHODS

In order to evaluate the influence of ion release, pH changes and hydrogen evolution produced by degrading magnesium alloys on the inflammatory process, undifferentiated (monocytes) and PMA stimulated (macrophages) U937 cells were cultured with three different magnesium alloys: WE43, Mg10Gd and Mg2Ag. Two different culture methods were employed: either the cells were exposed to an extract of the degrading material or they grew directly on the material. For the extract assay the three materials were incubated under cell culture conditions for 72h in cell culture media. During this time the materials degraded and extracts with defined Mg concentrations (measured by Xylidyl Blue Assay) were obtained. Then the cells (5×10^5 cells / mL) were subsequently cultivated with these extracts (diluted 1 to 10 to decrease the osmolality) for 1 and 10 days. For the direct assay the cells (5×10^5 cells / mL) were cultured on the surface of discs (1mm x 10mm) for 1 and 6 days. Cells without material contact were used as control.

inflammatory cytokines in the cell culture supernatant. The expression of specific genes such as CD36, TLR4, ICAM, IL-1 β and OPN were obtained by real time Polymerase Chain Reaction (RT-PCR). Every sample was tested in triplicates.

RESULTS AND DISCUSSION

Undifferentiated U937:

The analyses revealed that when cells are growing directly on the Mg alloys, the material can stimulate undifferentiated U937 cells (monocytes) to release chemotactic factors such as IL-8 (Interleukin-8) and MCP1 (Monocyte Chemotactic Protein-1) and anti-inflammatory cytokines such as IL-4 (Interleukin-4) and IL-10 (Interleukin-10).

PMA stimulated U937:

For PMA stimulated U937 – which we consider here to be differentiated U937 = macrophages – PCR analysis showed a decreased expression of inflammatory genes.

CONCLUSION

Our results indicate that at least for the three Mg alloys tested two mechanisms depending on the maturation of cells (monocytes / macrophages) play a role: (1) a recruitment of monocytes towards the damaged tissue is possible and (2) when differentiated into macrophages the material can induce the down regulation of the inflammatory reaction.

Fig. 1: Overview of cytokines analysed in this work.

The inflammatory activity of the cells was assessed by a Human Cytokine Array Panel (Fig. 1) which is a qualitative method for the simultaneous analysis of 36 cytokines. In addition standard and multiplex ELISA (Qplex) measurements were performed to detect

Surface modification of poly(D,L-lactic acid) scaffolds for orthopedic applications: a biocompatible, non-destructive route via diazonium chemistry

H. Mahjoubi¹, J. Kinsella², M. Murshed³ and M. Cerruti*¹

Materials Engineering, McGill University, Canada, marta.cerruti@mcgill.ca

Department of Bioengineering, McGill University, Canada

Faculties of Medicine and Dentistry, McGill University, Canada

We show that diazonium chemistry can be used to modify the 3D structure of poly(D,L-lactic acid) (PDLLA) scaffolds with phosphonate groups, using a simple 2-step method. This modification does not degrade PDLLA, and allows for the formation of a thick layer of hydroxyapatite (HA) upon immersion in simulated body fluid (SBF). MC3T3-E1 preosteoblasts seeded on PDLLA films treated in the same conditions as the scaffolds show greater spreading and growth than those seeded on bare PDLLA films. This work introduces diazonium chemistry as a simple and biocompatible technique to modify scaffold surfaces, allowing to covalently and homogeneously bind a number of functional groups without degrading the scaffold polymeric matrix.

INTRODUCTION

Scaffolds made with synthetic polymers such as polyesters are commonly used in bone tissue engineering due to their biocompatibility, biodegradability, and adequate mechanical properties¹. However, polyesters do not have specific biological cues and their surface is not ideal for cell adhesion and growth. Surface modification of these materials is thus crucial for enhancing the scaffold integration in the body. Most techniques used to modify biomaterial surfaces either provide weak bonds (physisorption) or are destructive (hydrolysis) or cannot fully coat the inner structure of 3D scaffolds (plasma). Here we test if diazonium chemistry can overcome these weaknesses. Diazonium chemistry was developed to modify a number of surfaces². Here we use it for the first time on PDLLA to first bind an amino terminated layer, and then transform this into a phosphonate layer. Phosphonate groups are known to enhance nucleation and growth of HA by attracting calcium cations³. An HA layer coating is ideal for biomaterials for orthopaedic applications. We test HA deposition on modified scaffolds by immersing them in SBF. Finally, we grow MC3T3 preosteoblasts on films modified with a similar procedure used for the scaffolds.

EXPERIMENTAL METHODS

We prepared PDLLA scaffolds by salt leaching, and modified their surfaces by diazonium chemistry. After generating an amino-rich layer using dianiline, we introduced phosphonate groups by adding 2-aminoethylphosphonic acid. We perform X-ray Photoelectron Spectroscopy (XPS) to confirm functionalization, and gel permeation chromatography (GPC) to check for PDLLA degradation. We then immerse all scaffolds in SBF and characterize them after 2 and 4 weeks with XPS, Raman and FT-IR

spectroscopy. We seed MC3T3 preosteoblasts on PDLLA films modified similarly to the scaffolds and test their viability and mineralization using standard bioassays.

RESULTS AND DISCUSSION

XPS shows that treated scaffolds contain both N and P on their surface, and that the amount grafted is controllable by simply changing the functionalization time. Both outer surface and inner pores of the scaffolds can be modified by evacuating the scaffolds prior to immersing them in the diazonium-containing solutions. GPC shows that despite the acidity of the diazonium reaction solution, PDLLA is not degraded.

After immersion in SBF, larger and more abundant agglomerates are observed on the treated scaffolds (Figure 1A). XPS shows that these aggregates are composed of Ca and P, and more Ca and P are present on the surface of the treated scaffolds compared to non treated scaffolds. Raman and FT-IR spectroscopy reveal that the Ca/P precipitates are HA. Cytocompatibility tests show that MC3T3 cells are alive on all films, and they proliferate and spread better on phosphonate-modified films than on unmodified PDLLA (Figure 1B). More mineralization is observed on modified than on bare films, too.

Figure 1. (A) SEM image of 2 h vacuum treated scaffold immersed in SBF for two 4 weeks; (B) live/dead assay showing only live cells (green) on phosphonated PDLLA membrane

CONCLUSION

PDLLA scaffolds can be easily and effectively modified with diazonium chemistry. The simplicity of this method, its biocompatibility and the fact that PDLLA is not degraded during the treatment makes it an ideal candidate to modify scaffolds for a variety of biomedical applications.

Bioactive glass for treatment of tooth hypersensitivity during or after treatment with bleaching agent

Nataša Drnovšek¹, Kaja Križman¹, Sebastjan Perko², Saša Novak^{1,3}

¹ Department for Nanostructured Materials/Jožef Stefan Institute, Slovenia

²Ustna Medicina d.o.o., Slovenia

³Jožef Stefan International Postgraduate School, Slovenia

natasa.drnovsek@ijs.si

INTRODUCTION

Dentin hypersensitivity is one of the most commonly occurred dental conditions and is also the biggest problem of the tooth bleaching. In the most bleaching agent the active ingredient is hydroxyperoxide or peroxide releasing agent, which is due to formation of free radicals a strong oxidizing agent. Free radicals released from the hydroxyperoxide chemically brake down the organic molecules of the stained tooth and also modify the enamel and dentin structure that results in tooth hypersensitivity, especially when peroxide penetrates into the pulp chamber. Due to the pain produced, hypersensitivity demands for treatment.

A possible solution is to use bioactive glass to occlude and to remineralize dentin tubules by formation of hydroxyapatite from bioactive glass dissolution products. Hydroxyapatite fills or reduces the size of open dentin tubules, which are the cause for making the teeth sensitive to outside stimuli, thermal, chemical, mechanical or osmotic, because the nerve receptors are stimulated by movement of the fluids through the dentin tubule. To prevent development of hypersensitivity, treatment with bioactive glass could be performed at the time of bleaching or right after it and thus avoid long lasting and repeating procedure².

In this study 3 different methods of bioactive glass treatments were compared: bioactive glasses added in a form of nanosized powder directly into a bleaching gel to prevent tubule opening during the treatment, bioactive glass in a form of a gel applied right after bleaching procedure for a rapid remineralization after the treatment and for comparison only bioactive glass powder in artificial saliva.

EXPERIMENTAL METHODS

Bioactive glass (BAG) was prepared by particulate sol-gel method by a dropwise addition of reagents and under controled pH maintained by Titrand 835. BAG powder was characterized by SEM, TEM and FTIR. Dissolution of ions from BAG in artificial saliva was analyzed by ICP-MS and by measuring the pH change. For bleaching test BAG powder was mixed with bleaching gel followed by the overnight bleaching treatment, BAG powder mixed with cellulose or glicerol, to form a gel was applied on a bleached teeth or teeth were soaked and brushed in a mixture of BAG powder and artificial saliva. Formation of hydroxyapatite in dentin tubules opened by a bleaching agent or by etching was then analysed by SEM and FTIR.

RESULTS AND DISCUSSION

Particulate sol-gel method resulted in formation of porous particles (Fig.1) for which the ion leaching test revealed fast formation of Ca-phosphate as the concentration of Ca and P ions in saliva started to decrease after an hour, whereas concentrations of Si and Na ions were increasing.

Figure 1: TEM image of porous BAG particle with a composition 70 SiO₂- 30 CaO (mol%)

Brushing the samples with particulate BAG powder in artificial saliva resulted in formation of Ca-phosphate layer on dentin and in dentin tubules. Interestingly, BAG in a form of gel stimulated growth of HAP in a form of rods. BAG applied to the teeth in the time of bleaching procedure resulted in less opened dentine tubules compared to the treatment with bleaching agent alone (Fig.2).

Figure 2: Dentin tubules after the treatment with a) composite BAG/bleaching agent and b) only bleaching agent.

CONCLUSION

Bioactive glass prepared by particulate sol-gel-method showed promising results for occluding dentin tubules and thus reducing dentin hypersensitivity caused by bleaching.

However, the method of BAG application is important as BAG applied directly into a bleaching agent was less effective than other two methods, where BAG was introduced after the bleaching procedure.

Selenium-containing hydroxyapatites – spectroscopic studies

J. Kolmas, E. Oledzka and M. Sobczak

Department of Inorganic and Analytical Chemistry/Faculty of Pharmacy, Medical University of Warsaw, Poland
joanna.kolmas@wum.edu.pl

INTRODUCTION

Hydroxyapatite (HA) is commonly used in bioceramics for reconstructive surgery applications [1]. An exceptional feature of apatite is the ability of various ionic substitutions determining its physicochemical and biological properties.

It is well known that selenium plays a significant role in diverse metabolic process [2]. Moreover, selenium may prevent carcinogenesis and inhibits the growth of tumor cells [2]. Recent articles shows that selenium deficiency is disadvantageous for the growth of human bone [3]. Thus, it seems reasonable to prepare Se-containing HA for a bioactive scaffold for the new bone.

EXPERIMENTAL METHODS

“Pure” hydroxyapatite and SeO_3^{2-} -containing hydroxyapatite (with various selenites content) were synthesized by the wet method. Precipitates were aged, decanted, washed and dried at 100°C . For physicochemical studies, the following methods were applied: powder X-ray diffractometry, scanning electron microscopy (SEM), atomic absorption spectrometry (AAS). Solid-state NMR techniques (standard Bloch-decay ^1H , ^{31}P , ^{77}Se and $^1\text{H} \rightarrow ^{31}\text{P}$ cross polarization kinetics), Raman and FTIR spectroscopies were used for structural analysis.

RESULTS AND DISCUSSION

The obtained materials are nanocrystalline hydroxyapatites; PXRD method shows that the materials do not contain any additional crystalline phases. The incorporation of selenite ions causes elongation of a axis of the unit cell. Crystallinity of substituted samples slightly decreases with increased value of selenium content. FTIR and Raman spectra shows the bands from selenites incorporated into the HA crystals.

Fig. 1. TEM image of selenium-doped HA.

The ^{31}P and ^1H solid-state NMR spectra confirm hydroxyapatite structure of the samples. The ^{77}Se NMR

experiments show that in the samples with lower concentration of selenium, selenite ions are located into the crystal interior, whereas in the samples with high selenium content, the selenites are present both in the crystal lattice and on the crystal surface.

Fig. 2. Raman spectra of “pure” and substituted HA.

CONCLUSION

Nanocrystalline selenium-doped hydroxyapatite were successfully synthesized by the wet method. Future studies will focus on evaluation the *in vitro* biocompatibility assays.

Determination of metallic biomaterials susceptibility to crevice corrosion

L. Joska*, J. Fojt, A. Bernatikova

*Department of Metals and Corrosion Engineering, Institute of Chemical Technology in Prague, Czech Republic, joskal@vscht.cz

INTRODUCTION

Implants are generally produced from stainless steels, alloys based on cobalt and nowadays the most frequently from titanium. Titanium alloys based on beta structure with low modulus of elasticity and excellent mechanical properties are studied at present. Corrosion resistance of all materials used for implantation into the human body has to be very high; corrosion rate should be lower than 0.25 $\mu\text{m}/\text{year}$. The most of metallic materials used in human medicine is not noble; their high resistance is generally based on passivity. Passive metals are susceptible to non-uniform forms of corrosion. Initiation of e.g. crevice corrosion leads to local increase of corrosion rate resulting in local body burden by corrosion products and/or as the worst result to malfunction of the implant. Whilst general corrosion behaviour of biomaterials is widely studied not too many publications are dedicated to non-uniform corrosion. Several methods, in principle exposure and electrochemical (potentiodynamic, potentiostatic) tests, are used for passivity breakdown studies. Two standards dealing with crevice corrosion are dedicated to biomaterials - ASTM F746 and ASTM F2129. Both methods are accelerated electrochemical tests.

The objective of this study was to assess resistance to crevice corrosion of titanium-zirconium-tantalum alloys and to compare results of the tests realised according to ASTM standards and exposure test.

EXPERIMENTAL METHODS

Measurements were done with experimental Ti-35Nb-2Zr, Ti-35Nb-2Zr-0.4O, Ti-35Nb-6Ta beta alloys and common Ti-6Al-4V material for comparison.

Samples were in all cases exposed at 37°C in physiological saline solution, pH was adjusted to several levels. With respect to application of these materials in dentistry fluoride ions were added. Exposure environment chosen was more aggressive than phosphate buffered solution required in ASTM standards.

Experimental procedure according to ASTM F746 – 1 h stabilisation of open circuit potential (OCP), potentiostatic polarisation to +850 mV/silver-chloride electrode (SCE) for 15 min, return polarization to pre-selected potential.

Experimental procedure according to ASTM F2129 – 1 h stabilisation of OCP, potentiodynamic sweep to +850 mV/(SSCE) and back to OCP.

Exposure setup - 24 h exposure in selected environment, specimens were adjusted in crevice former (fig. 1-c).

Artificial crevices were created in all cases (O-rings ASTM F746 and F2129, crevice former according to ASTM G-78 in exposure test).

RESULTS AND DISCUSSION

According to results of all used methods studied materials were resistant in physiological saline solution. This fact was not surprising, titanium and its alloys general corrosion resistance and resistance to non-uniform corrosion in chloride media is good known. Different were results acquired in environments containing addition of fluoride ions. This model is focused on application of these materials in dentistry. Fluorides in high concentrations and often at pH in acidic region are applied in this area. Results of both electrochemical methods were not-typical. Potentiodynamic curves were relatively smooth in the whole range of potentials without common sharp current increase after passive layer breakdown (Fig. 1a). Response of samples exposed potentiostatically at +850 mV/SSCE was always the same (Fig. 1b) – exponential current decrease. Samples exposed for 24h with crevice former were frequently attacked by crevice corrosion. The main reason for differences seems to be in dynamic character of short term electrochemical measurements in comparison with “static” exposure test.

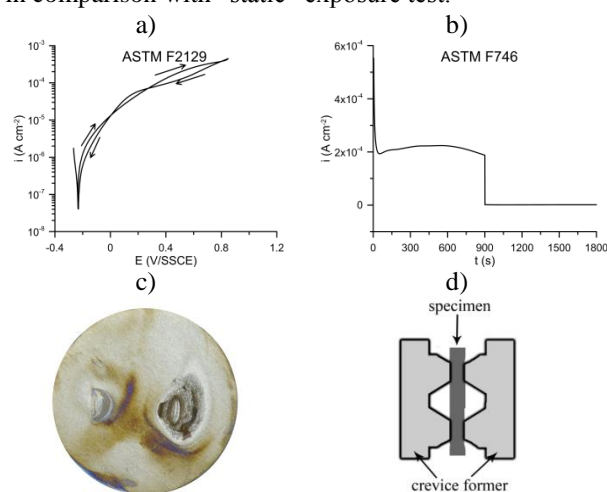

Fig. 1. Results of a) F2129, b) F746, c) exposure tests, d) sample prepared for exposure test.

CONCLUSION

Crevice corrosion is probably the most dangerous form of non-uniform corrosion. Both electrochemical methods are in principle able to detect breakdown of passivity. These measurements are helpful as screening tool. Detailed study must be based on combination of both short term electrochemical and exposure tests.

Characterization of Poly (Lactic-co-Glycolic Acid) / Poly (Isoprene) Blend for Application in Tissue Engineering

Douglas Ramos Marques¹, Luis Alberto dos Santos¹, Sarah Harriet Cartmell², [Julie Elizabeth Gough](mailto:Julie.Elizabeth.Gough@man.ac.uk)²

¹Biomaterial Laboratory / School of Engineering, Federal University of Rio Grande do Sul - UFRGS, Brazil

²Materials Science Centre / School of Materials, University of Manchester, United Kingdom, email@presenting.author

INTRODUCTION

Tissue engineering can be easily described as the in vitro seeding and attachment of human cells onto a scaffold in order to develop new tissue/organ substitutes to facilitate the restoration and maintenance of biological functions. The application of polymers as scaffolds brings desirable properties to this procedure, such as bioresorbability, biocompatibility and mechanical behavior similar to that presented by the original tissue.^{1,2}

Poly (Lactic-co-Glycolic Acid) (PLGA) is one of the most common biodegradable polymers used in the medical field since the 70's. The blend with Poly (Isoprene) (PI) generates a material with higher plastic deformation, that may be ideal for restoration of soft tissues. However, to apply the blend as a biomaterial, viability cell tests must be performed to detect the occurrence of toxic effects and the biological behavior of the material at the cellular level.

EXPERIMENTAL METHODS

PLGA ($M_n=250,000$) and PI ($M_n=295,000$) were dissolved in Chloroform (99.8%) in a 60% ww PLGA to 40% ww PI proportion, followed by homogenization and drying. FTIR spectra were obtained using a Perkin Elmer model Spectrum 1000 FTIR at room temperature (25°C). In order to investigate the polymers miscibility, differential scanning calorimetry (DSC) was carried on TA Instruments QS, between -80°C and 150°C.

For in vitro analysis, fibrous substrates were prepared by the dripping method.³ After dripping process, the fibers formed were left to dry in lyophilizer Terroni Enterprise II for 24h, vacuum, at -40°C. The dried fibers were then mounted onto coverlips, in cylindrical shape of Ø10mm #10µm. Human dermal fibroblasts were cultured in DMEM containing 2mM D-glucose and 10% Fetal Bovine Serum, at a density of 15×10^4 cell/well. Population density over the blend disks (treated group) and glass disks (control group) were observed after 1, 3, 7 and 14 days. Both groups had surface washed with phosphate buffered saline, cells fixed with paraformaldehyde 4%, and cells dyed in Toluidine Blue 1% for 1 minute. Observations were carried out using a Leica DMBR optical microscope, with cell counting procedure and statistical analysis using ANOVA ($\alpha=0,05$).

RESULTS AND DISCUSSION

FTIR analysis showed infrared spectrum bands relative to PLGA in the C=O and C-O bonds. Due to the structure of the PI, there was variation of intensity of the bands relative to the vibrations C=C and =CH. Pandey

et al (2008) reported that the use of chloroform in PLLA (Polylactic acid) blends and PGA (Polyglycolic acid) showed significant variation in polymer structure, in relation to materials used.⁴ This variation also indicated the formation of mixtures in the molecules, turning the material similar to a copolymer and no longer a blend. When several chlorine atoms are bonded to the same carbon atom, as is the case with chloroform (trichloromethane), the bands are more intense at 850cm^{-1} . For the blend, bands were observed at 756cm^{-1} , but it can also be deduced that the signals with low intensity are relative to the -C-H vibrations, given that this grouping is found in both polymer chains.

Through DSC analysis is possible to see that the glass transition temperatures (T_g) relative to raw PLGA and PI are 58,88°C and -65,74°C, respectively. For the blend, the T_g related with PI shows an expressive deviation to approximately 25°C. Deviation also observed for the PLGA T_g , to 48,95°C. This approximation of glass transition temperatures indicates a partial miscibility between the polymers.

The cell counting showed that the population over the material is significantly smaller than the population presented in the control group for all the periods. However, while the control group showed a population peak at 7 days, the treated group showed a bigger population after 14 days, with significant growth when compared to day 1. Therefore it can be assumed that the material is tolerable for further investigations around its application as biomaterial.

CONCLUSION

Both blending and dripping techniques have no major influence over the material's chemical structures, with no residual solvents presented. For the blend in this proportion, PLGA and PI showed a partial miscibility. In the biological analysis, the material seemed to present a biotolerable behavior, being viable for further investigations for biomedical applications.

Calcium phosphate nanoparticles carrying BMP-7 plasmid DNA induce osteogenic differentiation in MC3T3-E1 pre-osteoblasts

Chrystalleni Hadjicharalambous^{1,2}, Viktoriya Sokolova³, Diana Kozlova³, Matthias Epple³ and Maria Chatzinikolaïdou^{1,2}

¹ University of Crete, Dept. of Materials Science and Technology, 71003 Heraklion, Greece, ² IESL-FORTH, Vasilika Vouton, 71110 Heraklion, Greece and ³ Inorganic Chemistry and Center for Nanointegration Duisburg-Essen (CeNIDE), University of Duisburg-Essen, 45117 Essen, Germany, chad@materials.uoc.gr

INTRODUCTION

Calcium phosphate (CaP) nanoparticles (NPs) have gained increasing interest in medicine as bone substitution materials owing to their chemical similarity to human bone and teeth¹. These biodegradable materials can also be used as vehicles for transferring genetic information (plasmid-DNA) into living cells thus directing protein expression to enhance bone tissue regeneration locally. Such DNA-carrying systems have been previously used for the transfection of different cell lines and showed promising results².

In this study, we used CaP/PEI/DNA/SiO₂-SH (NPs-DNA) nanoparticles functionalized with plasmid DNA encoding for bone morphogenetic protein 7 (BMP-7), aiming to transfect MC3T3-E1 pre-osteoblasts. We investigated the transfection efficiency, cellular viability, as well as the production of hBMP-7 by transfected pre-osteoblasts. The subsequent induction of an osteogenic response triggered by hBMP-7 was examined.

EXPERIMENTAL METHODS

Synthesis of nanoparticles: Calcium phosphate nanoparticles were precipitated from aqueous solutions of calcium lactate and diammonium hydrogen phosphate, stabilized by polyethyleneimine (PEI) and loaded with DNA (plasmid BMP-7). In order to synthesize CaP/PEI/DNA/SiO₂-SH nanoparticles, a layer of silica was added followed by covalent functionalization of silanol groups, leading to a thiol-terminated surface³.

Transfection of MC3T3-E1 pre-osteoblasts: Transfection efficiency was determined by fluorescence microscopy, using CaP/PEI/Plasmid-EGFP/SiO₂-SH nanoparticles. Also, the concentrations of hBMP-7 in the cell culture medium following transfection with CaP/PEI/Plasmid-BMP7/SiO₂-SH (NPs-DNA) were measured using an ELISA kit (Abcam, UK). Cell viability and proliferation were assessed by the PrestoBlue™ assay (Invitrogen).

Osteogenic differentiation: We investigated the potential of the functionalized nanoparticles to induce differentiation by measuring alkaline phosphatase (ALP) activity, as well as calcium biomineralization by staining with the Alizarin Red S reagent (Sigma)⁴. Nanoparticles without DNA (NPs) were used as control. We performed at least three independent experiments in triplicates.

RESULTS AND DISCUSSION

The NPs-DNA did not affect the viability of MC3T3-E1 up to 7 days of culture. The transfection efficiency was measured at 25% and hBMP-7 was detected in cells

three days after transfection with NPs-DNA (figure 1). After 3 days of culture, NPs-DNA transfected cells showed higher levels of ALP activity, an early marker of osteogenic differentiation, compared to non-transfected control cells. In addition, the nanoparticles had a positive effect on matrix biomineralization as observed by the increase of calcium production detected after alizarin red staining at 14 days of culture (figure 2). Ongoing experiments aim to measure gene expression of specific osteogenic markers induced following transfection with NPs-DNA.

Figure 1: Expression of hBMP-7 in pre-osteoblasts transfected with NPs-DNA. Controls: untreated cells in primary medium and cells transfected with NPs.

Figure 2: Enhanced calcium mineralization in pre-osteoblasts transfected with NPs-DNA. *p<0.001 vs NPs and primary control.

CONCLUSION

Successful transfection of MC3T3 cells with CaP NPs functionalised with BMP-7-encoding DNA, led to expression of hBMP-7 and an enhanced osteogenic response. This indicates the potential of the NPs to be used as DNA carrier materials to enhance bone formation.

Synthesis and *in vitro* Bioactivity of Cu and Zn doped sol-gel- silicate bioactive glasses

J. Bejarano^{1*}, H. Palza¹, P. Caviedes²

¹Department of Chemical Engineering and Biotechnology, University of Chile, Chile, ^{*}jbejarano@ing.uchile.cl

²Center for Clinical Research and Pharmacological Studies, University of Chile, Chile

INTRODUCTION

Bioactive glasses are widely studied for replacement, repair and regeneration of bone tissue. These materials have the ability to form a biologically active apatite layer when exposed to body fluid allowing a strong bond to bone¹. The sol-gel process permits synthesis of bioactive glasses with different addition of inorganic metal ions that can be used as therapeutic agents in bone regeneration. Cu and Zn are essential trace elements of the body and act as enzyme cofactors. Controlled release of these ions from biomaterials improves its interaction with osteoblast cells increasing the bioactivity related with osteogenesis, angiogenesis and bacterial control². Despite the good properties of these metal ions, a comparative relationship between its presences and the glass microstructure and bioactivity has not been reported. The goal of the present contribution is to analyze the effect of adding Cu and/or Zn ions on the *in vitro* bioactivity and cytotoxicity of a bioactive glass.

EXPERIMENTAL METHODS

Bioactive glass microparticles based on 60SiO₂-25CaO-11Na₂O-4P₂O₅,% mol system (NaBG) doped with 1mol% of Cu (1Cu-NaBG) and Zn (1Zn-NaBG) (and co-doped, 1Cu1Zn-NaBG) were synthesized using a sol-gel process. The effect of incorporating Cu and Zn on the *in vitro* formation of calcium phosphate (CaP) layer during immersion in simulated body fluid (SBF) was evaluated by XRD and SEM techniques. The cytocompatibility (MTT cytotoxicity assay) was evaluated with osteoblast-like cells (SaOS-2). The Cu and Zn ion release was further measured in culture medium (DMEM/F12).

RESULTS AND DISCUSSION

NaBG glass crystallized from synthesis and showed apatite and Na₂SiO₄ phases. Cu²⁺ ions were present in the glass structure as CuO crystals while Zn²⁺ remained within the glass network. Cristobalite also was present in Cu and Zn doped glasses. Results from *in vitro* bioactivity showed that Cu allowed the formation of a CaP layer while Zn inhibited it. When Cu and Zn ions were together (1Cu1Zn-NaBG), CaP formation was observed. Figure 1 shows the glass surface of the soaked samples in SBF after 7 days. SEM images confirm the CaP formation (spherical particles) on NaBG, 1Cu-NaBG and 1Cu1Zn-NaBG, while on 1Zn-NaBG not was observed crystals of CaP.

Figure 1. SEM images of glasses after 7 days in SBF. A)NaBG, B)1Cu-NaBG, C)1Zn-NaBG and D)1Cu1Zn-NaBG.

Figure 2 (left-side) confirms that the doped bioactive glasses were able to release metal ions although the time evolution depends on the kind of metal.

Figure 2. (left side) Release of Cu²⁺ and Zn²⁺ ions in DMEM. (right side) MTT test of glasses with SaOS-2.

Figure 2 (Right-side) shows that NaBG glass was cytotoxic to the osteoblasts. However, Cu and/or Zn doped glasses were less cytotoxic than NaBG glass during the firsts 3 days. After 7 days Cu doped glass was more cytotoxic than Zn and Cu/Zn co-doped glasses because of the higher metal ion concentrations.

CONCLUSIONS

The presence of metal ions modified the microstructure and bioactivity of glasses. In particular, Cu allowed CaP crystallization while Zn inhibited the CaP formation on the bioactive glass. The cytotoxicity depended on the amount and kind of metal added to the glass.

A pH-responsive polymer-based drug-delivery platform demonstrating intracellular siRNA target-gene knockdown

D Roebuck^{1,2*} and R Chen¹

¹Department of Chemical Engineering, Imperial College London, UK

²MedImmune, Cambridge, UK, *droebuck13@imperial.ac.uk

INTRODUCTION

The successful delivery of siRNA therapeutics to the cell interior is often limited by their instability and poor cell penetration¹. These challenges prevent the effective use of siRNA in treating diseases, including cancers. PP-75, a novel, anionic and amphiphilic, pH-responsive polymer, demonstrates promise as an effective intracellular drug-delivery platform². Following endocytotic cell uptake, PP-75 undergoes a coil-to-globule conformational transition with the acidification of the endo-lysosomal pathway. This structural change facilitates endosomal membrane destabilisation, and subsequent delivery of payloads to the cell interior^{3,4}. Acidic tumour microenvironments can be similarly exploited by PP-75, enhancing the delivery of cancer therapeutics. Synthetic siRNA therapeutic payloads therefore present as ideal candidates for PP-75 intracellular delivery. The results presented here report the cellular applications of PP-75 for cytoplasmic siRNA delivery. Human breast cancer cell lines, MDA-MB-231 and SK-BR3, have been used to develop a model Dual-Luciferase[®] Reporter (DLRTM) cell system. Following intracellular siRNA delivery, the model system can distinguish between target-specific gene knockdown and non-specific cytotoxicity. Here we will demonstrate that PP-75 displays enhanced delivery efficiency and lower cytotoxicity, when compared against commercially available delivery systems.

EXPERIMENTAL METHODS

Model Reporter Cell System: Luciferase expressing reporter cells were developed by MedImmune (Cambridge, UK) following the stable transfection of wild-type MDA-MB-231 and SK-BR3 human breast cancer cell lines with firefly (Fluc) and Renilla (Rluc) luciferase gene constructs. Target gene inhibition was studied, discriminating between targeted knockdown (Fluc) and off-target cytotoxicity (Rluc). **Synthesis of PP-75 and PP-75-siRNA Conjugates:** PP-75 was synthesised according to the method of Chen *et al*⁵. Sulfhydryl cross-linkers were grafted onto PP-75 allowing conjugation with thiol containing siRNA payloads. **Cellular Uptake and Cytotoxicity of PP-75:** Confocal microscopy and flow cytometry were used to confirm cellular uptake of fluorescently labelled PP-75 (PP-75 FITC). The concentration dependent cytotoxicity of PP-75 was assessed by measuring viable, metabolically active, cells over 72 h via the CellTiter-Glo[®] Assay (Promega). **Intracellular siRNA Delivery and Target-Gene Knockdown:** MDA-MB-231 Fluc/Rluc and SK-BR3 Fluc/Rluc cells were treated with siRNA loaded delivery systems at various concentrations. Cells were harvested at 24 h intervals to assess relative levels of Fluc and Rluc. mRNA

knockdown was quantified using RT-qPCR, following extraction of total RNA. Protein knockdown was determined, measuring relative luminescence in the DLRTM assay (Promega). Results were plotted relative to control cells and compared to Lipofectamine[®], a cationic, liposomal delivery agent.

RESULTS AND DISCUSSION

The delivery of fluorescently labelled PP-75 to the cell interior was observed using confocal microscopy and confirmed by flow cytometry; FITC acting as a model delivery payload. PP-75 cytotoxicity was negligible in both MDA-MB-231 Fluc/Rluc and SK-BR3 Fluc/Rluc cell lines; viability remaining close to 100% following treatment with PP-75 up to 2.5 mg ml⁻¹ over 72 h, assessed using the CellTiter-Glo[®] viability assay. Fluc gene knockdown was observed in MDA-MB-231 Fluc/Rluc and SK-BR3 Fluc/Rluc breast cancer reporter cell lines following intracellular siRNA delivery. The results demonstrated concentration and time dependent intracellular knockdown, following treatment with 5-25 nM siRNA concentrations, over 72 h. RT-qPCR confirmed Fluc knockdown at the mRNA level relative to endogenous control genes (including Rluc) over 72 h and the DLRTM assay demonstrated parallel knockdown at the protein level, maintained with extended treatment times. Expression of endogenous mRNA and Rluc protein levels indicate high levels of Lipofectamine[®] associated cytotoxicity compared to untreated cells and siRNA only treated cells.

CONCLUSION

These results begin to validate PP-75 as an effective drug-delivery platform, promoting intracellular target-site delivery, of functional siRNA payloads.

INTRODUCTION

In the context of drug delivery, controlling the release of the drug in a specific target tissue becomes a crucial issue [1]-[2]. Numerous methods to deal and to optimize the delivery techniques were established by using diffusion model [3]. The Hydrogel matrix has dissipation properties inducing temperature change under cyclic load [4]. First this phenomenon may be used to optimize drug delivery device actioned by the temperature change, as in cartilage joint that is always under cyclic load [5]. Second temperature change may induce defect in the material and may influence the formation of transfer film and contact at the interface between biological tissues and implants [6]. Then, we need to develop a predictive model to qualify and to quantify the temperature effect in this material and to determine the maximum allowable temperature under various conditions. The mechanical loading is accompanied by a production of entropy and heat, which can influence the temperature and the behaviour of the material. Generally the behaviour is viscoelastic. Then, some part of the energy is converted into heat as dissipation, thus resulting into an irreversible temperature and entropy augmentation. The goal of this study is to investigate this evolution law by using models and numerical methods to analyse the response under a cyclic load.

EXPERIMENTAL METHODS

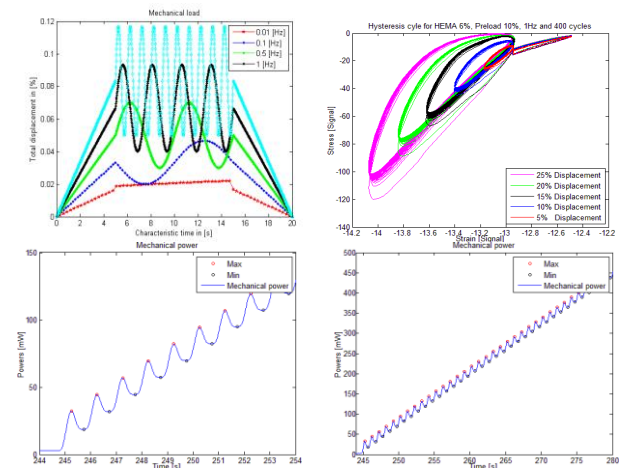

For measuring temperature change in sample under cyclic load, deformation micro-calorimetric test was used. It consists to apply in a cylindrical sample of hydrogel matrix (4 [mm] and 6 [mm] of HEMA-EGDMA hydrogels) a cyclic load. Experimentally, various frequencies are applied to observe the variations of entropy and temperature by using micro-calorimetric test. We assume that system is adiabatic.

MATHEMATICAL MODEL

Theoretical models include heat conduction, wave propagation, and constitutive laws of the hydrogels matrix. Transient analysis is investigated in the present study. A numerical approach based on finite element formulation is introduced to solve the problem. Numerous types of boundary conditions are treated. The model is designed to predict reversible and irreversible entropy and heat production. Numerical results vs. experimental measurements are presented in this work.

RESULTS AND DISCUSSION

Two cyclic mechanical loads were studied. For each test, we change the frequency of the load.

Figures report entropy production during cyclic loading: (a) 1st row: mechanical load vs. time (left); hysteresis curves of the material (right); (b) 2nd row: mechanical power (left); temperature change vs. time (right).

CONCLUSION

Theoretical model was successfully established in the present work to perform the thermomechanical behaviour of HEMA-EGDMA hydrogel. New constitutive equation was developed, by assuming an adiabatic system. Original numerical approach to solve the coupled partial differential equation by using finite element method has been developed. Reciprocal interaction between mechanical and thermal energy has been highlighted. This approach revealed detailed information to qualify and to characterize the entropy production under cyclic thermomechanical loads. It can be applied for biological tissues as tendon, ligament and cartilage. Results show that the heat effects to the dissipation energy are significant and may be exploited to control the drug delivery device driven by temperature change.

Using Bioactive Scaffolds to synthesise an *in vitro* 3D Bone Model for Implant Testing

G. Tetteh^{1,2}, I. U. Rehman¹, and G. C. Reilly^{1,2}

¹ Kroto Research Institute, University of Sheffield, Sheffield, UK S3 7HQ

² INSIGNEO Institute for in silico Medicine, University of Sheffield, Sheffield, UK S1 3JD,
gift.tetteh@sheffield.ac.uk

INTRODUCTION

Bone tissue engineering (TE) aims at improving musculoskeletal health, by providing a living bone graft substitute to fill and aid in the repair of bone defects caused by trauma, disease, or congenital malformations, or to augment bone stock around an implant site. Bone TE also has the potential to provide 3D experimental systems which can be used to test orthopaedic pharmaceuticals and materials.

Particulate leaching is an established fabrication technique which allows close control over pore size and interconnectivity, and has advantages for creating scaffolds for bone regeneration.

Our aim is to develop a tissue engineered bone construct that could be used for studying *in vitro* bone formation around implant materials. The scaffold therefore needs to have good mechanical strength and resilience with high porosity, low degradation rate and be osteoconductive.

EXPERIMENTAL METHODS

Polyurethane (PU) and Polyurethane-Hydroxyapatite (PU_HA) composite scaffolds were fabricated with the particulate leaching technique. 15%wt PU dissolved in 70/30 DMF/THF solvent was combined with NaCl particles (~250 µm) for PU scaffolds.

To create composite scaffolds, PU solutions were doped with either micro or nano-sized HA particles in a ratio of 3 PU: 1 HA. Micro-CT analysis and Scanning Electron Microscopy were used to analyse scaffold morphology, whilst FTIR and Raman spectroscopy were used for chemical and structural characterisation of the scaffolds.

Compression mechanical testing (Bose Electroforce-3200) was used to assess the mechanical properties of the fabricated scaffolds. Scaffolds were sterilised with an autoclave prior to cell culture and seeded with human Embryonic Mesenchymal Progenitor (hE-SMP's) cells. Assays for cell viability and matrix production were conducted over a 28 Day period.

RESULTS AND DISCUSSION

PU scaffolds had the highest pore size but the lowest Young's Modulus and yield strength. However, with an average pore size of $190 \pm 75 \mu\text{m}$, composites with nHA particles had the highest Young's Modulus and yield strength of $0.671 \pm 0.080 \text{ MPa}$ and $0.040 \pm 0.014 \text{ MPa}$, respectively.

Micro – CT analysis showed good pore interconnectivity in all scaffolds whilst FTIR and

Raman spectroscopy confirmed the presence of HA in all composite scaffolds before and after autoclaving. Alamar Blue cell viability assay showed that cells were viable on all scaffolds whilst Alazir red and Sirius red staining confirmed mineral deposition and collagenous extracellular matrix formation, respectively.

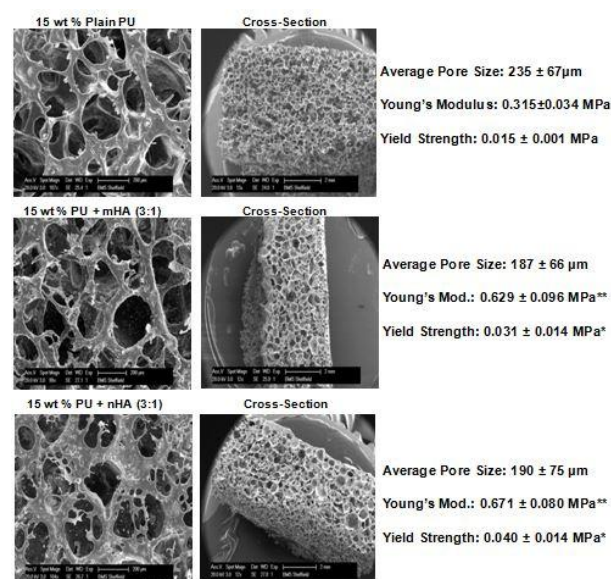

Figure 1: SEM images of particulate leached scaffolds; left: top view (scale bar=200µm) and right: cross-sectional view (scale bar=2mm) Text: Mean \pm standard deviation; (n=6) one way Anova **= $p < 0.001$ and *= $p < 0.05$

These particulate leached scaffolds composed of highly interconnected macro and micro porous network (>60% porosity) with pore sizes previously described as optimum for bone regeneration (>180µm)^[1,2], support bone matrix formation and have good mechanical properties in relation to their good porosity.

CONCLUSION

We therefore propose the use of these autoclavable scaffolds as a support for tissue engineered constructs, and for in-vitro studies of bone formation including testing of implant materials.

INTRODUCTION

Monomeric units in supramolecular polymers are held together via non-covalent interactions. Due to these reversible non-covalent interactions, supramolecular materials are dynamic in nature. The combination of order and dynamic behaviour makes supramolecular polymers promising materials for biomedical applications.

Urea groups are known to form strong bifurcated hydrogen bonds. Self-assembly of bisurea based bolaamphiphiles, UnU, led to formation of rod-like micelles in water (Figure 1).² Introduction of new functionalities to this supramolecular system can be readily done by mixing guest molecules with bisurea moieties, such as fluorophores. Self-sorting of bisurea based bolaamphiphiles has been studied by fluorescence spectroscopy using pyrene and dimethylaniline probes which form exciplex when in molecular contact with each other.^{2,3}

Inspired by the bisurea based bolaamphiphiles, we have designed segmented polymers with bisurea units in hydrophobic alkyl segments, and poly(ethylene glycol) (PEG) as hydrophilic segments (Figure 1). These bisurea-PEG polymers (PUnU) form hydrogels in aqueous environment.⁴

The bisurea supramolecular motif was also incorporated into biodegradable polycaprolactone (Figure 1).⁴ Supramolecular incorporation of bioactive guest molecules shows promising cell adhesion.⁵

Figure 1: Molecular structure of bisurea based bolaamphiphiles (top), fluorescent probe molecules (middle), Segmented PEG based bisurea polymer (PUnU), PCL-BU polymer (bottom).

The main goal of the current study is to use dynamic supramolecular interactions in a modular approach to bring together different properties of various bisurea based molecules. Prior to that, fundamental characterization of the system is required to understand potential use of our supramolecular materials as a scaffold for tissue engineering. Next, the biocompatibility of several bisurea-molecules were

investigated. At a later stage, molecules of different properties will be mixed to obtain a 'smart' biomaterial.

EXPERIMENTAL METHODS

Fluorescence spectroscopy was utilized to monitor dynamics and mechanism of the UnU exchange in an aqueous solution. Biocompatibility of UnUs was checked by resazurin assay.

RESULTS AND DISCUSSION

In figure 2, rate constants of exchange of UnUs were summarized from four different methods. These results show that the system is dynamic, and it takes approximately 20 min to reach equilibrium.

Figure 2: Rate constants of monomer exchange of U4U. Cell viability testing of different types of bisurea containing molecules showed no toxicity (Figure 3).

Figure 3: Cell viability tested by resazurin assay.

CONCLUSION

Bisurea based supramolecular systems were used to design a suitable platform to obtain smart biomaterials. Taking advantages of various molecules by just mixing is the key feature of our system.

INTRODUCTION

Biomaterialization is the process that gives rise to small and large inorganic-based structures in biological systems, and it often results in sophisticated materials having elaborate morphologies, excellent mechanical and vital biological functions. Thus, the convergence of the study of graphene with biomaterialization is expected to widen the horizons of material science. To date only few studies have analyzed the possibility to synthesize new and functional hybrid materials for tissue engineering combining Hydroxyapatite [$(\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$, HA] with carbon based materials such as graphene and its derivative, for example graphene oxide (GO). The presence of abundant epoxide, hydroxyl and carboxylic groups on the GO basal plane could provide enormous reactive sites for chemical interactions. Herein, we report a dual approach to prepare hydroxyapatite nanocrystals (HA)/graphene oxide (GO) in order to develop a new class of multi-functional biocomposite materials with excellent biological properties, and make them highly promising materials for biomedicine.

EXPERIMENTAL METHODS

HA/GO gel materials were prepared by a dual approach as sol-gel technology and biomimetic method. Sol-gel approach allows to obtain HA/GO hybrid materials in aqueous solution at room temperature where the gelation take place after 2hrs of magnetic stirring at room temperature. A second approach concerns the preparation of HA/GO biocomposite by a biomimetic method based on a simulated body fluid solution (SBF). The SBF having ion concentrations analogous to those of human extracellular fluid is often used for biomimetic process to precipitate hydroxyapatite. In order to accelerate the hydroxyapatite deposition, 5xSBF with ion concentrations 5 times those of SBF is also used. Physico-chemical characterization was carried out to evaluate the chemical interaction between two phases. The morphology of the biocomposites was characterized by using SEM and TEM microscopy. Furthermore, biological tests were performed to estimate the effect of biocomposites on cellular behavior by using human mesenchymal stem cells.

RESULTS AND DISCUSSION

Sol-gel technology allows to synthesize HA/GO hybrid materials at room temperature. Biomimetic mineralization was induced by incubating GO sheet in a supersaturated 5xSBF solution. The presence of anionic functional

groups in GO facilitates, in the first step of treatment, the nucleation of biomaterials by attracting more Ca^{2+} cations to deposit onto film surface and subsequently forming biomaterials with PO_4^{3-} . Moreover, TEM images demonstrated a hybridization of HA nanoparticles in GO sheet for materials obtained by sol-gel approach (Fig.1). In fact, spindle-like HA nanoparticles with a diameter of about 5 nm and a length around 70 nm, were intercalated uniformly and strongly with the GO sheets. The interaction between HA nanoparticles and GO improves the bioactivity of materials. In fact a layer of apatite on GO sheet was obtained after biomimetic treatment. Biological studies performed by using hMSC demonstrated that the presence of GO induces an osteogenic differentiation evaluated by using a media without osteogenic factors.

Fig. 1: TEM analysis of GO sheet (a), and HA/GO materials (b).

CONCLUSION

In this work, we have demonstrated that the combination of HA with GO leads to the further development of a broad new class of multi-functional biomaterials. *In vitro* bioactivity and biocompatibility results of biomaterialized graphene materials present the new prospect of utilizing graphene-based materials in clinical and biomedical applications. The combination of HA with GO leads to the further development of a broad new class of multi-functional biomaterials.

INTRODUCTION

Osteoporosis is a systemic disease "characterized by low bone mass and microarchitectural deterioration of bone tissue, leading to enhanced bone fragility and a consequent increase in fracture risk", which results from an impaired balance of bone resorption and formation by osteoclasts and osteoblasts, respectively. Various therapies have been developed for the clinical treatment of osteoporosis based on either the inhibition of bone resorption or the anabolic stimulation of bone formation. Strontium(II) ions have been demonstrated to both increase the bone formation by osteoblasts as well as to decrease the osteoclast-mediated resorption of the bone matrix. Here, we propose Strontium - modified CaP gels obtained at room temperature by using sol-gel method. In fact, sol-gel synthesis approach appears to be among the most suitable route towards performing injectable CPC. The effect of these modified gel materials on the proliferation and differentiation of mesenchymal stem cells have been studied in the light of the biomaterial compositional changes.

EXPERIMENTAL METHODS

Sr-HA gels containing 5 - 10 - 15 and 20 mol % Ca^{2+} replaced by Sr^{2+} were synthesized at room temperature by using calcium nitrate tetrahydrated $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ and di-ammonium hydrogen phosphate $(\text{NH}_4)_2\text{HPO}_4$ as precursors and using water as solvent. Strontium nitrate $\text{Sr}(\text{NO}_3)_2$ was dissolved in water and used to replace Ca^{2+} ions. The chemical composition of Sr-HA and the effect of strontium on viscosity properties have been evaluated by physico-chemical and rheological analysis. The morphology of the materials was characterized by using SEM and TEM microscopy. Furthermore, biological tests were performed to estimate the effect of strontium on cellular behavior by using human mesenchymal stem cells.

RESULTS AND DISCUSSION

A preliminary investigation showed a difference in the gelification time (from 1hr to 3hrs) of the biomaterials prepared at different Sr concentration. However, all gels synthesised at room temperature could be successfully equilibrated at pH 7.4 without any significant dissolution thus ensuring their compatibility with biological systems. From the TEM evaluation in Fig. 1, it is shown that the

HA particles show a length about 70-80nm and a diameter of 4-5nm. In 10 and 20mol% Sr-doped HA an agglomerate structure was observed; the particles were changed in size, in fact a length of 40 nm and diameter of 10nm were observed. An increasing in the amount of Sr ions doped into HA made the agglomerated particles smaller. The substitution of large Sr^{2+} into small Ca^{2+} lead to denser atomic packing of the system causing retardation of crystals growth. Biological results performed also by gene expression analysis show that HA-10Sr, HA-15Sr and HA-20Sr promote the expression of ALP; in contrast HA-10 and 20Sr promote the expression of OPN on lesser degree as compared with the expression of OPN promoted by HA-15Sr. Moreover, OCN expression was significantly enhanced on HA-15 and 20Sr meanwhile faint signal was detected on HA-10Sr.

Fig. 1: TEM analysis on HA gel and strontium-doped hydroxyapatite at 10 and 20 mol%.

CONCLUSION

In this study, strontium-substituted hydroxyapatite with different Sr content has been synthesized at room temperature by using a sol-gel approach. The strontium incorporated in the hydroxyapatite structure decrease slightly the size of HA nanoparticles as demonstrated by morphological analyses. Moreover, biological results demonstrated that strontium-doped hydroxyapatite gels up 20mol% show good biocompatibility without significative cytotoxic effect. This work confirms the ability of the hydroxyapatite modified Sr materials to induce hMSC differentiation towards the osteoblast-like phenotype

Development of Nerve Guide Scaffold with a Microstructured Intraluminal

Atefeh Mobasseri^{1,2}, Alessandro Faroni², Julie Gough¹, Giorgio Terenghi² and Adam Reid²

¹School of Materials, The University of Manchester, Manchester, UK

²Centre for Tissue Injury and Repair, The University of Manchester, Manchester, UK

Atefeh.mobasseri@manchester.ac.uk

INTRODUCTION

The management of peripheral nerve injuries is still a major clinical need. End-to-end neuroorrhaphy is only feasible when there is no nerve gap. Autologous nerve grafting is the current approach to repair the nerve injuries in presence of nerve loss. In order to minimise the complications associated with autografting, a bioengineered solution using a nerve guide scaffold has been sought. In the present study, we examined and evaluated a nerve guide scaffold with the micro-grooved inner surface made of a biodegradable polymer *in vivo*.

EXPERIMENTAL METHODS

Solvent casting of polymer solution (polycaprolactone (PCL)/ poly lactic acid (PLA) blend) on the patterned silicon substrate was used to make the ultra thin grooved films (1). The films were rolled around a cannula (gauge 16) and heat sealed to form a conduit with 1.6mm inner diameter and 12mm length. A rat sciatic nerve model with 10mm gap was used to assess the conduits *in vivo* for 3 and 16 weeks. The experimental groups were grooved conduit (C), differentiated adipose-derived stem cell (dASC)-primed conduit (C+C) and autografts (Ag) (n=5 each group/timepoint). Experimental outcomes analysed were axonal regeneration, myelination and end-organ re-innervation.

RESULTS AND DISCUSSION

At the time of harvesting, the conduits structure was maintained with no major deformation or degradation. Analysing the inner surface of conduit with SEM, it was shown that grooved structure was kept after 3 and 16 weeks of implantation, although several cracks were formed on the surface following 16 weeks experiment (Fig. 1). At 3 weeks nerve transection, the regenerated nerve bridged the gap in all experimental groups. At 16 weeks, the measured features of regenerating axons including axon size, myelination area and axonal density were comparable between C and Ag groups (Fig. 2). However, including dASCs inside the conduits did not improve the quality of nerve regeneration. Muscle atrophy measured by wet muscle weight ratio of injured/operated side was significantly lower in C+C group (44 ± 6.35) when comparing to C (63 ± 7.13) and Ag (58 ± 7.01). The skin re-innervation density at the footpad skin showed no significant difference across the groups.

Figure 1: SEM images of the grooved intraluminal structure of a conduit after A) 3 weeks and B) 16 weeks of implantation

A)

B)

Figure 2: A) Immunostaining images of regenerated nerves following 16 weeks of nerve transection at 3mm distally, B) Quantitative measurements of features of axonal regeneration

CONCLUSION

This investigation addressed the application of the biodegradable polymer conduits with the intraluminal structure to be used in peripheral nerve repair. The PCL/PLA conduit demonstrated a promising nerve regeneration length in 3 weeks study by bridging a 10mm gap. The features of axonal regeneration as well as end-organ re-innervation and muscle mass were similar to autograft group. The promising outcomes suggested the grooved PCL/PLA conduits could be a potential alternative to nerve grafting. Further experimental investigation needs to be conducted to develop the cell-primed conduits and improve their performance for peripheral nerve repair.

INTRODUCTION

Chronic obstructive pulmonary disease is the 4th leading cause of death worldwide. Extracorporeal lung assist devices that promotes oxygenation/decarboxylation of the patients' blood like the Novalung interventional lung assist device (iLA®) can improve lung protection and increase quality of life [1]. Those systems limit patients mobility. Due to that and to inappropriate material characteristics till nowadays there is no long term solution available. Therefore we aim to develop the first wearable miniaturized lung assist device [2].

EXPERIMENTAL METHODS

3D models and prototypes of new miniaturized hard- and software components as well as a suitable carrying system were developed. We designed a new gasexchange disposable with a optimized geometry to minimize blood damage and blood clotting events. Hemolysis tests were performed.

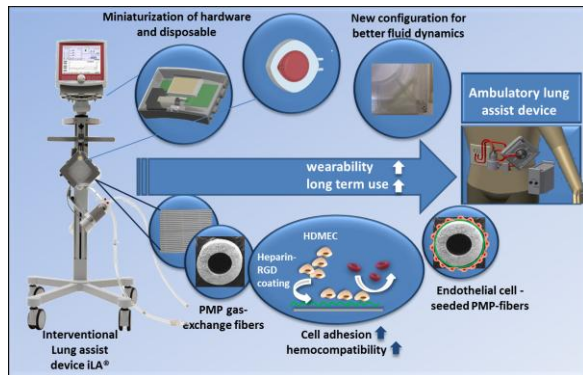

Fig1: necessary steps to transform the iLA to a longterm ambulatory lung assist device.

To improve the hemo- and biocompatibility of the gasexchange material Polymethylpentene (PMP), we managed to seed the fibers with human endothelial cells. Therefore a cell adhesion promoting biochemical surface with benzophenone modified heparin and suitable chemical side chains to perform both, peptide-coupling and covalent conjugation to PMP- membranes was developed. In order to provide cell adhesion sites RGD-peptides were coupled.

Human dermal endothelial cells (HDMEC) were seeded to the surface and analyzed with FDA/PI.

RESULTS AND DISCUSSION

We succeeded in miniaturization of all hardware components as well as in a new design of the gasexchanger to improve blood distribution (Fig.2a). Fig. 2b shows FDA stained vital endothelial cells after 48 h on the PMP fibers under static cell culture conditions condition (37°C, 5% CO₂).

Fig.2: a) lateral inflow and square shape design of the gasexchanger was successfully modified into a new central inflow with modified lid. B) HDMEC on PMP fibers stained with FDA/PI (vital cells are shown in green).

CONCLUSION

We developed the first miniaturized wearable lung assist device. In the future, cell seeding experiments will be performed under dynamic conditions in a bioreactor system. In a next step the whole device will be seeded with cells. Animal tests will be performed.

INTRODUCTION

Tissue engineering strategies rely on the use of cells, bioactive factors, and scaffolds or combinations thereof. The scaffold serves the purpose of a delivery vehicle, a space-filling and structurally supportive agent, and can be designed to be biointeractive, i.e. to guide tissue regeneration. The coordinated regeneration of multiple tissues in the complex osteocondral environment requires a deep understanding of their physiology and remodeling characteristics. Desirable osteochondral tissue engineering constructs are osteoconductive and osteoinductive. HA has excellent biocompatibility with hard tissues, and high osteoconductivity and bioactivity despite its low degradation rate and osteoinductive potential. Gelatin (GEL) is compositionally virtually identical to the collagen from which they are derived, and shows to be biocompatible and resorbable. A composite scaffold of HA and GEL is therefore expected to show increased osteoconductivity and biodegradation. In this context, chemically inspired approaches based on the sol-gel transition and colloidal precipitation of calcium phosphates may efficiently improve the particles dispersion by a direct control of precipitated grain sizes through the interaction between calcium and phosphate precursors under controlled temperature and pH conditions [1]. Proposed approach enables to efficiently exploit the peculiar features of composite material bulk and surfaces by modulating the spatial distribution of bioactive signals. The aim is create an HA gradient into the scaffold section, in order to modulate biological signals.

EXPERIMENTAL METHODS

The GEL-HA nanocomposite scaffolds were fabricated by sol-gel synthesis of HA within a gelatin sol and further freeze-drying. Two types of viscous sols, gelatin, type B (pH= 5) and gelatin type A (pH=4.5) solutions were prepared in distilled water at 40°C. The gelatin solutions were mixed progressively with calcium and phosphate solution and pH at alkaline values was adjusted to allow the sol-gel transition. The Ca/P ratio was fixed at 1.67 and the HA contents with respect to gelatin-HA were considered at 20 and 30 wt%. The gelatin amount respect the total water content is fixed at 10% w/v. The dried scaffolds were crosslinked for several hrs by using a specific amount of EDC as crosslinker agent. Chemico-physical characterization (XRD-FTIR), thermal (TGA) and morphological analyses (SEM-TEM) were performed to evaluate composition, chemical interaction among the phases and hydroxyapatite gradient into longitudinal section of scaffold. Furthermore, the effect of the organic and inorganic phases () on human mesenchymal stem cell (hMSC) was studied at 7, 14 and 21 days of

culture by evaluation both cell proliferation, osteogenic and chondrogenic differentiation.

RESULTS AND DISCUSSION

By sol-gel transition in gelatin solution combined with freeze-drying, is possible to obtain a tridimensional gelatin structure interconnected with hydroxyapatite crystals, internally and externally. As shown by SEM (figure 1A), and confirmed by TEM, the crystal shape and degree depend on HA/GEL ratio. The experimental data, reported by TGA analysis (figure 1B), confirm HA gradient in the sample with HA content of 30%w. Moreover, HA residual% calculate are very close to the original amounts of calcium phosphate used to prepare the scaffolds. As demonstrated by FTIR results, the Ca^{2+} ions will make a covalent bond with R-COO^- ions of GEL molecules.

Fig. 1: A) SEM image: cross-section of GEL/HA scaffold; B) TGA analysis of three different section of the same scaffold, and gelatin powder

Mechanical properties show crosslinking efficiency. In accordance with biological tests, material are nontoxic, not affecting the cell proliferation and support osteogenic and chondrogenic differentiation of hMSC.

CONCLUSION

This work demonstrated that, by an opportune GEL/HA ratio, is possible to create an HA gradient into the scaffold section, as confirmed by morphological, thermal and chemo-physical investigations. Thermal and mechanical analyses show that in GEL/HA scaffold, success of crosslinking by EDC depend on number of carboxyl group, content in polymer typology, and inorganic phase amount. Biological test performed by hMSC demonstrates that the materials have a good biocompatibility and support osteogenic/chondrogenic differentiation.

INTRODUCTION

The coordinated regeneration of multiple tissues in the complex bone environment requires a deep understanding of their physiology and remodeling characteristics. The extracellular matrix of bone has been described as a composite material constituted by collagen type I fibrils mineralized with nanocrystals of hydroxyapatite. Approximately 70% of bone by weight is composed of calcium salts, with hydroxyapatite $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ as the primary mineral constituent. Bone formation occurs in two phases: matrix synthesis followed by extracellular mineralization. Combining the literature with the target of mimic natural structure, we propose a strategy employs the use of a scaffolds (natural polymer such as gelatin) and a modulating bioactive factors (hydroxyapatite crystalline), where hydroxyapatite should improve the osteogenic differentiation meanwhile gelatin increases the chondrocyte proliferation. Here, we present three-dimensional (3D) porous gelatin scaffolds, firstly fabricated by freeze-drying followed by biomimetic method in order to obtain a superficial mineralization. Cross-linking treatments to produce the formation of molecular structures have been suggested to avoid a rapid gelatin degradation.

EXPERIMENTAL METHODS

Biomineralized gelatin scaffolds were obtained by a combination of two simple methods as freeze-drying and biomimetic approach. The contributes of gelatin type/amount (Type A and B at 5 and 10 % w/v) and crosslinking time (1, 3, and 6 hrs) were evaluated, in order to study crosslinking treatment, biomimetic approach and MG-63 cells response. Suitably choosing the time and freezing temperature, it is possible to obtain a 3D structure with interconnected pores. Accelerated Kokubo treatment is able to create an hydroxyapatite coating on the surface and into the porous wall. Swelling and degradation tests, chemico-physical (FTIR), thermal (DSC-TGA) analyses were performed to study the effect of the crosslinking time on the hydrogel materials properties. By compressive tests is evaluated the enormous EDC contribute: Young modulus increased from 0.179 KPa (non-crosslinked scaffold) to 180 and 150 KPa (without and with

biomineralized treatment). To evaluate the influence of material surface on the cellular behavior, it is compared biological study on crosslinked gelatin, before and after biomimetic treatment. For this purpose the adhesion, proliferation and differentiation studies using pre-osteoblast (MG-63 cell line) were done. Moreover, osteogenic and chondrogenic differentiation of hMSC in a basal medium was evaluated.

RESULTS AND DISCUSSION

Mineralized porous gelatin (A and B type) hydrogels were obtained by using a combined freeze-dried and biomimetic approach. The swelling and degradation tests show that the crosslinked samples maintains the original shape, and are able to reduce the water absorption since to 28 days. SEM images show a bi-dimensional microporosity and the regular deposition of hydroxyapatite into the hydrogel structure. Mechanical properties, FTIR-DSC-TGA analyses show the effectiveness of the crosslinking treatment and the difference between three crosslinking time (1, 3, 6 hrs). Cytotoxicity assay performed by using MG-63 cells demonstrated that the percentage of EDC cross-linker has not toxic effect on cell viability. Moreover, a promising viability of hMSC cells and increase of osteogenic proliferation and differentiation has been observed in gelatin scaffold crosslinked by EDC solution and biomineralized by modified Kokubo treatment.

CONCLUSIONS

Biomineralized gelatin scaffold was obtained by freeze-drying and biomimetic approach. Chemo-physical, thermal and mechanical analysis demonstrated the crosslinking efficiency by EDC and the compression modulus (E) improvement. Moreover HA crystalline phase is sufficient to obtain an increasing of osteogenic proliferation and differentiation.

Implantable biocomposite based radical oxygen species scavengers as a therapeutic strategy to manage age related macular degeneration

Marta O. Freitas¹, Ana S. Neto^{1,2}, B. Moreno³, E. Chinarro³, and Ana P. Pêgo^{1,2,4}

¹INEB – Instituto de Engenharia Biomédica, Universidade do Porto, Porto, Portugal, ²FEUP - Faculdade de Engenharia da Universidade do Porto, Porto, Portugal, ³Instituto de Cerámica y Vidrio, CSIC, Madrid, Spain, ⁴ICBAS – Instituto de Ciências Biomédicas Abel Salazar, Universidade do Porto, Porto, Portugal, mfreitas@ineb.up.pt

INTRODUCTION

Age related macular degeneration (AMD) is the leading cause of blindness in the elderly worldwide. Although AMD does not cause total blindness, there is a progressive loss of central vision attributable to degenerative and neovascular changes in the macula.¹ One of the key phenomena known to contribute to extra-cellular senescence is the shift in the reactive oxygen species (ROS) synthesis/degradation balance.²⁻⁴ The ultimate objective of this project is to develop a novel class of hybrid biomaterials based on TiO₂ with integrated bioactivity in terms of ROS scavenging. It is hypothesised that by modulating the ROS synthesis/degradation balance one counteract the processes, which contribute to systemic and tissue ageing of the eye and so the progression of AMD. Here we describe the effect of different TiO₂ powders in scavenging radical species generated chemically or biologically by means of inflammatory cells. Also, the non-toxic effect of these materials was assessed either with inflammatory cells or cells present in the blood-retinal barrier (BRB).

EXPERIMENTAL METHODS

TiO₂ nanopowders were synthesized by the precipitation route and then calcined in air at 200°C and 600°C for 12 hours. Mixtures of these powders were also prepared. Three commercially available powders with different ratios of anatase and rutile phases were obtained from Sigma-Aldrich. The ROS scavenging capacity of the different TiO₂ powders was addressed by generating chemically ROS using two methods: 1,1-diphenyl-2-picryl-hydrazyl (DPPH) and 3-morpholinonylhydronitrimine hydrochloride (SIN-1). A human monocytic cell line (THP-1) was cultured and further differentiated in macrophages. Non-activated and activated macrophages (lipopolysaccharide, LPS) were cultured in the presence of a range of concentrations of the different powders to address their scavenging capacity. RPE cells (ARPE-19 cell line) were cultured in the presence of different concentrations of the TiO₂ powders and the cell metabolic activity assessed (rezasurin assay).

RESULTS AND DISCUSSION

Characterization of the TiO₂ powders prepared showed higher agglomerate size for the 600°C calcined powder (0,5-50µm), comparing with the powders calcined at 200°C (0,2-30 µm). XRD patterns have shown that the powders have different crystal structure in relation to the calcination temperature and comparing with the commercial ones. In this study, we addressed the ROS scavenging capacity of different TiO₂ powders with chemical assays using artificial ROS. The results show that the 200°C and 600°C calcined TiO₂ powders promote the best reduction of ROS concentration. Next,

we assessed the bioactivity of these powders in the presence of macrophages. A viability assay showed that the powders have no toxic effect in macrophages at concentrations of 1mg/ml or below. Furthermore, at these concentrations TiO₂ powders do not promote macrophage activation. Also, we observed that, among the tested materials, the powder with the best scavenging capacity was the 600°C calcined TiO₂ powder, despite having the lowest specific surface, leading 30% reduction in the ROS detected inside macrophages when at 1 mg/ml (see Fig. 1).

Figure 1: ROS scavenging by different TiO₂ powders. Activated macrophages were incubated with a range of concentrations of different TiO₂ powders.

At present we are extending the work to RPE cells, components of the BRB. We performed a viability assay and observed that the powders have no toxic effect on RPE cells at concentrations of 0,1mg/ml or below. The effect of the powders is being assessed on RPE cells kept under oxidative stress conditions caused by the presence of ROS, induced by two different oxidants – tertbutylhydroperoxide (tBH) and 4-hydroxynonenal (HNE).

CONCLUSION

Taken together, these results suggest that the TiO₂ powders with the best ROS scavenging capacity are the 200°C and 600°C calcined powders, showing no toxic effect on cells at lower concentrations. The produced TiO₂ powders, being materials capable of ROS scavenging either of artificial ROS or ROS generated by inflammatory cells, present themselves as valuable tools in the design of new strategies for application in the treatment of AMD.

Soft Matrices vs. Hard Minerals: Biomimetic Morphogenesis of Calcium Phosphate in Lyotropic Liquid Crystals

Wenxiao He* and Martin Andersson

Department of Chemical and Biological Engineering, Chalmers University of Technology, Sweden

*wenxiao@chalmers.se

INTRODUCTION

Biomaterials are diversified in morphologies, the organic/inorganic organisation, etc. For example: bone, nacre, coccolith. The common feature is that: Biomaterialization occurs in viscous gel like matrix, which provide spatial delineation and diffusion limited conditions.

The organics: molecular self-assembly, collagen matrix, Liquid crystalline phases are of great interests, and relevance.

Organisms use “soft” organic compartments to control morphology of the embedded “hard” minerals. Here we present a simple method using liquid crystal (LC) phases as “soft” and “inert” templates to prepare nanostructured calcium phosphates (CaP), which are inorganics of known bioefficacy. Specifically, 6 nm-thick CaP nanowires and CaP sheets that precisely replicate a reverse hexagonal (H_2) and lamellar (L_a) LCs have been successfully synthesized and we attribute this to the sufficient spatial regulation offered by the negative (H_2) or flat curvature (L_a) of the aqueous domain. Normal hexagonal (H_1) phase possesses a positive curvature of the aqueous domain, therefore limited spatial restriction. For this reason, precise replication of H_1 phase by CaP has not been possible. Interestingly, the dynamic nature of the template allowed the construction of micron-sized brushite objects with a laminated structure decorating a specific facet, possibly as a result of epitaxial overgrowth of nano-sized brushite subunits.

Skeletal biomaterials possess distinctive morphological, compositional, crystallographic features and organizational order, and thereby exhibit superior material properties. An eminent example is the mineral phase in mammalian bone. Bone apatite nanoplatelets (a highly substituted polymorph of calcium phosphate, CaP) uniaxially align within collagen matrix, which provide mammals optimal protection, support and other specialized functions.¹ The synthesis of these biomaterials mostly proceeds within micro- to nanoscopic compartments, i.e. structural matrix assembled by insoluble biomacromolecules.¹⁻⁴ In addition to the spatial confinement, soluble components including ions and nonstructural biomacromolecules synergistically modulate the mineralization process.¹⁻⁴ To elucidate the geometric effects in tuning the morphology and polymorphism of biomaterials, herein, we report the “softly” confined morphogenesis of CaPs into well-aligned nanowires, nanosheets, ordered laminated structures in “inert” liquid crystal (LC) phases, as well as a site-specific-decoration strategy to construct CaP

superstructures with ordered nano-features. The precise control of CaP nanostructures by gentle spatial confinement and the possibility to add-on the structure onto pre-existed architectures offers new opportunities for rational design of nano-inorganics and hybrid materials for advanced applications including artificial bone, biocompatible sensing and nanophotonic devices.

Molecular self-assembly in nature is a key process for constructing a variety of hierarchical biological structures and materials. An elegant example is mammalian bone, where bone mineral (apatitic CaP) forms within the nanometric spaces in collagen matrix. The dimension of the compartments here regulates the size of grown mineral, while the intrinsic order in collagen matrix orients mineral along collagen fibrils, which ensure the optimal mechanical strength of bone.[1] To truly mimic bone, a well-organized organic matrix is a prerequisite. Polymer networks having LC structure are ideal for this purpose, since collagen matrix, in essence is polymerized LC.

Earlier we found that LCs are capable to provide spatial restriction of the growth of ACPs as c.a. 10 nm nanospheres are formed and stabilized in LC.

In this study, we would like to explore ... use a simple inert system-lyotropic liquid crystal phases to explore the role of organic matrices on constructing hierarchical CaP superstructures,...

EXPERIMENTAL METHODS

For synthesis using LC, $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$, 85% H_3PO_4 ($\text{Ca}/\text{P}=1.67$) were dissolved in Milli-Q H_2O . Then by mixing the salt solution with the surfactant (Pluronic L64 or F127) and oil (p-xylene or butanol), a reverse hexagonal (H_2) LC phase, a lamellar (L_a) phase and a normal hexagonal (H_1) LC were formed. The LC phases were placed in an ammonia atmosphere to start the reaction.

Development of titanium alloy-based scaffold by 3D printing for bone tissue engineering

Pavan Kumar Srivas,¹ Kausik Kapat,¹ Prabhsh Dadhich¹,

¹Indian Institute of Technology Kharagpur, Kharagpur, West Bengal, India
email: pavanks@smst.iitkgp.ernet.in

INTRODUCTION

Additive Rapid Prototyping technique is an advanced technique to develop 3D physical model by computer controlled sequential transfer of energy and/or material to identified points in space. This technique has been extensively studied to develop customized implants through manipulation of geometrical distribution, modification of mechanical properties and creating porous structures for tissue in-growth as well as better fixation. Amongst all other biomaterials, metals have great potential for long-term load-bearing applications due to its excellent resilience and mechanical strength. Titanium and its alloys exhibit better performance in this aspect.

EXPERIMENTAL METHODS

A 3D model was created in SolidWorks software that was used to develop the 3D physical model. Ti6Al4V loose powder (Good Fellow, U.K.) was mixed with 4 wt% chitosan solution in 2% acetic acid into a homogeneous dispersion suitable for printing. The slurry was printed to a 3D scaffold by a 3D printer machine and finally sintered at 1450°C in inert atmosphere.

RESULTS AND DISCUSSION

The scaffolds showed good compressive strength which is close to natural bone. It also showed promising results in *in vitro* study for 3 days, 5 days and 7 days and bio-compatibility *in vivo*.

CONCLUSION

The scaffolds showed good compressive strength which is close to natural bone. It also showed promising results in *in vitro* study for 3 days, 5 days and 7 days and bio-compatibility *in vivo*.

INTRODUCTION

Temperature-responsive cell culture surface (TRCS) has been used for fabrication of cell sheets from various tissues and organs. Conventionally, EB irradiation method has been used for the preparation of TRCS, grafting nano-scaled PIPAAm gel in tissue culture polystyrene (TCPS) (PIPAAm-TCPS). It was reported that the temperature-induced cell attachment and detachment character of PIPAAm-TCPS depended on the graft polymeric gel thickness. In the case of the fabrication of bovine carotid artery endothelial cell sheets (BAECs), 20-nm thickness PIPAAm layer was optimal to express the character.¹ In contrast, cell adhesion character depends on the cell species to be cultured. The graft polymer thickness was modulated, depending on the target cell species for the fabrication of their cell sheets. Based on the concept that graft PIPAAm thickness would be modulated by stretching the basal substrate, we developed PIPAAm-grafted PDMS (PIPAAm-PDMS) surfaces as a new TRCS and characterized the PIPAAm-PDMS surfaces at stretched and shrunk states. As a result, it was found that PIPAAm-PDMS at a stretched state showed more hydrophobic property than that at a shrunk state.²

In this presentation, based on the concept that the mechanical-stretching affects the cell detachment character as well as the surface properties, we applied the PIPAAm-PDMS surface to rapid cell sheet recovery by using the mechanical-stretching method. After culturing BAEC to reach confluent on stretched PIPAAm-PDMS surfaces, cell detachment behaviors from shrunk and stretched PIPAAm-PDMS were investigated at 20°C. For comparison, cell detachment behavior from shrunk PIPAAm-PDMS at 37°C was also investigated for comparison.

EXPERIMENTAL METHODS

PIPAAm-PDMS was prepared according to a previous report.² In brief, IPAAm monomer dissolved in 2-propanol (10 wt% - 50 wt% monomer in 2-propanol) was spread onto PDMS surfaces (4-well PDMS chamber purchased from STREX, Inc.) followed by O₂ plasma and (3-aminopropyl)trimethoxysilane (APTMS) treatments. And then, the surface was subjected to EB irradiation treatment to graft PIPAAm on the PDMS surface. PIPAAm-PDMS was characterized by FT-IR / ATR, XPS analysis, contact angle measurement and cell detachment / attachment assay. For the evaluation of rapid cell sheet recovery from PIPAAm-PDMS, PIPAAm-PDMS with 14.1 µg/cm² of PIPAAm graft density was used.

RESULTS AND DISCUSSION

PIPAAm-PDMS surfaces were characterized by various method. Through the characterization, PIPAAm was successfully grafted onto PDMS surfaces. In addition, contact angle measurement of shrunk and

stretched PIPAAm-PDMS surfaces revealed that shrunk PIPAAm-PDMS surface was more hydrophilic, probably because the graft polymer density increased and the PIPAAm-PDMS become more hydrophilic by shrinking the PIPAAm-PDMS.

BAECs were seeded and cultured on the stretched PIPAAm-PDMS surface. BAECs were adhered and proliferated to reach confluency at 37°C in 4 days. After confluency, cell sheets detachment behaviors were evaluated by using three different approaches as shown in Fig. 1 (a)-(c). Time required for complete cell detachment from stretched PIPAAm-PDMS surface was 126 min by decreasing temperature at 20°C (Fig. 1 (a)). Stretched PIPAAm-PDMS surfaces showed characteristic of TRCS. By shrinking PIPAAm-PDMS to an upstretched state after the confluency, cell sheets were not recovered (Fig. 1 (b)). In contrast, cell sheets were more quickly recovered by decreasing temperature to 20°C followed by shrinking PIPAAm-PDMS to an unstretched state (Fig. 1 (c)). These results suggested that the mechanical-stimuli increased the PIPAAm graft density as well as the surface hydrophilic property, resulting in the rapid cell sheets recovery.

Fig. 1. Cell sheets detachment behaviors from the stretched PIPAAm-PDMS surfaces (20% stretching). Times required for the complete cell sheets recovery from the surface were shown in the photographs.

CONCLUSION

By applying mechanical-stress to PIPAAm-PDMS surface, the surface property as well as cell attachment and detachment behavior on the surface are modulated. The PIPAAm-PDMS was expected to be a new type of TRCS, which possessed a stretchable property.

INTRODUCTION

Since ever scientists and engineers have been looking into Nature as inspiration for the development of new materials, architectures, design, functions, devices, etc. Marine environment in particular has been the source of a myriad of natural products with diverse chemistries and biological activities, which are being explored as pharmaceuticals, including some examples on the market. Besides, several marine biopolymers have been produced and are used in fields from food and biotechnology to cosmetics, pharma and medicine. In the latter case, marine biopolymers can be found as wound dressings, membranes, drug delivery devices and biomaterials¹. In this presentation, the authors will address the advances that are being made in our research group concerning the development of marine inspired biomaterials towards tissue regeneration, from biopolymer extraction and processing, to biomaterials development and applicability assessment, including nature-made scaffolds.

EXPERIMENTAL METHODS

Biopolymer extraction

Collagen has been extracted from fish skins with acid aqueous solutions, complemented by enzymatic treatment by using pepsin. In parallel, it has been also extracted from marine sponges with acid or basic aqueous solutions, including with chaotropic agents.

Chitin has been extracted from squid pens by NaHO treatment and further converted into chitosan with concentrated NaHO solution.

Sulfated polysaccharides have been extracted from algae with hot water and precipitated with organic solvents. Additional steps can be added for matters of purity improvement.

Development of biomaterials

Solutions of the extracted biopolymers with different concentrations (1 to 4%) have been prepared and further used to produce porous structures. Different processing techniques have been used, in particular, freeze-drying (chitosan and collagen), agglomeration of previously prepared particles (chitosan and composites with nanohydroxyapatite, coagulated in NaHO solutions) and rapid prototyping (carrageenans, following ionic gelation) and will be presented. Crosslinking with different chemical agents, namely genipin (chitosan and collagen), EDC/NHS (collagen) and HDMI (collagen), has also been explored to tune mechanical stability of the developed constructs. Their morphological properties were assessed by SEM and micro-computed tomography (μ CT) and mechanical properties evaluated by compression tests.

Moreover, natural collagenous structures were produced from marine sponges after supercritical fluid processing to both decellularize and extract toxic compounds from the samples.

Applicability assessment

Biological performance of the developed constructs has been tested with chondrocyte-like cell line ATDC5 (chitosan and collagen scaffolds), osteoblast-like cell line SaOS2 (collagen structures) or adipose derived stem cells, ASCs (chitosan scaffolds).

RESULTS AND DISCUSSION

Marine collagen has been crosslinked with genipin for the production of hydrogels. Alternatively, freeze-drying of collagen solutions rendered membranes, which were successfully crosslinked with EDC/NHS. Crosslinking of freeze-dried collagen structures was also achieved with genipin, under dense CO₂, which supported the culture of ATDC5 cells.

The porous structure of marine sponges and its collagenous composition has inspired the development of nature made scaffolds by decellularization and removal of toxic compounds, in which osteoblast-like cells have been successfully cultured.

Carrageenan-based scaffolds were produced by 3D plotting and ionic gelation with K⁺ solutions, revealing to be non cytotoxic to a fibroblast cell line.

Chitosan scaffolds were produced by freeze-drying, with different pore sizes. ATDC5 cells adhered and proliferated to the interior of the scaffold when squid chitosan was used. Porous scaffolds made by agglomeration of squid chitosan particles or composites with nanohydroxyapatite supported the culture of ASCs for up to 7 days.

CONCLUSION

Several polymeric constructs have been produced with marine origin polymers and assessed as 3D support for culture of different cell types. The development of marine inspired biomaterials is being taken to the next level, envisaging the promotion of their use on tissue regeneration therapeutic approaches.

Development and Characterization of Lithium-Releasing Silicate Bioactive Glasses for Bone Repair

Valentina Miguez-Pacheco¹, A. Malchere², J. Chevalier² and Aldo Boccaccini¹

INTRODUCTION

Bioactive glasses (BGs) are biocompatible materials developed to aid bone repair and regeneration, which are based on amorphous silicate compositions [1]. 45S5 Bioglass® is a well-known BG formulation that has been demonstrated to be bioactive and osteoconductive and is already in clinical use [2], [3]. In the search for improving the biochemical properties of Bioglass® for bone tissue engineering applications, different metallic ions are being incorporated into the glass compositions to stimulate healthy bone formation [4]. In this study, different amounts of Li₂O were substituted for Na₂O in the original Bioglass® formulation to obtain lithium-containing bioactive glasses (Li-BGs) at 2.5, 5 and 10 wt% Li₂O. Lithium (Li) was chosen because it has been reported to increase bone mineral density and enhance osteogenic gene expression [5], [6].

EXPERIMENTAL METHODS

High purity SiO₂, CaCO₃, CaPO₄, NaCO₃ and LiCO₃ powders were weighed and mixed. The homogenized powders were melted in Pt crucibles at 1400 °C for 1 hour. The melt was then quenched rapidly in water and then milled into fine powders. 45S5 Bioglass® powder was used to as a base material to compare the properties of the Li-BGs.

The sintering behaviour of the Li-BGs was investigated by heating glass samples at a constant rate. It was monitored by environmental scanning electron microscopy (E-SEM) to observe the morphological changes in the glass particles as a function of temperature. The bioactivity of the Li-BGs was investigated by immersing sintered pellets in SBF for up to 30 days and examining the deposition of hydroxyapatite (HA) on their surface.

X-Ray diffraction (XRD) was carried out in powdered samples at characteristic temperatures to examine the crystallization behavior of the Li-BGs. Fourier-transform infrared (FTIR) spectroscopy was performed on samples treated in SBF to confirm the formation of HA. Scanning electron microscopy (SEM) images of the samples treated with SBF were obtained to investigate the deposition of HA on the surface of the samples.

RESULTS AND DISCUSSION

In the E-SEM images, changes in morphology of the BG granules were evident as temperature increased. A softening of the granule edges and viscous flow of the glass was achieved, leading to fusion of particles in close proximity (Fig. 1).

Fig. 1: Morphological changes of 10% Li-BG particles during sintering observed by E-SEM

The XRD spectra for the unsintered Li-BG samples exhibited broad peaks, thus confirming the amorphous nature of the materials. After sintering, the diffraction patterns of the samples showed that there was partial crystallization, as expected. Characteristic peaks for the formation of HA were observed in the FTIR spectra of samples soaked in SBF solution, and SEM micrographs showed that there was formation of HA crystals on the surface of the Li-containing samples.

CONCLUSION

From these experiments it can be speculated that the addition of Li to the glasses causes a decrease in their glass transition, as evidenced by the softening of the BG particles at lower temperatures and an earlier densification with an increasing proportion of Li in the glass increases. Furthermore, the addition of Li did not impair the bioactivity of the Li-BGs as evidenced by the deposition of a layer of HA on the surface of samples immersed in SBF, however further studies are necessary to fully ascertain the effect of Li ions on the bioactivity of Li-BGs and to monitor Li release kinetics in suitable media.

berengere.luthringer@hzg.de

INTRODUCTION

Even if already investigated during the first half of the last century, the interest of using magnesium-based implant material declined until recently. The unique properties of Mg and its alloys to combine metal related mechanical properties, biocompatibility, and biodegradability (up-to now restricted mainly to polymers and calcium-phosphates) justify this renewal of attention¹. Magnesium-based implants have been shown to influence the surrounding bone structure². In an attempt to partially reveal the cellular mechanisms involved in the remodelling of magnesium-based implants, the influence of increased extracellular magnesium content on human osteoclasts was studied.

EXPERIMENTAL METHODS

Peripheral blood mononuclear cells were driven towards an osteoclastogenesis pathway *via* stimulation with receptor activator of nuclear factor kappa-B ligand (RANKL) and macrophage colony-stimulating factor (M-CSF) for 28 days. Concomitantly, the cultures were exposed to variable magnesium concentrations (from either magnesium chloride or magnesium extracts). Osteoclast proliferation and differentiation were evaluated based on cell metabolic activity, total protein content, tartrate-resistant acid phosphatase activity, cathepsin K and calcitonin receptor immunocytochemistry, and cellular ability to form resorption pits.

RESULTS AND DISCUSSION

While magnesium chloride first enhanced and then opposed cell proliferation and differentiation in a concentration dependent manner (peaking between 10 and 15 mM magnesium chloride), magnesium extracts (with lower magnesium contents) appeared to decrease cell metabolic activity (50% decrease at day 28) while increasing osteoclast activity at a lower concentration (twofold higher).

Fig. 1. TRAP staining at day 28: (A) MgCl₂ and (B) Mg extract assays. (1–3) Micrographs of TRAP staining for dentine (A: 0, 15 and 25 mM, respectively; B: 0 mM, 30x and 5x, respectively; scale bar 100 µm). (4) The number of TRAP-positive cells recorded for the 0 mM treatment was set as the control (100%), to which the numbers of TRAP-positive cells under the other concentrations (A) or dilutions (B) were normalised. (5) The respective statistical analyses are presented in multiple comparison graphs.

CONCLUSION

Together, the results indicated that (i) variations in the *in vitro* extracellular magnesium concentration affect osteoclast metabolism and (ii) magnesium extracts should be used preferentially *in vitro* to more closely mimic the *in vivo* environment.

Fabrication of bilayer nano/microfibrous scaffold for skin tissue engineering

Pallabi Pal ,Pavan Kumar Srivas, Prabhash Dadhich, Bodhisatwa Das, Santanu Dhara

School of Medical Science & Technology, Indian Institute of Technology Kharagpur, West Bengal, 721301, India,
pallabipal@smst.iitkgp.ernet.in

INTRODUCTION

Layered architecture of human skin with epidermis and dermis is separated as compartments by specialized extracellular matrix, basement membrane, with nano/micro fibrillar arrangement allowing formation of a highly interconnected porous network with adequate structural resilience essential for cellular function. For successful development of skin graft, it is important to reciprocate the nano/microscalar architecture of tissue matrix as well as its biological cell recognition character. Biodegradable and biocompatible polymer, polycaprolactone has been fabricated into 3D printed scaffold onto which electrospun chitosan nanofibers were attached. Collagen molecules were further attached to increase its hydrophilicity, biodegradability and cell recognition cues finally giving rise to a nano/microscalar structure in an attempt to mimic extracellular matrix.

EXPERIMENTAL METHODS

PCL in glacial acetic acid was used for fabricating 3-D printed scaffold. Chitosan in acetic acid and PCL in chloroform/methanol were used for electrospinning while the collagenous layer was freeze dried on the 3-D printed layer. The microstructures of samples were evaluated by scanning electron microscopy (SEM). FTIR spectroscopy, porosity percentage, mechanical properties, rheological properties, contact angle, swelling behavior, biodegradation kinetics of matrices was studied for their suitability as tissue engineering scaffold. MTT assay, Rhodamine-DAPI staining, live/dead assay, SEM analysis were carried out to evaluate matrix cytocompatibility, cell attachment and proliferation using keratinocytes and fibroblasts cells.

RESULTS AND DISCUSSION

SEM results showed 3-D printed PCL layer attached to the nanofiber layer. The matrices showed moderate swelling of upto 60% , slower degradation rate, high mechanical strength and contact angle of nanofiber is 90° $p < 0.05$. FTIR data of PCL and chitosan blends showed characteristic peaks of both PCL and chitosan. SEM results showed good cell attachment on 3-D printed PCL layer as well as on nanofiber layer. MTT assay Rhodamine-DAPI staining, live/dead assay indicated cytocompatibility of the scaffold

CONCLUSION

Incorporation of chitosan and collagen increased hydrophilic as well as well degradation rate of the scaffold. Results using primary keratinocyte and fibroblast showed, non-toxic and cytocompatible nature of the matrix. Material characterization yielded definite results proving the scaffolds potential for tissue engineering application.

Chemical Guiding of Magnetic Nanoparticles in Dispersed Media Containing Poly(methylmethacrylate-co-vinylpyrrolidone)

Myriam G. Tardajos^{1,3}, Inmaculada Aranaz³, Carlos Elvira³, Helmut Reinecke³, Erhan Piskin², Alberto Gallardo^{3*}

¹Polymer Chemistry and Biomaterials Group, Ghent University, Belgium

²Department of Chemical Engineering, Hacettepe University, Turkey

^{3*}Institute of Polymer Science and Technology, Consejo Superior de Investigaciones Científicas, Spain,
miriam.gomezardajos@ugent.be

INTRODUCTION

The conventional free radical copolymerization of methyl methacrylate (MMA) and N-vinylpyrrolidone (VP) in methanol under stirring yields, at high conversion, a high compositional heterogeneity which displays unusual phase separation behavior; the dispersed phase is rich in copolymers with a high content of hydrophobic MMA while the continuous phase is rich in copolymers with a high content of hydrophilic VP.¹ The hypothesis of this work is that the dispersed and the continuous phase of the parent emulsion may be functionalized quite selectively just by adding a third methacrylic or vinyl comonomer to the copolymerization. This differentiated functionalization may be translated to the different components of the solid microspheres in water (partial functionalization of VP or MMA may respectively imply a functionalization of the surface or core).

In this work, this has been tested by incorporating methacrylic comonomers bearing sulfonate and carboxylic acid, and a sulfonate VP derivative. The selective functionalization has been shown by adding and guiding magnetic nanoparticles (mNPs).

EXPERIMENTAL METHODS

Copolymerizations were carried out in methanol at 60°C for 48 h using AIBN as the initiator.

The details of production and characterization of the (Fe₃O₄) mNPs were given elsewhere.²

Emulsion droplets were hardened under stirring in a shaker by slowly dropping water into the emulsion giving rise to the formation of solid particles.

RESULTS AND DISCUSSION

Interactions of several dispersed systems based on poly(MMA-co-VP) copolymers with mNPs stabilized with tetramethylammonium hydroxide have been studied. The mNPs have a cationic surface that may interact with complementary anionic groups such as sulfonate units. Therefore, the influence of the incorporation of a very small amount (0.5% molar fraction) of the sulfonate functionality by using sodium sulfopropyl methacrylate (Met-Sulf) and sulfopropyl-vinylpyrrolidone³ (VP-Sulf) has been studied. Methacrylic acid (Met-Carb) was also studied for comparison reasons.

When mNPs are incorporated into the control emulsion, they are located, partially agglomerated, in the continuous phase. If the sulfonate functionality is introduced via the VP derivative (VP-Sulf), the mNPs are located preferentially in both the interface and in the continuous medium. Also, the location of mNPs at the

interface indicates that the VP-rich chains are effectively interacting and stabilizing the MMA-rich droplets. The use of Met-Sulf causes all of the mNPs to be located in the inside of the dispersed phase while the use of Met-Carb gives rise to a very peculiar result: most of the mNPs were located at the interface. These results confirm the initial hypothesis: both phases can be functionalized selectively.

Figure 1: Scheme of the location of the functionality in the emulsions and optical images showing the location of the mNPs in each type of emulsion.

The emulsions can be easily hardened by adding water dropwise at room temperature rendering solid microspheres. EDAX measurements proved that the selectivity moves to the microspheres incorporating the mNPs either at the surface or in the core.

CONCLUSION

Methanolic emulsified systems containing heterogeneous poly(MMA-co-VP) can be selectively functionalized in a simple one pot procedure by using small amounts of homologous functionalized monomers. This selectivity has been confirmed by monitoring the location of mNPs with cationic surfaces. This allows preparing composite microspheres selectively locating the mNPs for different purposes. Particles covered with magnetic materials may be of interest as active beads in different fields. Also mNPs have been proposed as nanoheaters so their encapsulation in polymer beads may be used in medicine to combine this hyperthermia effect with other complementary purposes in the drug delivery field.⁴ Tardajos, M. Influence of Surface Roughness Parameters on MG63 Cell Viability: Studies on Laser Microtextured Ti6Al4V Surfaces

Sumanta Mukherjee^{1*}, Partha Saha¹, Santanu Dhara²

^{1*}Mechanical Engineering Department, Indian Institute of Technology Kharagpur, India

²School of Medical Science and Technology, Indian Institute of Technology Kharagpur, India, talk2sumanta@gmail.com

INTRODUCTION

Surface roughness has long been considered an important aspect of orthopaedic implants. Researchers have suggested that in some average roughness ranges, the surface shows improved biocompatibility both in-vitro and in-vivo. But, the average roughness does not reveal the exact nature of roughness on the surface. Moreover, the mechanism through which the surface roughness can influence the cell behaviour is yet to be fully understood.

In this study, attempt has been made to correlate the surface roughness parameters with cell viability on the surface. For this, laser microtexturing has been performed on Ti6Al4V surfaces, and the viability of human osteoblast-like MG63 cells has been studied on them.

EXPERIMENTAL METHODS

Using a 2 kw Ytterbium fibre laser, grooves of depth ~20 µm and width ~200 µm were created on Ti6Al4V samples by operating the laser with different power, scan speed, duty cycle and frequency settings. MG63 cells were cultured on three types of surfaces that were similar in terms of average roughness but different in terms of other roughness parameters. The parameters that were used to create the three types of samples are presented in Table 1. The experimental details have been reported elsewhere [1].

Sample ID	Laser Power (w)	Scan Speed (mm/min)	Duty cycle (%)	Frequency (%)
2381	200	3,000	80	100
3561	300	5,000	60	100
2366	200	3,000	60	60

Table 1

The cell counts after 3 and 5 days of culture were estimated from MTT assay. The average spread area and the fractal dimension of the cells were calculated using ImageJ software by taking fluorescence micrographs of Rhodamine/Dapi stained cells. Anselme et al [2] earlier proposed a detachment index and a proliferation index to draw relationship between the 2d surface roughness parameters and cell behaviours. In this study, we used their model, and after fitting the curve, the residual values for different 3d surface roughness parameters were compared.

RESULTS AND DISCUSSION

Anselme's work suggested that new surface roughness parameters may be required to reveal the relationship between surface features and cell behaviour. But, according to our findings, 3d surface parameters like

surface kurtosis and surface skewness are strongly correlated with the cell viability on the surface.

The cell spread, i.e., average surface area of the cells was also found to be higher on the surface that had higher surface kurtosis value.

Fig. 1: Standard deviation of residual values for the different surface parameters, after fitting the cell count to the Anselme's equation. The lower the standard deviation of the residuals, the higher the correlation with cell viability.

CONCLUSION

Surface kurtosis is the measure of sharpness of the peaks present on the surface. Higher value of kurtosis means sharper peaks. The surface of Ti6Al4V is negatively charged in an aqueous environment because of the presence of TiOH⁻ ions. On a surface with sharp peaks, the charge density on the peaks is high. The positive ends of the quadrupolar protein molecules get clustered around those sharp peaks. The MG63 cells also have negative charges on their surface. As a result, the cells get attached to those preferred adherence points. This may be the reason for higher cell attachment and cell spread on the surface with higher kurtosis value.

Extended Release Drug Layer for POSS-PCU Cardiac Stents

Megan Livingston¹ and Alexander Seifalian¹

¹Division of Surgical and Interventional Sciences, University College London, United Kingdom;
megan.livingston.13@ucl.ac.uk

INTRODUCTION

Coronary Artery Disease (CAD) is the most common type of heart disease and is the leading cause of death for both men and women in the United States¹. Coronary angioplasty is used to treat CAD by expanding a cardiac stent at the site of the vascular occlusion in order to restore blood flow. The most common types of stents used are Bare Metal Stents (BMS) and Drug Eluting Stents (DES) but each of these come with long-term health risks like restenosis and late stent thrombosis due to the stents inability to keep the vessel wall clear.

DES incorporate a drug release system, most commonly utilizing an anti-proliferative drug such as paclitaxel or sirolimus. It has been suggested that rates of success with DES could be increased if the drug release occurred over a much longer time than observed with currently approved DES². The research presented here works to create an extended release drug layer for POSS-PCU coated cardiac stents by utilizing organic-inorganic hybrid liposomes, called cerasomes, loaded with paclitaxel, developed by Katagiri, et al³.

EXPERIMENTAL METHODS

Cerasome-Forming Lipid Synthesis

Synthesis protocol to create cerasome-forming lipids was adapted from the work published by Katagiri, et al³.

Drug Release Profile

Paclitaxel-loaded cerasomes (PTX-CS) were formed using protocol published by Cao, et al⁴. Release profiles were established over 8 weeks in both a PBS (pH ~ 7.4) with tween 80 solution and serum. PTX-CS were held in dialysis tubing spinning in the release medium. At each time point, samples from the release medium were analysed with UV/Visible Spectroscopy in order to measure paclitaxel concentration.

Smooth Muscle Cell Proliferation

PTX-CS attached to a POSS-PCU polymer sample was incubated *in vitro* with human vascular smooth muscle cells (hVSMCs) for 4 weeks in order to determine the long-term anti-proliferative ability of the drug layer. Proliferation of hVSMCs was determined with a total DNA assay at each time point. Controls included a polymer control (only POSS-PCU) and non-loaded cerasomes bound to POSS-PCU.

RESULTS AND DISCUSSION

Illustration of the PTX-CS fabrication with drug loading can be seen in Figure 1. The surface of the lipid bilayer of the cerasomes incorporates silicon oxide groups which degrade slower than organic groups, allowing for extended drug release.

Figure 1: Paclitaxel-loaded cerasome fabrication⁴

Release profiles and cell studies have not yet been performed but will be collected prior to and presented at the conference.

CONCLUSION

The extended drug release layer for POSS-PCU cardiac stents composed of paclitaxel-loaded cerasomes presents significant potential for cardiac technologies because of the variability available. Cerasomes can be loaded with any drug, whether hydrophilic or hydrophobic, and functionalised for attachment to any amine-expressing polymer surface. The results should support the potential for this application of extended release technology.

Practical Application of Whole Slide Imaging in Biomaterial Science

C. Brochhausen¹, H. B. Winther¹ and C. J. Kirkpatrick¹

¹REPAIR-lab, Institute of Pathology, University Medical Centre, Mainz, brochhausen@pathologie.klinik.uni-mainz.de

INTRODUCTION

Whole slide imaging (WSI), also known as virtual microscopy, has gained relevance in teaching, routine diagnostic activity and scientific research. We created a new WSI application called Pate (<http://pate.um-mainz.de>). This application was originally developed with an emphasis on student teaching for histopathological courses.

Many WSI applications are based on proprietary technologies, such as Adobe Flash and Microsoft Silverlight. These technologies require the installation of a specialized browser plug-in.

EXPERIMENTAL METHODS

We created a client application based on modern internet technologies, such as the Hypertext Markup Language 5 (HTML5), Cascading Style Sheets (CSS) and JavaScript. The server is powered by Python, utilizing the TurboGears 2 framework. The Apache 2 is employed as application server. So far, two glass-slides with tissue-biomaterial-interactions have been digitized and uploaded to Pate.

RESULTS AND DISCUSSION

Although initially an emphasis was placed on medical-student teaching, the tools implemented are also highly instructive for students in the field of biomaterials. The tools for training histomorphological skills enable an effective illustration of complex tissue reactions in the

context of biomaterial applications *in vivo*. Furthermore, Pate is suited for displaying any kind of high resolution images, thus offering the potential for various applications such as evaluation of new vessel formation. We published the slides “[Full thickness cartilage defect](#)” and “[Punch-Biopsy Skin-wound](#)” to demonstrate the potential benefits of WSI applications in biomaterial research. These slides are enriched using non-destructive annotations as well as points of interest. Each slide in Pate can be shared by distributing the Uniform Resource Locator (URL). This allows easy sharing of large images as soon as the slides are digitized. Utilizing modern internet technologies, such as HTML5, CSS and JavaScript, enables the user to view the image material with a modern web browser. No proprietary plug-in is required.

CONCLUSION

Whole slide imaging offers huge potential benefits in the field of biomaterial sciences. The technology enables quick and easy sharing of large images as well as non-destructive annotations and points of interest. This opens up new perspectives in teaching of biomaterial-tissue interactions and various evaluation skills in biocompatibility and tissue regeneration.

ACKNOWLEDGMENTS

We thank “Grüne Kommunikationsdesign” for assistance in creating a comprehensive user interface.

Figure 1: Screenshot of Pate, demonstrating the features of non-destructive annotations, points of interest and latitude in the slide. Different magnifications of the slide “[Punch-Biopsy Skin-wound](#)” can be seen.

Cryostructured hierarchical scaffolds with zonal biochemistry and anisotropic porosity for biomimetic in situ cartilage tissue engineering

Kai Stuckensen¹, Jenny Reboredo², Andrea Schwab², Uwe Gbureck¹, Heike Walles² and Jürgen Groll¹

¹Department for Functional Materials in Medicine and Dentistry, University of Würzburg, Germany

²Department for Tissue Engineering and Regenerative Medicine, University of Würzburg, Germany

kai.stuckensen@fmz.uni-wuerzburg.de

We present the fabrication of cartilage mimetic scaffolds by an oriented cryostructuring process. The resulting collagen-based scaffolds feature distinct biochemically different zones with oriented continuous pores and show evidence for inducing zonal specific differentiation of human mesenchymal stem cells in culture.

INTRODUCTION

Articular cartilage and meniscus are specialized collagenous tissues with spatial varying compositions and aligned structure of the extracellular matrix.^{1,2} The local cells, so called chondrocytes, maintain the structural and functional integrity of the matrix. Characteristic zones, each with distinct physicochemical and biological properties and functions, work together to impart shock absorbing and wear resistant behaviour to these kinds of cartilage.

Like in native tissues, the respective composition of different areas in our osteochondral and meniscus scaffolds is mimicked by the presence of collagen I, collagen II, glycosaminoglycans (GAG) and calcium phosphates. An integral cell ingrowth is facilitated by a continuous pore system which in turn approaches the pathway of the collagen fibers in the native tissues. The fabrication of these monolithic tissue mimetic scaffolds is enabled by a novel cryostructuring based processing route.

EXPERIMENTAL METHODS

Collagen I and collagen II was isolated from murine and bovine sources, respectively. Together with chondroitin sulphate (GAG), brushite ($\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$) and acidic acid multiple solutions with tissue zone mimetic composition were prepared. These aqueous precursors were arranged inside a custom build cryostructuring device. Being subjected to a directional temperature gradient, anisotropic ice crystals grew continuously through the precursors. After ice crystal removal by lyophilisation, the porous structures were covalently cross linked by using carbodiimide (EDC). On the surface of osteochondral scaffolds electrospinning of polyester-based fibers was additionally applied.

The scaffolds were seeded with human mesenchymal stem cells and cultured under static and perfusion conditions. Additionally endothelial cell seeded decellularized porcine jejunal segments (BioVaSc) were co-cultured together with the meniscus scaffolds.

RESULTS AND DISCUSSION

Osteochondral and meniscus scaffolds with tissue mimetic structure and composition were fabricated and cell cultured. (Figure 1) Human mesenchymal stem cells established chondrogenic differentiation. The first

evidences of still ongoing studies suggest, that the tissue mimetic zonal composition (collagen I, II and varying GAG content) is causing zonal stem cell differentiation.

Figure 1: Schematic scaffold design (b) and colored SEM images of osteochondral scaffolds (a, c). Consecutive pores run perpendicular to the joint surface through subchondral (collagen I & brushite), deep and middle chondral zone (collagen I, II & GAG) (a), while electrospun polyester-based fibers of the superficial chondral zone run parallel to the joint surface (c). Meniscus scaffolds (Photographs d, e) consist of an inner (collagen I, II & GAG) and an outer meniscus section (collagen I & GAG) which are penetrated by shape following pores. Co-culture of meniscus scaffold inside a vascularized porcine jejunal segment (Photograph f).

CONCLUSION

Our scaffolds represent promising candidates for biomimetic in situ tissue engineering of osteochondral and meniscus tissue. In ongoing cell culture studies we want to prove that biochemical stimuli together with the imitation of the structure of native tissue is inducing zonal specific stem cell differentiation and thus might facilitate biomimetic cartilage tissue engineering and eventually the formation of functional tissue.

⁴ICBAS – Instituto de Ciências Biomédicas Abel Salazar, Universidade do Porto, Porto, Portugal

INTRODUCTION

The gold standard approach in tissue engineering (TE) strategies involves the use of a three-dimensional (3D) artificial extracellular matrix (ECM), commonly referred to as scaffold¹. In addition to supporting the growth of neo-tissue, the properties of these structures must be tailored to enhance tissue regeneration. It is well established that surface topography, from the micro- to the nanoscale, can influence stem cell behaviour². However, most of the current studies have been carried out on 2D polymeric substrates³, with just a few reports in 3D³, mainly due to the challenge to transfer in a controlled manner the tailored surface topographies onto 3D scaffolds. In this study, we aimed at combining wet-spinning, a non-solvent induced phase separation technique that has been used to produce polymeric fibres with different characteristics, with additive manufacturing (AM), which allows the processing of scaffolds with a defined architecture, based on layer-by-layer fabrication from 3D model data⁴. A library of scaffolds with controlled surface roughness can be then obtained to study their effect on human mesenchymal stem cells (hMSCs) behaviour.

EXPERIMENTAL METHODS

A PEOT/PBT copolymer (PolyVation, The Netherlands) with a 300/55/45 composition was used. Following an *a*PEOT*b*PBT*c* nomenclature, *a* is the molecular weight in g/mol of the starting PEG blocks used in the copolymerization, while *b* and *c* are the weight fractions of the PEOT and PBT blocks, respectively. 300/55/45 was dissolved in chloroform (20 wt%) overnight at room temperature to obtain a homogeneous solution. The prepared solution was placed into a glass syringe fitted with a stainless steel needle. A syringe pump (NE-1000, New Era Pump Systems Inc., USA) was used to control the extrusion flow rate of the polymer solution. A container with two different PEOT/PBT non-solvent solutions (isopropanol and 90% v/v ethanol in water) was fixed to the fabrication platform and used as coagulation bath. Scaffolds were fabricated using a Bioplotter (Envisiontec GmbH, Germany), which is basically an XYZ plotting machine as previously described⁵. Scaffolds geometry and architecture were characterized by scanning electron microscopy (SEM). hMSCs were seeded (125000 cells/scaffold) and cell activity, morphology, and tissue growth were assessed by SEM and fluorescence microscopy.

RESULTS AND DISCUSSION

From the different 300/55/45 solvent/non-solvent combinations studied, the use of chloroform as solvent and isopropanol and 90% v/v ethanol (in water) as non-solvents allowed the most reproducible plotting of 3D scaffolds with defined geometry (Fig.1). These different non-solvents allowed the tuning of fibre-surface topography without the need to treat the scaffolds after plotting. hMSCs attached and proliferated on the scaffolds during 15 days of culture (Fig.2).

Figure 1

Figure 2

CONCLUSION

The combination of an AM with wet-spinning allowed the processing of PEOT/PBT scaffolds with a defined structure and, more interestingly, with different fibre-surface topographies by varying the non-solvent. The preliminary *in vitro* studies indicate that these scaffolds support hMSCs culture. Therefore, further studies will be performed to better understand the hMSCs fate-instructive character of these scaffolds.

Biodegradable Biopolymer and Calcium Phosphate Composites Manufactured via Impregnation Method

Marina Sokolova¹, Janis Locs¹

¹Rudolfs Cimdins Riga Biomaterials Innovations and Development Centre,
Riga Technical University, Riga, Latvia; marina.sokolova@rtu.lv

INTRODUCTION

Bioresorbable materials are promising candidates in the field of bone regeneration. Hydroxyapatite (HAp) and tricalcium phosphate (TCP) are one of the most used implant materials in the reconstructive surgery to repair damaged hard tissues¹. Calcium phosphates (CaP) have excellent biomaterial properties due to their similarity to the inorganic component of the bone matrix. However, their clinical applications are restricted because of inherent brittleness and poor shape ability². To capitalize the advantages and overcome drawbacks of CaP, it is combined with polylactic acid (PLA) to generate biocomposite material. Polylactic acid is a thermoplastic, biodegradable, biocompatible, synthetic polymer with high strength and modulus³. It can be easily processed into shapes such as screws, pins and plates for orthopedic applications, and fabricated into scaffolds for replacement and regeneration of tissues. Calcium phosphate and polylactic acid composites have received a great deal of interest in orthopedic and dental applications, which is attributed to their good osteoconductivity, biodegradability and high mechanical strengths⁴.

EXPERIMENTAL METHODS

CaP slurry was prepared by wet chemical precipitation synthesis method from calcium oxide and orthophosphoric acid solution. The method is characterized by low cost and easy application in industrial production, and that the only by-product is water. Synthesized calcium phosphates phase composition is found to be highly depended on the changes in synthesis technological parameters. Synthesized precipitates were filtered, homogenized and pressed into cylinders using a PTFE mold, and dried using three-stage drying procedure to avoid formation of cracks.

CaP/PLA composites were prepared using vacuum impregnation technique. First, CaP cylinders were placed into a vacuum vessel and held in 400 mbar vacuum for 15 minutes, then immersed into 5 – 20 wt% PLA solution for 15 minutes until pressure normalization. This procedure was repeated for three times. Another batch of the cylinders were processed with subsequential pressure impregnation, also for three times. The samples were pressed isostatically in PLA solution at 300 MPa for 3 minutes. All samples were dried and weighted after each processing step to determine PLA uptake. To improve composite mechanical strength, after impregnation all samples were pressed isostatically at 0.15 GPa and 0.20 GPa. Compressive strength of fabricated CaP/PLA composites was measured at ambient temperature. The crosshead was run at 0.05 mm/min.

Fourier-transform infrared spectroscopy (FT-IR) was used to determine the various functional groups in the nanocomposite samples. X-ray diffractometry (XRD) was used to analyze phase composition of obtained calcium phosphate samples. Scanning electron microscopy (SEM) is used to characterize the morphology of the obtained samples.

RESULTS AND DISCUSSION

Highest PLA uptake was achieved using 10 wt% PLA solution and three cycles of vacuum impregnation – 7 wt%. PLA mass fraction after three impregnation cycles increased for only 0.3 wt% (Fig. 1). Impregnation efficiency for samples treated with 10 wt% PLA solution in first processing cycle is 87 ± 3 %. Isostatic pressing didn't significantly increase PLA uptake into CaP matrix.

Fig. 1 Composite mass increase vs impregnation cycles of used PLA solutions in vacuum impregnation

CaP/PLA composites with 5 – 7 wt% PLA have porosity of 48 – 47 %, and compressive strength 20 – 30 MPa, which is similar to trabecular bone.

CONCLUSION

CaP/PLA composite strength can be adjusted by varying PLA amount in the composite. Highest compressive strength of 20 – 30 MPa is achieved for composites with 7 wt% PLA. FTIR studies indicated, that there is a concentration gradient of PLA in the prepared CaP/PLA cylinders.

INTRODUCTION

Due to a limited oxygen diffusion depth of 100-200 µm the field of Tissue Engineering is restricted in manufacturing transplants with a certain thickness and complexity¹. An approach in Tissue Engineering is the generation of blood vessels to supply complex tissues with oxygen and nutrients. In angiogenesis blood vessels, which are generated by sprouting processes, are supported by smooth muscle cells attaching to the endothelial cells². Furthermore the vessels are strengthened by endothelial cell mediated collagen expression in the basement membrane³. Here we show the generation of blood vessel-like structures within a 3-D fibrin gel under dynamic flow conditions with subsequent analysis of collagen IV production and fibroblast attachment by Two-Photon Laser Scanning Microscopy (TPLSM).

EXPERIMENTAL METHODS

Following experiments (n=3) were performed with venous endothelial cells isolated from umbilical cord (HUVECs) and human foreskin fibroblasts (HFFs). The fibrin gel scaffold consisted of fibrinogen (5 mg/mL), thrombin (3 U/mL), CaCl₂ (4.75 mM). Additionally HFFs were added with a concentration of 4.5x10⁵/mL and HUVECs with 9x10⁵/mL. The total volume of the fibrin gel scaffold was 150 µL. The scaffolds were cultivated under dynamic (perfusion bioreactor) and static (well) conditions for 14 days and stained afterwards with CD31/Alexa Fluor 594 and anti-collagen IV/Alexa Fluor 488. The analysis was done by TPLSM with an Olympus FluoView 1000MPE two-photon microscope equipped with a 25X NA1.05 water dipping objective for imaging. For excitation of Alexa Fluor 594 and 488 the laser was tuned to a wavelength of 800 nm. The emission of Alexa Fluor 594 and 488 was collected at 590-650 nm and 495-540 nm, respectively. Fibroblast attachment was imaged additionally by using autofluorescence at an emission of 419-465 nm. The supportive software was Imaris 7.6 (Biplane).

RESULTS AND DISCUSSION

Figure 1 represents the generation of blood vessel-like structures under static (A) and dynamic conditions (B) stained with CD31 as endothelial specific marker (red). Additionally we imaged the collagen IV expression in both conditions (C, D) under performance of anti-collagen IV staining (green). The static controls showed increasing formation of blood vessels compared to scaffolds cultivated under perfusion conditions. Furthermore the collagen IV expression and fibroblast attachment was dependent on the level of angiogenesis.

Figure 1: TPLSM images of static (A, C) and dynamic (B, D) cultivated scaffolds, stained for CD31 (A, B) and anti-collagen IV (autofluorescence in blue) (C, D); scale: 300 µm (A, B) and 50 µm (C, D).

The results imply an inhibitory effect of dynamic cultivation conditions on the level of angiogenesis. This is probably caused by high shear stress and dilution of growth factors. These parameters also have a negative effect on the attachment of fibroblasts, causing a lacking support for blood vessels⁴. Furthermore there is less expression of collagen IV which leads to a reduced formation of extracellular matrix surrounding and supporting the blood vessel-like structures.

CONCLUSION

The results of the present study demonstrate a highly significant effect of cultivation conditions on the amount of vessel-like structures in *in vitro* 3-D angiogenesis models. Dynamic cultivation by perfusion of the scaffolds leads to a reduced number of blood vessel-like structures, less attachment of fibroblasts, decreasing collagen IV expression in endothelial cells and a depressed basement membrane formation. However in the static culture vessel-like structures developed well and a distinct network was generated.

INTRODUCTION

Since cardiovascular diseases are nowadays considered one of the main causes of death in western world, searching for new treatment solutions and improving existing ones seems crucial¹. This applies particularly to the wide field of biomaterials and tissue engineering. Vascular tissue engineering focuses especially on developing new solutions for replacement of diseased small-calibre (inner diameter < 6 mm) blood vessels as biomaterial solutions currently available on the market are unsatisfying. Synthetic vascular prostheses cannot be applied when it comes to the small blood vessels because they often fail due to early thrombosis. Therefore, small cylindrical biodegradable constructs with appropriate properties are intensively investigated^{2,3}. This work focuses on designing and manufacturing tube-shaped biodegradable scaffolds with different microstructures of outer and inner layers destined for use in tissue engineering of small blood vessels.

EXPERIMENTAL METHODS

Scaffolds with inner diameters of 5 mm were fabricated with the use of two methods, that is electrospinning and freeze-drying. Pure polylactide (PLA) nonwoven tubes were coated with polycaprolactone (PCL) solution (1g/40ml of glacial acetic acid). Then, samples were frozen in -20°C for 0,5h and freeze-dried for 24h. Microstructural observations were performed with NOVA NANO SEM 200 (FEI EUROPE COMPANY). Mechanical (tensile test, Zwick 1435) and wettability (water contact angle, Kruss 10 DSA) tests, and also cell culture assays (HAoEC) and spectroscopy (ATR) analysis were performed too.

RESULTS AND DISCUSSION

Figure 1 shows different microstructures of outer (A) and inner (B) surfaces of the scaffold.

Scaffold were asymmetric. Inner surface comprised of polylactide nanofibres, outer of porous polycaprolactone, and there was also an intermediate layer between them. Such construction was created to distinguish growth conditions of vascular endothelial cells (inner surface) and smooth muscle cells (outer surface).

Covering of PLA nonwoven with PCL solution enhances tensile strength (R_m) and Young's modulus (E) of the scaffold⁴ as it is shown in table 1.

Material	R_m [MPa]	E [MPa]
PLAes	$0,83 \pm 0,04$	$2,27 \pm 0,05$
PCL40	$0,76 \pm 0,23$	$13,11 \pm 1,94$
PLAes/PCL40	$1,98 \pm 0,24$	$150,43 \pm 4,58$

Cell tests confirmed biocompatibility of designed scaffolds. HAoEC adhered well to the surface and began to organize in chain-like structures.

CONCLUSION

Designed scaffolds can potentially be used in vascular tissue engineering. Their asymmetric construction reflects structure of natural blood vessel and creates different conditions for growth and proliferation of EC and SMC. Utilisation of such simple manufacturing methods like electrospinning and freeze-drying as well as use of medically verified biodegradable polymers (PLA and PCL) for creating vascular scaffolds opens possibilities for many different modifications, e.g. addition of DNA encoding growth factors.

Biodegradation studies on some magnesium alloys without Al for biomedical application

Julian Antoniac, Florin Miculescu, Aurora Antoniac and Ana-Iulia Blajan

Department Materials Science and Engineering, University Politehnica of Bucharest, Romania
antoniac.iulian@gmail.com

INTRODUCTION

Studies regarding biodegradable materials have shown that magnesium alloys are potential biomaterials for orthopedic application due to its major advantage to biodegrade in biological medium¹. One of the most used alloying elements for magnesium in order to obtain biodegradable magnesium alloys for biomedical application is calcium, considering that the degradation products are expected to be non-toxic^{2,3}. In this study, we evaluate the biodegradation of magnesium alloys from Mg-Ca, comparatively with the alloys from Mg-Zn-Zr systems, in different simulated biological medium.

EXPERIMENTAL METHODS

Different binary Mg-Ca alloy with 1% and 2% calcium content obtained in our laboratory and an commercial alloy type ZK60 (from Mg-Zn-Zr system) was chosen as experimental material. For experimentally obtained alloys, ingots of commercial available high purity magnesium (99.96 %) and calcium (99.8%) particles were used as starting materials. Experimental samples of circular shape and 2mm x10mm size were polished on metallographic papers and washed with ethanol. For immersion tests were used three different mediums: Phosphate buffer solution (PBS), Hanks' Balanced Salt Solution (HBSS) and Dulbecco Modified Eagle Medium supplemented with fetal bovine serum (DMEM + 10% FBS). Mg-1Ca alloys were immersed in 50 ml solution each (total surface area to volume of solution =314mm²:50mL) at 37 °C for 3, 7, 14, 21 and 30 days. The samples were weighted before and after the immersion. For microstructural characterization of the experimental samples was used an Olympus BX51 optical microscope and a Philips XL30-ESEM scanning electron microscope. Also, the chemical composition determination was performed using EDS.

RESULTS AND DISCUSSION

The degradation process of experimental Mg alloy was evaluated during the immersion period on the basis of loss/gain weight. Also, the surface macro-morphologies of investigated alloys were analyzed using SEM. Immersed samples show different patterns of degradation depending on the type of medium and an accelerated corrosion process with increasing immersion time. In the case of phosphate buffered solution (PBS) it can be noticed a fine crystals deposit on the surface. Chloride ions from saline solution exhibit a reduced action on the alloy due to formation of a partially protective Mg (OH)₂ layer. For the samples tested in Hanks' Balanced Salt Solution (HBSS) we observed a different pattern of degradation with rapid accumulation of corrosion products and loss of integrity up to the end of the test. Corrosion products formed are

adherent to the surface and EDS results showed that these products are mainly formed of magnesium hydroxides, phosphates and carbonates. An relevant example for Mg-1Ca alloy related to the SEM micrographs and EDS result of the samples after immersion in PBS (A), HBSS (B) and DMEM + 10% FBS (C) for 21 days are shown in figure 1. When we used Dulbecco Modified Eagle Medium supplemented with fetal bovine serum (DMEM + 10% FBS) we observed that the proteins seems to form a passivation layer on top.

Fig. 1. SEM micrographs and EDS result of Mg-1Ca alloy samples after immersion in PBS (A), HBSS (B) and DMEM + 10% FBS (C) after 21 days

CONCLUSION

The aim of this study was to evaluate the effects of different mediums on magnesium alloys and to determine the optimal degradation medium. Regarding this issue it have been used both phosphate-based and cell culture medium to observe the influence of amino acids and vitamins and also proteins present in the added amount of fetal bovine serum. Best results were obtained in case of Dulbecco Modified Eagle Medium supplemented with fetal bovine serum (DMEM + 10% FBS). Hanks' Balanced Salt Solution (HBSS) proved to be the most aggressive medium given the highly porous surface morphology and the fact that experimental sample almost desintegrated after 30 days. Considering the immersion test results the experimental Mg-1Ca alloy appear to be suitable for medical applications.

Glucose sensitive gelation of hydrogel based on hyaluronan-tyramine conjugate

Lenka Kohutová, Martin Pravda, Julie Bystroňová, Lucie Wolfová, Vladimír Velebný

¹ Contipro Biotech s.r.o., Dolní Dobrouč, Czech Republic
Lenka.Kohutova@contipro.com

INTRODUCTION

Hyaluronan-tyramine conjugates (HA-TA) are promising materials for application in biomedicine. HA-TA is capable to form covalently crosslinked hydrogel by horseradish peroxidase (HRP) mediated reaction.¹ Crosslink reaction is initiated by addition of highly diluted H₂O₂. Our group developed new type of HA-TA conjugate where tyramine moiety is attached to the polymer backbone via suitable aliphatic linker (HA-LIN-TA). Presence of the aliphatic linker increases flexibility of HA polymer segments and variability of polymer microconformations. This effect leads to enhancement of mechanical properties of formed hydrogels and rapid gel formation.² Recently Sakai et al. described generation of H₂O₂ by glucose oxidase (GOx)-catalysed glucose oxidation for triggering of HRP mediated hydrogelation of alginate-tyramine conjugate. Aim of this study was to optimize an amount of used enzymes (HRP and GOx) to gain a system capable of rapid hydrogelation of HA-LIN-TA solution at concentration of glucose close to glycaemia.

EXPERIMENTAL METHODS

HA-LIN-Ta derivative was prepared according previously published procedure.² Briefly polyaldehydic derivative of hyaluronan was prepared by TEMPO mediated reaction. This was further conjugate with 6-amino-*N*-[2-(4-hydroxyphenyl)ethyl]hexanamide via reductive amination. Gained HA-LIN-TA derivative was characterized by NMR (degree of substitution 1.5%) and SEC-MALLS (*M_w* = 360 kDa). Precursor gel solutions containing HA-LIN-TA 2% (w/w), HRP (0.25 – 2.91 U/ml) and GOx (2.5 – 50 U/ml) were prepared. Hydrogelation was initiated by addition of glucose. Final concentration of glucose in the solution was 5 mM. Influence of concentration both HRP and GOx on gelation time and mechanical properties was studied. To determine the gel point the complex moduli was measured as a function of time. The critical gel point (GP) was detected as cross-over point where the elastic and viscous moduli were equal ($G' = G''$). Time of gelation was determined at 37 °C. Young's modulus (Y), compressive stress at breaking point (S) and toughness (T) were chosen as parameters for hydrogel mechanical properties evaluation. Measuring of mechanical properties was 3 times repeated with variability $\pm 10\%$.

RESULTS AND DISCUSSION

In situ forming hydrogel are valuable system for cell and drug delivery in the field of regenerative medicine.

Rapid gel formation prevents undesirable leakage of delivered material out of site of implantation. Sufficient mechanical strength of hydrogels is necessary proper cell proliferation. HRP mediated crosslink of HA-LIN-TA derivatives leads to hydrogels which fulfil these criteria. To prepare a glucose sensitive crosslinking system we used GOx as source of H₂O₂ for incitation of hydrogelation. Gelation time of system was clearly dependent on the concentration of HRP. Chosen concentration of GOx were able at level of glucose close to glycaemia supply H₂O₂ to system at rate which did not influence rate of gel formation.

Experiment	1	2	3	4	5	6	7
H ₂ O ₂ [mM]	1	-	-	-	-	-	-
HRP [U/ml]	0,36	0,42	0,42	0,42	2,91	2,91	2,91
GOx [U/ml]	-	5	10	25	5	10	25
GP (s)	15	11	10	10	<6	<6	<6

Table 1: Influence of enzymes concentration on time of gelation

Evaluation of mechanical properties showed that both glucose and peroxide triggered systems produce hydrogels with comparable mechanical properties.

Experiment	1	2	3	4	5	6	7
H ₂ O ₂ [mM]	1	-	-	-	-	-	-
HRP [U/ml]	0,36	0,25	0,42	0,97	2,91	2,91	2,91
GOx [U/ml]	-	5	5	25	25	2,5	10
Y[kPa]	6	6	6	6	5	7	6
S [Pa]	266	174	324	309	236	393	314
T [kJ/m ³]	18	13	24	21	12	25	23

Table 1: Evaluation of mechanical properties prepared hydrogel

CONCLUSION

Glucose sensitive hydrogelation of HA-LIN-TA derivative is promising approach for exploitation in situ crosslinkable hydrogels suitable for cell and drug delivery. For practical use it will be necessary to properly investigate biocompatibility of whole system.

INTRODUCTION

Injectable microspheres offer a minimally invasive approach to deliver cells for tissue repair. As substrate elasticity has been shown to direct stem cell fate¹, this study aims to harness this effect by developing a method to alter the surface elasticity of PLGA microspheres. To achieve this, methacrylated gelatin (gelMA) was immobilised on PLGA microspheres using surface entrapment. Cross-linked gelMA is known to support cell growth², and its elasticity can be controlled by altering the methacrylate content and cross-linking time³. The technique of surface entrapment was selected as it is used to immobilise molecules on a polymer surface without changing its chemical composition⁴. Developing a method to modify the surface of injectable microspheres with gelMA presents the opportunity to tune the microsphere surface elasticity and thus influence cell fate for regenerative medicine applications.

EXPERIMENTAL METHODS

Gel-MA Hydrogel characterization: Gel-MA was prepared by methacrylating porcine and fish gelatin. GelMA hydrogels were formed by UV crosslinking gelMA with photo-initiator (Ergacure 2959). Hydrogel elasticity was assessed with aTA.HD+ texture analyser.

Surface modification of PLGA microspheres: PLGA microspheres ($32 \pm 12 \mu\text{m}$) were surface modified using a modifying mixture of TFE/GelMA solution. Immobilised GelMA was UV cross-linked.

Surface Analysis: Microspheres were visualised using fluorescent microscopy and scanning electron microscopy (SEM). The bicinchoninic acid (BCA) protein assay was used to quantify immobilised gelMA.

Figure 1 Images of blank PLGA microspheres (Left) and gelMA modified microspheres (Right) as shown in (A) fluorescent microscope, and (B) scanning electron microscope SEM.

RESULTS AND DISCUSSION

The presence of FitC-labelled gelMA was observed on the surface of modified microspheres using fluorescent microscopy (Figure 1A).

Differences in surface morphology between non-modified (blank) and surface modified microspheres were visualised by SEM (Figure 1B).

The BCA assay results demonstrated the presence of a

Figure 2 BCA assay results showing the change in gelMA concentration on modified PLGA microspheres.

protein (gelMA) on modified microspheres (Figure 2). A significant increase in the detection of gelMA was observed between blank and modified microspheres, and between different concentrations of solvent (TFE) used in the entrapment process.

CONCLUSION

A promising approach for modifying the surface of PLGA microspheres with gelMA hydrogel was developed in this study. Solvent concentration was also found to affect the level of gelMA entrapment. Future work will focus on altering the thickness and elasticity of the gelMA layer to create a tuneable cell delivery system for regenerative medicine applications.

INTRODUCTION

The functionalization of resorbable oligomers such as those based on polyester with unsaturated groups and subsequent radical polymerization and crosslinking has been extensively studied¹. Typically, photocrosslinkable resins are composed of mixtures of two or more monomers that combine a relatively viscous dimethacrylate base monomer². The diffusion of unpolymerized methacrylates is one of the most important factors causing irritation in tissues³. Another anticipated risk of acrylates is a higher level of skin sensitization as compared to most vinyl ethers. Stannous Octoate Sn(Oct)₂ has been widely used as the initiator for ROP⁴ of Caprolactone (CL) and, although very efficient, its cytotoxicity has recently caused deep concern about biosafety of the materials synthesized from it and used for implantation purpose⁵. In this work, a Sn-free catalyst has been used for the ROP of CL, achieving more than 95% monomers conversion at room temperature, with hydroxyethyl vinyl ether (HEVE) as both initiator and photo-curable functional group. Fumarate functional group has been added to this precursor, to improve the degrees of reticulation in order to investigate the feasibility to photo-polymerize oligomers with hybrid functionalities.

EXPERIMENTAL METHODS

A Sn-free catalyst based on Al⁶ has been used in the polymerisation of CL at room temperature, coupled with HEVE as photocurable initiator⁷, according to the scheme below. The initiator/CL ratio has been varied to achieve a range of M_w comprised between 2000 and 5000 g/mol, as determined via rheological experiments and NMR. Following the synthesis of the vinyl-terminated PCL, its reaction with fumaryl chloride results in chains containing photocrosslinkable vinyl units at both ends and in the middle of the chain.

Figure 1: Synthetic procedure of the divinyl-fumarate PCL

Differential scanning calorimetry (DSC) has been used to evaluate the dependence of glass transition

temperature (T_g) and melting temperature (T_m) from polymer molecular weight.

RESULTS AND DISCUSSION

In the preliminary experiments, we polymerized CL by using HEVE in the presence of AlMe(OR)₂. Vinyl-PCL was reacted with Fumaryl Chloride to obtain a divinyl-fumarate-PCL. The resulting polymer was characterized by its molar weights, functional end groups and transition temperatures, using several techniques including Rheometry, Nuclear Magnetic Resonance (NMR), Fourier Transformed Infrared Spectroscopy (FTIR), Differential Scanning PhotoCalorimetry (DPC) and Differential Scanning Calorimetry (DSC). NMR and FTIR confirm the presence of functional groups linked to the PCL oligomers. Moreover vinyl double bond conversion is confirmed by the DPC exothermic peak.

Figure 2: FTIR spectra of functionalized PCL

CONCLUSION

PCL network was successfully produced from UV curing of V/F hybrid oligo-caprolactone. This is an attractive alternative to diacrylated-PCL in reducing the potential immune effect related to acrylates.

Novel radiopaque UHMWPE sublaminar wires in a growth-guidance system for the treatment of early onset scoliosis: feasibility in a large animal model

Alex Roth, Rob Bogie, Paul Willems, Lodewijk van Rhijn, Jacobus Arts

¹Department Orthopaedic Surgery, Researchschool Caphri, Maastricht University Medical Centre, Maastricht, the Netherlands j.arts@mumc.nl

INTRODUCTION

Growth-guidance or self-lengthening rod systems are an alternative to subcutaneous growing rods for the surgical treatment of early onset scoliosis (EOS). The main advantage in comparison to growing rods is the marked decrease in subsequent operative procedures. Ultra high molecular weight polyethylene (UHMWPE) or other polymeric sublaminar cables have already been introduced for spinal deformity surgery; the soft and flexible structure of woven UHMWPE wires decreases the risk of neurological injury, while the broad shape distributes contact forces over a greater area, thus allowing for higher correction forces. Radiolucency of UHMWPE wires has limited the possibility for postoperative radiological assessment and subsequent clinical use. The goal of this study consists of two parts: (1) to test the stability and biocompatibility of novel radiopaque UHMWPE wires as sublaminar wire, and (2) to assess the potential of using UHMWPE sublaminar wires in a growth guidance system for EOS

EXPERIMENTAL METHODS

In 12 immature sheep, thoracolumbar spines were instrumented with radiopaque (Bismuth Oxide additive) UHMWPE sublaminar wires. Wires were placed at 5 levels (T11-L3), while pedicle screws at L5 held dual CoCr rods in place. A control group consisted of 4 age-matched animals. Radiographic control was performed at 4 week intervals. After a follow-up period of 24 weeks, the animals were sacrificed and the spines were harvested. Harvested spines and vertebrae were embedded in PMMA for histological evaluation.

Fig 1. (a) 4mm wide, woven radiopaque UHMWPE sublaminar wire (b) SEM close-up image of radiopaque UHMWPE wire showing homogenous bismuthoxide particle distribution (c) double-loop sliding knot (d) intra-operative view of UHMWPE sublaminar wires looped around the laminae and after tensioning the knots

RESULTS AND DISCUSSION

No neurological deficits occurred during the postoperative period. One animal died during follow-up (7 weeks postoperatively) due to unknown cause. At sacrifice, none of the cables had loosened and all instrumentation remained stable. Substantial growth occurred in the instrumented segments (L5-T11) in the intervention group (2.67 ± 0.16 cm). Spinal growth was slightly higher in the control group, (2.96 ± 0.35 cm),

but this difference was not statistically significant ($p=0.42$).

Fig 2. Lateral radiograph of the instrumented spine (a) directly post-operative and (b) after 24 weeks. The red circle clearly illustrates growth by sliding of the cable along the rod.

Fig 3. Quantification of spinal length shows no significant difference between the operated and control groups. (b) Histological slice of PMMA-embedded vertebrae (Hematoxylin & Eosin stained) showing fibrous encapsulation of the wire, which is a typical physiological reaction to foreign materials (also seen around rods, arrows)

Histological analysis revealed fibrous encapsulation of the novel radiopaque UHMWPE sublaminar wires in the epidural space, with no evidence of chronic inflammation or wear debris. HR-pQCT analysis showed interlaminar ossification, possibly a result of periosteal stripping during opening of the flaval ligament. Typical bone formation encircling the posterior rods coupled with degenerative facet joint changes were also seen.

CONCLUSION

Despite the occurrence of spontaneous ossification, UHMWPE sublaminar cables allowed for almost normal continued growth of the instrumented spinal segments during follow-up. Fibrous encapsulation of the cable and preservation of instrumentation stability during the course of this study show that the application of these novel radiopaque UHMWPE sublaminar cables in spinal deformity correction surgery is safe. Further research into the fate of bismuth-oxide particles however is ongoing.

3D Plotting of hydrogels based on fibrillar collagen to create scaffolds with defined inner and outer architecture

Anja Lode¹, Kristin Faulwasser¹, Sophie Brüggemeier¹, Birgit Hoyer¹, Hagen Baltzer², Michael Meyer², Claudia Winkelmann³, Frank Sonntag³, Michael Gelinsky^{1*}

¹Centre for Translational Bone, Joint and Soft Tissue Research, Technische Universität Dresden, Dresden, Germany, michael.gelinsky@tu-dresden.de

²Research Institute of Leather and Plastic Sheetting (FILK) Freiberg, Germany

³Fraunhofer IWS Dresden, Germany

INTRODUCTION

The rapid prototyping technique of 3D plotting (3DPI) allows the processing of a variety of synthetic and natural materials in form of slurries, highly viscous solutions, suspensions, blends and melts. The mild process conditions enable the application of biopolymers such as collagen and even the integration of sensitive components like growth factors or living cells.

We have investigated the conditions for 3DPI of pure, fibrillar collagen as well as of mineralised collagen, a nanocomposite artificial extracellular bone matrix.

EXPERIMENTAL METHODS

3DPI was performed using a BioScaffolder™ from GeSiM (Grosserkmannsdorf, Germany). As plotting materials, highly concentrated fibrillar collagen type I pastes, derived from porcine skin (FILK, Freiberg, Germany), as well as bovine tendon collagen (Syntacoll, Saal/Donau, Germany), mineralised with nanocrystalline hydroxyapatite ("mineralised collagen¹") were used. If necessary, blending with carboxymethyl cellulose or gelatine was done to prevent liquid segregation. The porous, cubic 3D scaffolds were freeze-dried and crosslinked chemically after plotting in air with an EDC solution and characterised concerning their structural and mechanical properties.

The suitability of the plotted 3D scaffolds for soft (pure collagen) as well as bone tissue engineering (mineralised collagen) was evaluated in cell culture experiments with human mesenchymal stem cells (hMSC). The cell-matrix constructs were cultivated in the presence of adipogenic and osteogenic supplements, respectively, and adhesion, proliferation and differentiation of the cells was investigated.

RESULTS AND DISCUSSION

At low pH values, the native collagen type I paste was plottable without additives to generate pure collagen scaffolds which were subsequently stabilised by chemical crosslinking with the carbodiimide derivative EDC. At neutral pH, the collagen suspension was processible by 3DPI only if blended with other biopolymers like carboxymethyl cellulose which were able to counter the liquid segregation (phase separation) during the plotting process. The same strategy was used to manufacture plotted scaffolds from mineralised collagen but here the blending with gelatine was successful for preventing phase separation (Fig. 1).

EDC crosslinking led to sufficiently stable constructs for all investigated scaffold compositions which could be stored under cell culture conditions for several weeks

without disintegration. Beside the macroporosity, originated by 3DPI according to the predesigned geometry, the freeze-drying process generated an additional microporosity within the strands.

Fig. 1: 3D plotted scaffold, consisting of mineralised fibrillar bovine collagen type I (scale bar = 2 mm)

Human MSC could adhere, proliferate and differentiate towards the adipogenic (non-mineralised collagen scaffolds) or osteogenic (mineralised collagen) lineage in presence of the established supplements. Adipogenic differentiation was proven by measurement of GPDH enzyme activity and expression of perilipin, PPAR γ , FABP4 and LP lipase on RNA level, osteogenic differentiation by observation of a strong increase of specific alkaline phosphatase (ALP) activity over time.

By combining pure and mineralised collagen pastes (or other suitable biomaterials like calcium phosphate bone cement (CPC) or biopolymer hydrogels like alginate or gellan gum) in a multi-channel 3D plotting process, complex scaffolds suitable for the treatment of defects at tissue interfaces (soft tissue/bone or cartilage/bone) can easily be fabricated – as recently demonstrated by combining a CPC paste with alginate hydrogel².

CONCLUSION

Rapid prototyping of scaffolds and tissue engineering constructs is a fast growing research field and provides new options for individualised therapies. We have demonstrated that collagen as well as mineralised collagen pastes can be used for 3D plotting of porous scaffolds of defined architecture and that those matrices are suitable for hMSC culture and differentiation towards the adipogenic and osteogenic lineage, respectively.

INTRODUCTION

Larry Hench's original Bioglass® 45S5 composition [1] cannot be made into porous scaffolds while maintaining an amorphous glass structure due to its susceptibility to crystallise during sintering. Melt-derived glasses have recently been developed which avoid this crystallisation, enabling bioactive glasses to be manufactured into porous constructs. The aim was to use a new modified gel-cast foaming technique to create porous glass scaffolds using three different glass compositions. The new process switched *in situ* polymerisation [2] for thermal gelation of a polymer binder. The effect of composition on the glass structure, processing and *in vitro* and *in vivo* behaviour was investigated.

EXPERIMENTAL METHODS

Glasses: ICIE16 (49.46 SiO₂, 36.27 CaO, 6.6 Na₂O, 1.07 P₂O₅ and 6.6 K₂O, in mol.%), 13-93 (6.0 Na₂O, 7.9 K₂O, 7.7 MgO, 22.1 CaO, 1.7 P₂O₅, 54.6 SiO₂ in mol.%) and SBP-3 (4.0 Na₂O, 4.0 K₂O, 7.5 MgO, 17.80 CaO, 17.80 SrO, 4.5 P₂O₅, 44.50 SiO₂ in mol.%) were manufactured via melt quenching. Frit was formed and ground into particle size less than 32 µm. A new gel cast foaming technique with a polymeric gelling agent was used to produce porous glass scaffolds, which were then freeze dried and sintered. Sintering effectiveness was optimised for each glass composition. Scaffolds were characterized via XRD, SEM, FTIR, porosimetry, solid state phosphorous NMR, ICP and SBF testing. *In vivo* comparison, using a rat tibia model (3 mm defect), between SBP-3 and ICIE16 scaffolds was completed. Sample sizes were 3.06 ± 0.20 mm diameter, 2.02 ± 0.07 mm thick.

RESULTS AND DISCUSSION

Fig. 1: SEM of sintered ICIE16

Surfactant concentration and sintering profile was optimised to create scaffolds (e.g. Fig. 1) with modal interconnects (mercury porosimetry) of 100-200 µm and 85% porosity. Each glass had different network connectivity (NC^{*}): 2.13, 2.84 and 3.01 respectively,

suggesting that ICIE16 should be the most bioactive and 13-93 the least, however SBF data showed SBP-3 reacted the slowest (Fig. 3), implying the cations in SBP-3 are acting as network intermediates, slowing dissolution.

Fig. 3: ICP data of P content of SBF.

In vivo results: scaffolds implanted had equivalent modal pore diameter. Defects containing the scaffolds showed bone integration at 12 weeks although the composition of the glass affected rate of regeneration (Fig. 4). More bone seemed to fill the ICIE16 scaffolds, which was in agreement with ICIE16 forming an apatite layer more rapidly *in vitro*. Quantification of bone ingrowth will be presented.

Fig. 4. X-ray tomography images of a rat tibia at 12 weeks of (a) SBP-3; (b) ICIE16.

CONCLUSION

In a rat model, bone ingrowth through a bioactive glass scaffold with lower network connectivity, and faster rate of HCA formation in SBF, was greater than for a scaffold with higher network connectivity, even though the latter contained Sr.

INTRODUCTION

Nanoparticles (NP) can passively accumulate into tumors, taking advantage of enhanced permeation and retention (EPR) effect.

Major criticisms for the therapeutic effect of anticancer drugs loaded in NP are a limited NP cell internalization and/or the release of the loaded drugs before NP uptake.

Furthermore, the chemotherapeutic drugs suffer from the lack of specificity toward tumors, thus causing severe systemic effects. In this context, hyaluronic acid (HA) is attractive for tumor-targeted delivery since it can specifically bind to cancer cells, which overexpress CD44 receptor.

For this reason, several HA-based drug carriers have been studied for tumor targeting. A major challenge of this task is the development of the drug-carrier not altering the HA binding affinity to the receptors¹.

In this context, the aim of this work was to formulate HA-coated biodegradable NPs for the intracellular targeting of chemotherapeutic(s). In particular, NPs made of poloxamers and poly(lactic-co-glycolic acid) (PLGA) blends were coated with HA by a modified emulsion technique. NPs were characterized for their size, morphology and zeta potential (ZP).

Irinotecan (IRI) and Doxorubicin (DOX), two widely employed chemotherapeutic drugs, were loaded into NPs, and their *in vitro* release kinetics assessed.

EXPERIMENTAL METHODS

NPs were produced by a single emulsion/solvent evaporation technique. Briefly, solutions of PLGA (Boehringer Ingelheim, Germany), and poloxamers (F127 and F68 1:1 w/w; Lutrol, Basf, Germany) in acetone, at different weight ratios, were prepared. The organic phase was emulsified by sonication with an aqueous phase containing different HA (Novozymes Biopharma, 850 KDa) and poloxamers amounts.

The obtained NPs were characterized in terms of size and zeta potential by means of Photon Correlation Spectroscopy (PCS; N5 Submicron Particle Size Analyzer, Beckman-Coulter, Malvern, USA). Morphology was studied by transmission electron microscopy (TEM, FEI Tecnai G12 Spirit Twin).

In vitro drug release studies were carried out by placing NPs in dialysis membranes in phosphate buffer solutions (PBS) and quantifying the drug by spectrophotometric

assay. NP stability was evaluated by measuring their size over time.

RESULTS AND DISCUSSION

The obtained HA-coated NPs were spherical and with a mean size of approximately 110- 290 nm depending on HA/PLGA/poloxamer weight ratio. In figure 1 a selected TEM micrograph of NPs was reported.

Figure 1: Selected TEM micrograph of nanoparticles

ZP was negative for all formulations, and decreased from approximately -27 mV to -40 mV when HA was added. Morphological, ZP and size analyses confirmed an effective HA coating on NP surface.

The presence of HA on NP surface promoted device stability for at least 10 days compared to NPs made up of PLGA alone, which immediately aggregate in PBS.

Both IRI and DOX were efficiently loaded, and these studies demonstrated NP ability to sustain their delivery for at least 14 days.

CONCLUSIONS

Biodegradable and biocompatible NPs, exposing superficial tumor targeting HA, were produced. NPs possessed a negative ZP, were stable in suspension over 10 days and could provide a sustained drug delivery.

Human bone marrow as a unique source of both microvascular endothelial cells and mesenchymal stem cells for vascularised bone tissue engineering

Julien Guerrero^{1*}, Hugo de Oliveira¹, Sylvain Catros¹, Robin Siadous¹, Reine Bareille¹, Mohammed Derkaoui², Didier Letourneur², Joelle Amédée¹

^{1*}Inserm, U1026 Tissue Bioengineering, University of Bordeaux, France, julien.guerrero@inserm.fr

²Inserm, U698 Cardiovascular Bioengineering, University Paris Sorbonne, France

INTRODUCTION

In the field of bone tissue engineering, one of the main clinical limitations resides in the repair of large bone defects. In this sense, biomaterials may offer alternatives to autografts but most do not promote sufficient vascularization as to support the process of tissue regeneration. One approach to tackle this limitation is the pre culture of vascular endothelial cells and mesenchymal cells in the tissue-engineering construct. Nonetheless, this approach presents some drawbacks, as it comprises the use of different cell sources and at distinct stages of differentiation. The identification of a sole source of reparative cells represents a major challenge for the development of bone tissue engineering products applicable in a clinical scenario. Stem cells from bone marrow are an important reservoir of reparative cells. In this context, our aim was to develop a simplified approach for bone tissue engineering by using a total human bone marrow cell fraction (hWBMCs) without the need for a step of selection and amplification.

EXPERIMENTAL METHODS

Our strategy involved the identification and characterization of two specific populations of cells (microvascular cells¹ and mesenchymal stem cells) among all the cells of the human bone marrow. As such hWBMCs, obtained from hip placement procedures (66 years \pm 11 years), were characterized for endothelial and mesenchymal markers by flow cytometry. For the *in vitro* studies, hWBMCs were seeded in pullulan/dextran matrices² and cultured in standard conditions. The formed aggregates were characterized in terms of osteoblastic and endothelial phenotype at 1, 6 and 12 days. The colonized materials were equally subcutaneously implanted in NOG female mice for 3 and 8 weeks (n=10). The animals were then sacrificed, the matrices recovered, fixed and processed for histology. Immunohistochemistry for CD31 and HLA-I, and Masson trichrome staining were performed as to characterize material endothelialisation, the fate of the human implanted cells and the formation of an osteoid tissue, respectively.

RESULTS AND DISCUSSION

The flow cytometry analysis reveals that we have 13,3 % \pm 5,0 % of mesenchymal stem cells and 7,0 % \pm 2,2 % of endothelial cells into the total human bone marrow cells. *In vitro*, when in a three-dimensional microenvironment, cells spontaneously form cell aggregates and show the establishment of communicating junctions. Additionally, we observed the augmentation of osteoblastic markers and the formation of a pseudo vascular network within the

aggregates. We also evidenced the promotion of cell to cell junctions, as observed by the expression of Connexin43, known to play a major role in the differentiation of mesenchymal stem cells to osteoblastic cells². Ectopic implantation of the matrices, loaded with hWBMCs, validated the suitability of the spheroidal structures to support bone and vessel formation *in vivo*. Indeed, osteoid formation significantly increased by two fold with time of implantation from 3 to 8 weeks. Importantly, we also demonstrated that hWBMCs spheroid-seeded scaffolds supported an increased vascularization in the periphery of the scaffold and inside the matrix, with time of implantation (Figure 1).

Figure 1 : Number of vessels during the time, outside the scaffold and inside the scaffold.

The role of the human cells loaded within the matrix and their impact in the neovascularization process was assessed by HLA-I immunolabelling (marker for human cells). Human cells were detected in the aggregates inside the scaffold up to 8 weeks of implantation, suggesting their contribution to the bone formation and/or the vascularization of the tissue. In addition, human cells were also observed associated with host vessels in the periphery of the implants. However, the exact mechanism involved in the communication and the cell interactions formed between human and murine cells remains unknown.

CONCLUSION

Here we demonstrate the potential of the total human bone marrow cell population, without preliminary isolation or expansion, for the development of a bone regeneration and vascularization strategy, once seeded in an appropriate bioactive matrix.

Effect of Calcium Phosphate Ceramics Substrate Geometry on Mineralization and Cell Organization and Differentiation

E.R. Urquia Edreira¹, A. Hayrapetyan¹, J.G.C. Wolke¹, J.A. Jansen¹, J.J.J.P. van den Beucken¹

¹*Department of Biomaterials, Radboud UMC, The Netherlands, EvaRaquel.UrquiaEdreira@radboudumc.nl

INTRODUCTION

Calcium phosphate ceramics in combination with implant surface geometry have been shown to influence biological performance. Ripamonti et al. have extensively investigated the osteoinductive effect of repetitive surface concavities on bulk ceramics and calcium phosphate coated titanium implants¹⁻³. These studies have shown that the presence of concavities allows for osteoinductive capacity without loading the ceramic scaffold osteogenic soluble factors or osteogenic cells.

In our previous study, we tried to rationalize the mineralization process through an *in vitro* test in SBF⁴. Bianchi et al. showed that the mineralization process started preferentially within the concavities in hydroxyapatite (HA) disks sintered at 1200 °C and concavity size controlled the extent of mineralization.

It is also known that micro- and nano-scale morphology of the calcium phosphate surface can strongly influence osteoblast and stem cell adhesion, proliferation, and differentiation⁵⁻⁷. In our current study, we aimed to investigate how cells populate concavities and to what extent concavity size influences cellular mineralization. We hypothesized that surface concavities facilitate cell proliferation and mineralization and that these effects are increased in the smaller concavity due to increased 3D cellular organization.

EXPERIMENTAL METHODS

Cavity sizes of 400, 800 and 1600 µm were created on the surface of HA disks sintered at 1200°C and cultured with adipose tissue mesenchymal stem cells (AT-MSCs) in osteogenic medium for up to 28 days at 37°C. At selected time points (3, 7, 14, 21, and 28 days), samples were removed and after fixation cells were fluorescently labelled with phalloidin-Alexa 568 (1:250; molecular probes) for filamentous (F-) actin and DAPI (1:2500) for nuclear staining. Cells were imaged and examined with a confocal laser scanning microscopy (CLSM) Olympus FV1000.

RESULTS AND DISCUSSION

Immunofluorescence-based three-dimensional (3D) image analysis showed differences in cell number between concavities at early culture time points (3 days). The highest number of cell nuclei was found in the 400 µm cavity (Figure 1) and the lowest number in

the 1600 µm. Additionally, cells were able to migrate towards the concavities and adhere to their edges and walls. Preferential mineralization was observed inside the concavities. Cells spread over and to the bottom of concavities covering all their volume and creating multilayers on their surfaces.

Figure 1. Immunofluorescence images at three days showing cell nuclei within the 400 µm concavity.

CONCLUSION

High resolution 3D images gave qualitative and quantitative data on concavity volumes. CaP ceramics with surface concavities induced cell (AT-MSCs) organization within the concavities and were able to create cell multilayers. Results from this study suggest a correlation between concavity size, cellular organization, mineralization and concavity induced osteoinductive properties.

Biomechanical & morphological analysis of blend polymeric electrospun scaffolds for Cardiovascular Tissue Engineering

Alexandros Repanas¹, Birgit Glasmacher¹ and Dimosthenis Mavrilas^{2*}

¹Institute for Multiphase Processes, Leibniz University Hannover, Germany

^{2*}Laboratory for Biomechanics & Biomedical Engineering, Mechanical Engineering & Aeronautics, University of Patras, Greece, mauril@mech.upatras.gr

INTRODUCTION

Polycaprolactone (PCL) and chitosan (CS) are polymers with attractive properties (excellent biocompatibility & degradation time, resp. cytocompatibility)^{1,2}. However their mechanical properties separately do not satisfy the needs for cardiovascular tissue engineering. In the present work we aimed to optimize electrospinning parameters to obtain a flexible PCL/CS polymeric scaffold, with combined nano- and micro-fiber architecture and appropriate mechanical properties for cardiovascular tissue engineering in regenerative medicine.

EXPERIMENTAL METHODS

PCL and CS were dissolved in acetic acid (AAC) and 2,2,2-trifluoroethanol (TFE) using different concentrations. Electrospinning was performed at a custom made apparatus, at room temperature. Morphology of the fibrous membranes was examined by SEM. Cyclic sinusoidal uniaxial mechanical tests were performed with a Bose electroforce dynamic tensile testing system. Rectangular, 15x10 mm strips were cut and tested at 0-30% strain, 1 cycle/sec, RT, dry conditions, room temperature. The applied force and the local principal strain were monitored and stress/strain data was computed. Mechanical properties like Young's modulus (the elastic modulus at high slope - post transition phase - linear portion of stress/strain curve) were evaluated³. For biophysical characterization FTIR spectroscopy and contact-angle studies were performed. Statistical differences (One-way ANOVA) considered significant if $p < 0,05$.

“An example of the combined nano/micro-fiber network form the combination CS and PCL”

RESULTS AND DISCUSSION

SEM observations showed a micro fibrous (2 μm) structure in PCL scaffolds and a combined nano/micro- (0.25-2 μm) arrangement in PCL/CS blend scaffolds. For a 0-30% strain range, Young's modulus showed a significant drop from $18,48 \pm 2,04$, $n=8$ MPa (PCL in TFE) to $4,80 \pm 1,84$ or $5,06 \pm 1,69$ ($n=8$) MPa (flow rates 1 & 1,5 ml/hr resp., PCL in AAC). For blended PCL+CS the modulus was lowered to $11,85 \pm 2,85$, $n=8$ MPa for TFE and $2,89 \pm 1,02$, $n=8$ MPa (1 ml/hr) for AAC, changed with increasing CS concentration. Hydrophilicity of the scaffolds was significantly higher with the addition of CS in the polymeric blend as the contact angle experiments showed.

“Difference in fiber diameter (mean \pm SDEV, $n=8$) between different process conditions during the PCL electrospinning process without and with the addition of CS. (FR: flow rate).”

CONCLUSION

From the obtained results it seems that the concentration of CS plays an important role in structural appearance of electrospun PCL fibers. A combination of small porous nanofibers with a greater porous microfibers arrangement was obtained in polymer blends, suitable for potential cell seeding. Elastic modulus of polymer blends, especially in higher CS concentration, was close to properties measured in soft cardiovascular tissues.

INTRODUCTION

Osteoporosis is a global public health problem currently affecting more than 200 million people worldwide. It is characterized by an imbalance in bone remodelling process, leads to progressive loss of bone mass and microarchitecture that increased fracture risk¹. Various therapies have been developed for the treatment of osteoporosis. Biphosphonates therapies and methyl methacrylate cements, used in advanced osteoporosis fractures, show several side effects and confine the problem without resolving it^{2,3}. A promising solution may be represented by the use of new strontium-substituted apatitic bone cements (Sr-BCs), endowed with ability to induce new bone formation, to be progressively resorbed and with sufficient mechanical strength for early physical stabilization of the defect. Such injectable devices can be integrated into the surrounding bone, due to its biomimetic and biodegradability characteristics, and can act as a local release system of Sr into the bone defect. Sr²⁺ has been shown to enhance the proliferation and differentiation of mesenchymal stem cell and pre-osteoblast into bone-forming osteoblast, with a mechanism probably involving membrane-bound calcium sensing receptor (CaSR)⁴.

The aims of this works were to investigate the biological interaction occurring between mouse mesenchymal stem cells (MSCs) and BCs substituted with two different concentration of Sr²⁺.

EXPERIMENTAL METHODS

Strontium (Sr)-substituted BCs powders with different strontium content (2% and 5% mol) were synthesized by solid state reaction of stoichiometric amounts of calcium carbonate, dicalcium phosphate dibasic anhydrous and strontium carbonate. The pure BC without Sr, was used as a control; the samples and control names are indicated in Table 1.

The powders were dry-mixed, thermally treated at 1400 °C for 1 hour and then rapidly quenched. The product was then milled and mixed with an appropriate amount of aqueous solution containing a natural polymer. Milling times and liquid-on-powder ratio (L/P) were optimized to obtain a final product in accordance with clinical needs.

Mouse mesenchymal stem cells (MSCs) were seeded at 1.5×10^4 cells/cm² on the top of the each cements and cultured for 24, 48, 72 hours, 7 and 14 days in osteogenic culture media. pH measurement of the culture media, cell viability and proliferation (MTT assay), cell morphology (Actin staining), and the expression of osteogenic related gene (qPCR) were investigate (Runx2, ALP and Col 15).

Name	Sr ²⁺ % mol
BC	0
Sr2%-BC	2
Sr5%-BC	5

Table 1 shows the name and composition of the samples tested,

RESULTS AND DISCUSSION

MSCs viability and proliferative potential were increased in the cells grown in direct contact with both Sr2%-BC and Sr5%-BC, compared to BC. These results were confirmed by the morphological evaluation indicating that, after 72 hours, cells were spread with good morphology and firmly attached to the BCs surface, without any differences among the samples.

Moreover, the evaluation of osteogenic related genes, after 7 days of culture, showed that Sr2%-BC increased significantly expression of Runx2 and ALP mRNA compared to the inductive effect exert by Sr5%-BC; both Sr2% and Sr5%-BCs strongly increased also Col15 mRNA respect to BC, after 7 days of culture (fold-change 3.1 and 2.4, respectively). These differences in mRNA levels disappear after 14 days.

CONCLUSION

The results obtained in this *in vitro* study, showed the positive influence of Sr²⁺ modification of bone cement on proliferation and osteogenic differentiation of MSCs. The combination of biomimetic characteristics of the bone cements with the inductive effect of Sr²⁺ open brilliant prospective for the *in vivo* use of this biomaterial as innovative strategy for the osteoporosis therapy.

INTRODUCTION

Lactoferrin (LF) is a bioactive glycoprotein that becomes recently interesting in field of bone biology for its modulatory effect on cells regulation to bone remodeling, that results compromised in some pathological conditions, as osteoporosis^{1,2}. We have already showed that the coupling of LF and HA leads to a combined effect in the induction of osteogenic differentiation of mesenchymal stem cells³.

On the basis of these evidences this study aims to combine LF with biomimetic hydroxyapatite (HA) nanocrystals, a bioactive material well known for its osteoconductive proprieties⁴, to study their combined effect as anabolic complex (HA-LF) on bone cells, and its modulatory effect on bone homeostasis.

EXPERIMENTAL METHODS

HA were functionalized by mixing (37°C, 24h) 50 mg with 7.5 ml of cow's milk LF solution at 0.5 mg/ml concentrations (HEPES buffer, pH 7.4). Murine pre-osteoblast cells line (MC3T3-E1) an murine osteoclast cells line (Raw 264.7) were cultured in presence of two concentration of HA with 6.6 wt% amounts of surface loaded LF (10 and 100 µg/ml); HA only, LF only at the same concentrations, and cells grown without material, were used as a controls. Histological analysis were done to evaluated cellular morphology and interaction with the conjugate HA-LF. Osteogenic differentiation of MC3T3-E1 was evaluated by mRNA analysis (qPCR). Cell viability and anti-apoptotic effect of HA-LF on MC3T3-E1 were evaluated by Live&Dead assay and nuclear fragmentation analysis. TRAP staining was used to detect the inhibitory effect of the conjugate on the osteoclastogenesis.

RESULTS AND DISCUSSION

No differences in cellular morphology and spreading were detected among all the samples tested. Gene expression analysis showed that HA-LF exerts its inductive effect in pre-osteoblast differentiation, as indicated by the increasing in OSTERIX and IBSP mRNA. The pre-osteoblast viability seems to be not compromised by the presence of HA-LF in the osteoblast culture; besides, the nuclear fragmentation analysis showed an inhibition of apoptosis induced by HA-LF conjugate. Preliminary results on the

inhibition of osteoclastogenesis, detected by TRAP staining, showed also a weak effect exert by HA-LF conjugate.

CONCLUSION

The promising *in vitro* results obtained in this work showed that the coupling of LF and HA leads to a combined effect in the modulation of bone cells. The possibility to combine the unique features of HA and LF in a complex, that not only maintains their individual stimuli, but enhances the anabolic bone activity, opens future prospects in the use of this functionalized material in bone tissue engineering and regenerative medicine.

INTRODUCTION

Irreversible or extensive damages to skin impair skin functions which might even lead to death¹. Human amniotic membrane (AM) has been widely used as wound dressing. In spite of all attributes, AM suffers from inferior mechanical strength² and enzymatic digestion²⁻³. Electrospun silk fibroin nanofibres⁴ have the potential to biomimic the microstructure of natural extracellular matrix (ECM) of skin. Surface modification through plasma treatment has been attempted to enhance cell adhesion⁵. In this study we have introduced a novel scaffold aiming to regenerate ECM of skin tissue which has been fabricated through coating de-epithelialised AM (DA) with electrospun silk fibroin nanofibres (DAF) followed by surface plasma treatment (DAFP). Subsequently, scaffolds were fully characterized.

EXPERIMENTAL METHODS

Scaffold Fabrication: After procurement of AM, the spongy layer was removed avoiding inconsistencies in clinical outcomes⁶ and de-epithelisation was carried out⁷ through optimised method. Next, AMs were freeze-dried for convenient use. Fibroin extracted from silkworm cocoons⁸ was dissolved in formic acid (20% wt.v⁻¹). The solution was electrospun at a rate of 0.2 ml·min⁻¹ in an electric field generated by 20 kV. At a tip-to-collector distance of 80mm, nanofibres were collected on the basement membrane side of de-epithelialized AMs (1500 rpm). For plasma treatment, specimens were put on the electrode within reactor chamber. After chamber evacuation, the pressure was stabilised at 70 mTorr and by controlling the electrical power of 30 W at 13.56 MHz radio frequency, specimens were exposed to oxygen plasma for 2 min.

Characterisation: To assess cell denudation, AM and DA were stained histologically with H&E. Tissue continuity was evaluated by fibronectin immunofluorescent staining. The microstructure of electrospun fibres was visualised using Scanning Electron Microscope (SEM). Mechanical strength of HAMs before and after cell denudation and coating with nanofibres was investigated using a Santa Mechanical Testing Device. Water contact angle on surface of specimen was measured using Sessile Droplet Method. Proliferation of mouse embryonic fibroblast (MEF) on DA was studied for 14 days *in vitro*.

RESULTS AND DISCUSSION

Histological characterisation and immunohistochemical localisation of fibronectin is demonstrated in Figure 1. Bead-free silk fibroin nanofibres were obtained (Figure 2) with the mean diameter of 249±116 nm.

Figure 1 Amnion Characterisation

Figure 2 Electrospun fibres

Figure 3 Water contact angle measurements

Figure 4 Mechanical Evaluation

Figure 5 In vitro studies

Contact angle decreased from 68.5±5.8 to 26.3±6.4 after coating with nanofibres and reached zero value after oxygen plasma treatment (Figure 3), representing a rise in hydrophilicity of scaffolds. Mechanical evaluation of DAF showed significant enhancement in terms of Young's Modulus (Figure 4). *In vitro* study of MEF cells cultivation on DA revealed that processed amniotic membrane remarkably supported the cell proliferation (Figure 5).

CONCLUSION

The de-epithelialised AM/silk nanofibres scaffold exhibited promising mechanical properties and water permeability. Ongoing studies focus now on the evaluation of these novel scaffolds in an *in vivo* model as wound dressing.

Bioprinting of vasculature at cell-compatible conditions

Jing Yang¹(jing.yang@nottingham.ac.uk), Kevin Shakesheff¹

¹ Division of Drug Delivery and Tissue Engineering, School of Pharmacy, The University of Nottingham, UK

INTRODUCTION: Metabolically active tissues must reside within 200 μm of a capillary lumen to gain sufficient oxygen and nutrients for survival. Incorporation of a perfusing blood supply in tissue engineering design is vital for the scalability, survival and integration of almost all tissues with the exception of a few poorly vascularised tissues such as skin epidermis and cartilage. Delivery of angiogenic growth factors, genes and regenerative cell types as well as combination therapies have been employed to promote vascularisation. However, the integration of these engineered tissues with the host remains a monumental challenge. To meet this challenge, the establishment of functional vasculature in engineered tissue constructs is likely to be required before transplantation. To this end, a recent research highlight has been the use of a sacrificial lattice of carbohydrate fibres to fabricate vascular-like tubule networks.¹ Here, we demonstrate a novel method for engineering vascularised tissues using 3D printing. A construct with an embedded tubule network in a hydrogel matrix has been successfully printed at cell-compatible conditions. The tubule network was then perfused with endothelial cells to form vasculatures.

METHODS: A Fab@HomeTM printer was used to print the tubule network and the hydrogels. To form tubule network, a thermo-responsive material and alginate were printed into a pre-designed structure. The printed network was then dissolved away at physiological conditions to form tubes which were later perfused with endothelial cells. In addition, human umbilical vein endothelial cells (HUVECs) were mixed in Matrigel, and printed into a network within alginate. Cells were labelled by live/dead fluorescent stains or labelled by a red cell tracker, and imaged using a fluorescent microscope.

RESULTS: HUVECs after 8-days culture were labelled with live/dead fluorescent stains (Figure 1). A tubule network facilitating the perfusion of HUVECs was printed within alginate (Figure 2).

CONCLUSIONS: The method reported here allows the fabrication of a vascular network at physiological

Figure 1 A stitched image of a printed network with HUVECs embedded in Matrigel (Left). An image of encapsulated HUVECs showing spreading of some cells (Right).

Figure 2 Images of tubule networks embedded in a hydrogel perfused with a protein solution (Left) and HUVECs (Right)

conditions, which is an advance compared to methods in which materials are printed at elevated temperatures unsuitable for cells and biomolecules. The cell-compatible printing environment permits the patterning of the tubule networks which mimic blood vessels, biomolecules and multiple cell types in a single printing process. Future work will look to improve, measure and validate the architecture and function of the engineered vasculature.

ACKNOWLEDGEMENTS: The authors would like to thank the Nottingham Research Fellowship scheme and the ERC Advanced Grant (227845) for supporting this work.

INTRODUCTION

Failure of some blood-contacting medical devices has been associated with thrombus formation initiated by the adsorption of certain blood proteins onto the biomaterial surface. This protein layer can induce complex and interlinked processes, such as activation of the intrinsic coagulation system and adhesion and activation of platelets¹. Biomaterial haemocompatibility can be improved by coating its surface with antithrombotic agents² or with compounds that can adsorb albumin from blood plasma in a selective and reversible way, since this protein is not involved in the coagulation cascade and in platelet adhesion/activation³. This work reports that the immobilization of the thrombin inhibitor D-Phe-Pro-D-Arg-D-Thr-CONH₂ (fPrt)⁴ onto nanostructured surfaces (self-assembled monolayers - SAM) induces selective and reversible adsorption of albumin, delaying the clotting time when compared to peptide-free surfaces.

EXPERIMENTAL METHODS

Peptide: fPrt was synthesized with two glycine residues attached to the *N*-terminus (GGfPrt) to improve its exposure from the surface.

SAMs: Pure solutions of (1-Mercapto-11-undecyl) tri(ethylene glycol) (EG3) and (1-Mercapto-11-undecyl) hexa(ethylene glycol) carboxylic acid (EG6-COOH) were prepared at a concentration of 2 mM in absolute ethanol. Mixtures of EG3 and EG6-COOH-thiols were obtained by mixing the pure solutions in different ratios at final concentrations of 1 mM.

GGfPrt immobilization: SAMs were immersed in a freshly prepared solution of NHS (*N*-hydroxysuccinimide) and EDC (1-(3-dimethylamino-propyl)-*N*-ethylcarbodiimide hydrochloride) at a final concentration of 0.05 and 0.20 M, respectively. NHS-activated SAM were immersed in GGfPrt solution (1 mM) prepared in sodium phosphate buffer (25 mM, pH 8.0) for 24 h at RT and 100 rpm. As control, the same reaction was performed without the peptide. SAM were washed with Milli-Q water and preserved under Argon.

SAMs were characterized by ellipsometry, infrared reflection absorption spectroscopy (IRRAS) and X-ray photoelectron spectroscopy (XPS). Protein adsorption was followed using ¹²⁵I-labelled proteins. The effect of GGfPrt on thrombin proteolytic activity was evaluated by assessing the protease ability to cleave *N*-p-tosyl-Gly Pro-Arg-p-nitranilide and fibrinogen in solution. The anticlotting capacity of the surfaces was evaluated using the recalcified plasma clotting assay.

RESULTS AND DISCUSSION

In solution, GGfPrt was able to inactivate the enzymatic activity of thrombin and to delay plasma clotting time in a concentration-dependent way. After surface immobilization, and independently of its concentration, GGfPrt lost its selectivity to thrombin and its capacity to inhibit thrombin enzymatic activity against the chromogenic substrate. In contrast, immobilized GGfPrt was able to adsorb albumin from plasma in a selective and reversible way (Fig.1).

Fig.1. ¹²⁵I-Labelled human albumin adsorption on different surfaces from pure albumin solution and from 1% human plasma. The percentages designate the reduction of adsorbed albumin due to the presence of plasma proteins.

Surfaces with low concentrations of GGfPrt could delay the capacity of adsorbed thrombin to cleave fibrinogen, but high GGfPrt concentrations induced the procoagulant activity of the adsorbed enzyme. However, all GGfPrt-coated surfaces had a plasma clotting time similar to the negative control (empty polystyrene wells), showing resistance to coagulation, which is explained by their capacity to adsorb albumin in a selective and reversible way.

CONCLUSION

Immobilized GGfPrt avoided the coagulation activation induced by GGfPrt-free SAMs, due to the adsorption of albumin in a selective and reversible way. This work opens new outlooks to improve the haemocompatibility of biomaterials.

Electrochemical deposition of calcium phosphate coatings on Ti6Al4V substrate

Richard Drevet, Nader Ben Jaber, Ahmed Tara, Joël Faure And Hicham Benhayoune

LISM EA 4695, Université de Reims Champagne-Ardenne, France, richard.drevet@univ-reims.fr

INTRODUCTION

Titanium and its alloys are widely used as implant materials in orthopaedic surgery because of their good biocompatibility with bone. However, a way to make them bioactive is to coat them with calcium phosphate ceramics which are able to form a real bond with the surrounding bone tissue *in vivo*. In our laboratory, we are developing an innovative process to produce prosthetic calcium phosphate coatings: electrodeposition¹⁻³.

EXPERIMENTAL METHODS

Electrodeposition is carried out by using a three-electrodes system (the cathode (Ti6Al4V substrate), the counter electrode and the reference electrode, immersed in an electrolyte prepared by dissolving 0.042 M $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ and 0.025 M $\text{NH}_4(\text{H}_2\text{PO}_4)$). We are also developing an original electrodeposition protocol which combines pulsed current mode and the incorporation of hydrogen peroxide (H_2O_2) into the electrolytic solution.

The morphology of the coatings is observed with a LaB6 electron microscope (SEM JEOL JSM-5400LV) operating at 0-30 kV associated to an ultrathin window Si(Li) detector for X-ray measurements (GENESIS, Eloïse SARL, France) and by a standardized method based on XRD (Bruker D8 Advance using a $\text{Cu}_{K\alpha}$ radiation), determining the characteristic Ca/P atomic ratio of these coatings. Moreover, the thermal treatment of the material is optimized under controlled atmosphere to improve the mechanic properties of the coatings and to obtain an appropriate value of their adhesion to the metallic substrate.

On the other hand, the bioactivity of the elaborated coatings is evaluated in a physiological environment by studying firstly their corrosion behaviour (polarization curves and impedance spectroscopy) and secondly by studying the dissolution-precipitation reactions that occur during a prolonged immersion.

Finally, the flexibility of the electrodeposition process is used to uniformly incorporate strontium (an active agent) in the calcium phosphate coating.

RESULTS AND DISCUSSION

The original electrodeposition protocol developed leads to homogeneous and compact calcium phosphate coatings whose chemical composition is controlled. They may consist of a calcium-deficient hydroxyapatite with a variable deficit or of a stoichiometric hydroxyapatite.

After prolonged immersion in physiological solution, we observed the formation of a “bone-like” apatite layer on the surface of the electrodeposited coating.

In the case of calcium phosphate coatings electrodeposited with strontium, we have observed that the incorporation of this element in the coating modifies the proportion of the phases that compose the coating after a suitable thermal treatment.

The elaboration protocol developed allows the modulation of the different behaviours in physiological medium (kinetic of the bone-like layer formation, strontium release in the physiological environment).

CONCLUSION

In this work, we succeeded the synthesis of calcium phosphate coatings by pulsed electrodeposition. The effects of hydrogen peroxide on the stoichiometry of the coating have been demonstrated. The behaviour of the coating in physiological medium has been studied by corrosion tests and by observing the formation of a bone-like layer on the implant surface.

Finally, the original protocol has been used to produce coatings that contain a doping element (strontium) whose release in physiological environment is controlled by the parameters used during the electrodeposition protocol.

INTRODUCTION

Hydrogels from naturally occurring polymers are widely used due to their unique properties, especially regarding the cell environment and morphology similar to the extracellular matrix (ECM) of native tissues.¹ Our aim was to blend alginate (Alg) with keratin (K) extracted from wool. The self-assembly properties of K, and its ability to mimic the ECM were combined with the excellent chemical and mechanical stability and biocompatibility of Alg to produce hybrid hydrogels. The synergistic effects of each blend component were analysed using different techniques. Furthermore, the cell-material interaction was assessed by primary human umbilical vein endothelial cells (HUVECs).

EXPERIMENTAL METHODS

Preparation of hybrid hydrogels

K was previously extracted from merino wool using a reductive treatment. To obtain the hybrid hydrogels, Alg (2%, w/v) was mixed with K (1%, w/v) to prepare blends of 50/50. The hydrogels were obtained by ultrasound treatment under specific conditions.²

Physico-chemical characterization

To study the water uptake (WA), the weight loss (WL), as well as protein release (PR), the blends were immersed in HBSS and DMEM, over 21 days (d). The mechanical properties were performed over time using the dynamical mechanical thermal analysis (DMTA). Measurements were recorded in triplicate.

Cell-material interaction

HUVECs were isolated from freshly collected umbilical cords. 3×10^5 cells/film were seeded onto hydrogels. The culture medium was changed on the day after seeding, and then every 3d. Mitochondrial activity was assessed using the WST-8 assay kit. The viability of cells was determined by live staining with Calcein, AM and the nuclei were visualized by DAPI after 10d.

RESULTS AND DISCUSSION

The physico-chemical characterization of hybrid hydrogels was performed in HBSS or DMEM medium. The addition of K protein leads to a decrease of the amount of WA in the presence of either HBSS or DMEM. This fact can be attributed to the diffusion of water inside the network, which decreases due to the electrostatic and hydrophobic interactions that occur between the K chains and also with Alg molecules. The WL of hybrid hydrogels was lower as compared with Alg. This fact can be related to the sonication treatment: The ultrasound induces the degradation of polysaccharides producing fragments with lower

molecular weight that lead to a decreased stability of the hydrogels.

Table1: Physico-chemical characterization

Material		WA after 3d (%)	WL after 21d (%)	PR after 21d (%)
Alg	HBSS	3372±70	53±9	---
	DMEM	3554±80	57±5	---
Alg/K	HBSS	2269±23	28±6	8±0.9
	DMEM	2288±31	35±2	12±1

Regarding the PR, the amount of protein released over time is low, indicating that a significant quantity of K remained in the material that could enhance cell-material interactions. The DMTA analysis demonstrated a small increase in storage modulus (E') with the increase of frequency and revealed that the blend with K promotes an increase of E' from ≈ 100 to ≈ 400 kPa (evaluated to 10 Hz), indicating that the addition of K increases material stiffness. To investigate the cell-material interactions, the attachment and growth, as well as cell morphology and mitochondrial activity of HUVECs were analysed. The results demonstrated that the cells seeded on the surface of Alg/K hydrogels have a significant increase in mitochondrial activity, and form monolayer, demonstrating the typical cobblestone-like endothelial morphology after 10d of culture.

CONCLUSION

The hydrogels were successfully produced and an extensive physico-chemical characterization was carried out. The cell-material interaction demonstrated that the Alg/K supported cell attachment, spreading and proliferation. Thus, the developed hybrid hydrogels represent a promising candidate biomaterial for tissue engineering and regenerative medicine.

INTRODUCTION

Classical monolayer culture systems are regularly used to determine *in vitro* biocompatibility and mechanism of action of biomaterials and pharmacological agents. However, it is well known that in 2-dimensional (2D) cell culture, primary cells may not fully retain or express the same cell phenotype and biological responses observed in the native tissues. Hence, 2D systems may not truly reflect the *in vivo* activity of a test compound. In contrast, in 3-dimensional (3D) culture systems usually promote retention or permit re-differentiation of the cultured cells and should therefore be more reflective of the native tissue. Nanohydroxyapatite (nHA) pastes have promise as agents for bone augmentation *in vivo*^{1,2}. Therefore, the aim of this study was to compare the biocompatibility of nHA pastes using human bone-derived cells (osteoblastic cell lines, primary osteoblasts) and bone marrow-derived mesenchymal stem cells (MSCs) in 2D and 3D cell culture systems.

EXPERIMENTAL METHODS

Cells: human MSCs and human primary osteoblasts (HOBs) were purchased from Promocell Ltd. The human osteoblastic cell lines Saso2 and MG63 were obtained from Sigma Aldrich.

Cell cultures: 2D cultures: 5×10^4 cells/well were added to 24-well plates and incubated for 48h with nHA pastes [BP1, BP2, OP2a, OP2b (particle sizes 60-70nm) and an injectable, commercially available nHA bone graft material]. For 3D cultures, 2×10^6 MSCs or osteoblastic cells were seeded onto polyglycolic acid (PGA) discs 5mm x 2mm for 72h before incubation with the nHA pastes for 48h.

Assays: Viability of the cell cultures was assessed by measuring reduction of resazurin dye to resorufin using PrestoBlue (Invitrogen). Cellstain (Sigma Aldrich) was used to visualise live and dead cells. Potential cellular uptake of nHA was investigated by transmission electron microscopy (TEM) after exposure of cells to nHA.

RESULTS AND DISCUSSION

Exposure of all cell types to all the nHA pastes (including the commercial nHA graft material) caused a reduction in cell viability which was particularly marked in the 2D cell cultures [For example, cell activity in the presence of BP1 was $29.2 \pm 6.3\%$ (HOB) $16.1 \pm 5.8\%$ (MSCs) $72.9 \pm 29.3\%$ (MG63) and $23.0 \pm 7.0\%$ (Saso-2) of the control values]. The nHAs did not cause any changes in pH or osmolarity of the culture media. Prewashing the nHA pastes did reduce

this apparent toxicity. 3D cultures showed a lower impact of nHA on the cell viability of the cells (For example: MG63 and MSCs exposed to BP1 showed 70-90% cellular activity compared to controls). TEM showed numerous nanoparticles in the cytoplasm of the cultured cells (Figure 1)

Figure 1: TEM image showing hydroxyapatite nanoparticles in the cell after exposure of MG63 cells to BP1. Arrows indicate location of the nanoparticles.

2D cultures exhibited greater toxic effects of the nHA pastes than 3D cell cultures. This may be because of the greater numbers of cells used in 3D models compared to 2D and their phenotype is more reflective of the *in vivo* environment. Interestingly, MSCs and the more mature osteoblastic phenotype (HOB, Saos-2) were more sensitive to the nHA than cells with a more immature osteoblastic phenotype (MG63). The mechanism of the apparent toxicity of the nHAs is unknown but is likely to be a result of the cellular uptake of nanoparticles released by the nHA pastes.

CONCLUSION

We conclude that 3D culture systems may be preferable for the study of *in vitro* biocompatibility of nanoscale materials as they may be more reflective of the reported *in vivo* activities of nHAs^{1,2}.

INTRODUCTION

Staple fibres are added to polymeric materials and cement-based matrices to engineer fibre reinforced composites (FRC) that have superior mechanical properties as compared to pure matrix materials. In the sub-micro- and nano-meter regime, To obtain fibres in the micron- to nanoscale range E-spinning is the method of choice a process that typically yields continuous, oriented or randomly aligned, fibre non-wovens. Therefore, subsequent processing steps are required to cut¹ and unbundle aggregates into free-standing staple fibres of desired length, which can be further dispersed into relevant polymer or inorganic matrices. The goal of the present work was to demonstrate the potential of particle-assisted ultrasonication² to engineer submicron- to nano-metre diameter staple fibres from biopolymers such as PLLA, without any additional chemical pre- or post-treatments. The staple fibres/nanoparticle dispersions were then used to fabricate calcium phosphate-based cements that can be used as bone substitute material.

EXPERIMENTAL METHODS

Bioabsorbable Poly-L-Lactic Acid (PLLA) was electrospun from a solution of 5% (w/w) PLLA in chloroform : DMF : formic acid (8:1:1 w/w). The obtained fibres were further ultrasonicated at low temperatures in the presence of Hydroxyapatite nanoparticles in order to obtain fibres with small aspect ratios. The influence of the dispersion medium, the sonication bath temperature and time on the respective length distribution of the obtained nanofibres was investigated. To manufacture the cement, one part of the resulting particle/fiber precursor was mixed with two parts (w/w) 2.6 M aqueous solution of monocalciumphosphate monohydrate and allowed to react in a cement reaction and allowed to set and harden for 72h.

RESULTS AND DISCUSSION

Electrospinning yielded continuous fibres with diameters in the range of 244 ± 78 nm. The sonication resulted in separation of the fibres and a homogeneous dispersion within the HA particle matrix (Fig. 1a). The resulting staple lengths were in the range between 60 μ m and 39 μ m depending on the bath temperature. With lower bath temperatures shorter fibres were obtained with narrower distributions (Fig. 1b). The resulting set bone void filler composed of Brushite and 5% (v/v) PLLA fibres exhibited an approximately 90% increase

in compressive strength when compared to non-reinforced control cement.

Figure 1: a) SEM micrograph showing staple PLLA fibres sonicated together with HA nanoparticle agglomerates. b) Box plot showing lower temperatures yielding shorter staples fibres with narrower length distributions.

CONCLUSION

Staple PLLA nanofibres were produced by electrospinning and subsequent sonication at low temperatures. Lower temperatures resulted in shorter fibres and narrower length distributions. Increased sonication time resulted in an asymptotic decrease of fibre length and a narrowing of fibre length distribution. The addition of nanoparticles reduced the efficiency of the fragmentation process and fibres with higher average lengths were obtained. Particle-assisted sonication allowed a good distribution of the particles between the nanofibres. This effect further allowed the homogeneous dispersion of the fibre-particle precursor within a HA-based matrix, making the technique suitable for the fabrication of fibre-reinforced cements, demonstrated in this work by successful production of a PLLA-Brushite composite cement with high compression fracture strength. The method presented is thus a promising technique for the fabrication of FRCs with very good mechanical properties, which can be further integrated in biomedical products.

INTRODUCTION

Titanium is a key material for biomaterial applications. Its resistance to corrosion due to the presence of a stable oxide layer and its good mechanical properties make titanium an ideal material for the development of dental and orthopaedic implants as well as for the design of drug delivery devices^{1,2}. With the aim of developing implantable devices an accurate control of the surface device is needed since the surface structural properties modulate the bio-integration process. Recently, large attention has indeed been focussed on the growth and characterization of titanium dioxide layers^{3,4}. In this study we investigate the structural properties of titania mesoporous layers grown by anodic oxidation in order to correlate the growth conditions with the resulting surface layer structure.

EXPERIMENTAL METHODS

Mechanically polished titanium sheets were electrochemical oxidized by: i) anodic spark deposition (ASD) in 1M H₂SO₄ or 1.5 M H₃PO₄ for 1 min at voltages ranging from 70 V to 150 V; ii) anodization in 1M H₂SO₄/0.5%wt HF for 20 min at 20V. Oxidized samples were thoroughly rinsed with Milli-Q water and dried.

Titania surfaces were analysed by Tapping Mode Atomic Force Microscopy (TM-AFM), Scanning Electron Microscopy (SEM) and Raman Spectroscopy (RS).

RESULTS AND DISCUSSION

Titania layers grown by ASD in both H₂SO₄ or H₃PO₄ solutions are characterized by a mesoporous structure. Typical SEM and AFM images of this typology of samples are reported in Fig. 1a and b.

Fig. 1. a) SEM image and b) AFM image of a TiO₂ surface prepared by ASD in 1M H₂SO₄.

The typical pore diameter varies from 100 nm up to 400 nm when the anodization potential is increased from 70 V to 150 V.

Titania layers grown by anodic oxidation in H₂SO₄/HF solution are characterized by a nanotubular structure as shown in Fig. 2.

Fig. 2. a) SEM image and b) AFM image of a TiO₂ surface prepared by anodic oxidation in H₂SO₄/HF solution.

Nanotubes are found to have an average inner diameter of about 80 nm and an average wall thickness of about 30 nm.

Raman spectroscopy measurements on the TiO₂ surface indicate the ASD grown oxide layers are characterised by the anatase phase.

CONCLUSION

We investigated the influence of the anodic oxidation conditions on the structural properties of the resulting TiO₂ layers. The possibility of tailoring the TiO₂ surface structure makes this system interesting for biomaterial development.

Characterisation of DNA Interactions with Cationic Polymer Brush

Mahentha Krishnamoorthy* and Julien Gautrot

School of Engineering & Materials Science, Queen Mary, University of London, UK

*m.krishnamoorthy@qmul.ac.uk

INTRODUCTION

Polymeric nanoparticles adsorb or encapsulate oligonucleotides/gene and act as sustained release matrices for genetic drugs. Poly (2-(dimethylamino) ethyl methacrylate), PDMAEMA, is a cationic polymer known for its efficiency in gene transfection as a non-viral gene delivery vector¹. It has the ability to condense DNA and form complexes to allow efficient uptake via endocytosis. However, the homopolymer's high cytotoxicity prevents it from being used in gene therapy. The physicochemical properties of the vector is crucial for controlling gene delivery as is indicated by several independent reports however there isn't one system that allows the control of all these parameters hence the focus of this work is to develop such a system.

EXPERIMENTAL METHODS

We developed a cationic system, using surface-initiated polymerisation, to understand and control the physicochemical properties (chemistry, charge, architecture, size & shape) and biopharmaceutical behaviour of the gene delivery agent, and its interaction with cells.

DNA interaction studies were performed to characterise the particle-DNA complexes formed at various N/P ratios via dynamic light scattering, zeta potential measurement and surface plasmon resonance. This also allowed us to probe the strength and reversibility of polymer brush/DNA binding².

RESULTS AND DISCUSSION

Characterisation of DNA interactions showed that a change in the N/P ratio affected the charge and size of the complexed system, with DNA being condensed well at equal ratio, causing aggregation at an intermediate N/P ratio or having very little effect at a higher N/P ratio.

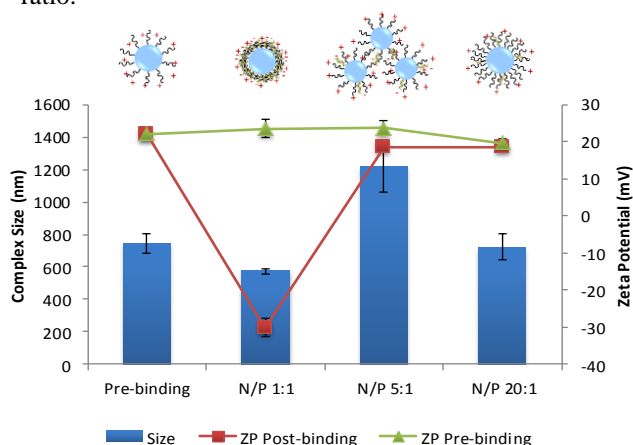

Figure 1 shows changes in complex size and zeta potential (ZP) before and after DNA binding with

PDMAEMA-grafted silica nanoparticles at varying N/P ratios.

Figure 2A is an SPR sensorgram trace which shows DNA binding following a 2-step injection, washed with HBS, B) shows changes in the association and dissociation phase of DNA to PDMAEMA brush when injected with pH 9 (blue) and pH 5 (red) HBS buffer.

The SPR results confirmed that there was indeed binding of DNA to PDMAEMA brush and the interaction is relatively strong as DNA remained following the washing step. Increase in pH significantly affected the interaction and it was also observed that the DNA could recurrently interact with the brush.

CONCLUSION

Our results show that there are very strong and stable interactions between PDMAEMA and DNA which raises the question of whether the polymer brush could be a good candidate for releasing DNA once the complexes enter the cell. In this respect, we have been investigating complex-cell interactions, gene delivery and expression efficiency as well as the origin of PDMAEMA cytotoxicity and the influence of N/P ratios on cells. Lower cytotoxicity, reduced immunogenicity and better gene delivery can lead to the cationic vector's use in clinical applications.

Physicochemical Characterization and *In Vitro* Hemolysis Evaluation of UV Poly(ethylene glycol) Hydrogels

M. Flores-Reyes¹, J. Flores-Estrada², M.V. Dominguez-Garcia³, M.S. Camarillo-Romero³, M.V. Flores-Merino^{3*}

¹Faculty of Medicine, Autonomous University of the State of Mexico (UAEM), Mexico

²Faculty of Chemistry, UAEM, Mexico

^{3*}Research Center in Biomedical Science, UAEM, Mexico, mvfloresm@uaemex.mx

INTRODUCTION

Hydrogels are polymeric tridimensional networks attractive for numerous biomedical applications^{1,2}. A commonly used method for hydrogel synthesis is photopolymerization, which is employed in regenerative medicine applications (i.e. cell encapsulation, blood contact devices, etc...). Irigacure 2959, the most frequently used photoinitiator, displays different toxicity depending on cell type³. Therefore, efforts are focused on studying novel hydrogel systems and photoinitiators to improve performance of biomaterials. Here, a facile synthesis of poly(ethylene glycol) (PEG) hydrogels using a photoinitiator scarcely reported for polymers and not described for polymer network formation was studied. Physicochemical properties and *in vitro* hemolysis, most common method to determine the hemocompatibility properties of biomaterials⁴, was evaluated.

EXPERIMENTAL METHODS

Hydrogel preparation. Poly(ethylene glycol) dimethacrylate (PEGDM) was obtained by microwave synthesis (700 watts, 6 minutes; Daewoo) of linear PEG (MW = 4000 g.mol⁻¹; Polioles, MX) and methacrylic anhydride (Sigma-Aldrich, USA). Hydrogel was prepared by long wavelength UV light photoinitiated free radical polymerization of aqueous solutions of PEGDM and α , α' -azodiisobutyramidine dihydrochloride (Sigma-Aldrich, USA).

Physicochemical characterization. Chemical structure and bulk reaction kinetics of PEGDM and PEG hydrogel were analyzed by FTIR, the test was done by triplicate. Swelling behavior was studied by gravimetry of previously dried cylindrical samples of hydrogels (n = 9) until equilibrium was reached in a phosphate buffer saline solution (PBS; pH = 7.4).

Biological characterization. Direct *in vitro* hemolysis assay was performed based on ISO 10993-4 (1992). Briefly, sterile PEG hydrogel samples were incubated in a solution of human red blood cells (RBC; 5 %) obtained from blood samples of healthy volunteers. UV spectrophotometry was used to measure the percentage of hemolysis. All incubations were performed twice with different donors and triplicate sets of samples in parallel (n = 6). The authors certify that all research involving human subjects was done under full compliance with all government policies and the Helsinki Declaration (2013).

RESULTS AND DISCUSSION

A PEG hydrogel was obtained by photopolymerization (Fig. 1A). Quantitative hemolysis by UV

spectrophotometry (data not shown) and qualitative (Fig. 1B) analysis showed that samples are compatible (<5% hemolysis). Hydrogel reached equilibrium at 12h with a maximum swelling ratio of 4.55 ± 0.7 (Fig. 1C).

Figure 1. PEG hydrogel. A) Photograph after 10 min photopolymerization of solutions of PEGDM and photoinitiator, B) qualitative hemolysis assay (5% human RBC, 60 min incubation, 37 ± 1 °C) C+ and C- = positive and negative control and C. weight swelling behavior in PBS of dried cylindrical samples at room temperature (n=9).

CONCLUSION

A PEG hydrogel was prepared using a single molecule system for the photoactivation and initiation of the crosslinking reaction. The synthesis reported in this work is a simple but useful method to obtain polymer networks. *In vitro* hemolysis study as initial biocompatibility assay, showed that PEG hydrogel is hemocompatible. This hydrogel is a promising biomaterial for blood contact or tissue engineering applications.

Gold-Containing PMMA Microspheres. A Route to New Highly Radiopaque Cements for Vertebroplasty

Leo H. Koole^{1,*}, Keti Saralidze¹, Eva Jacobs², Alex Roth², and Paul Willems²

¹Department of Biomedical Engineering/Biomaterials Science, Faculty of Health, Medicine & Life Sciences, Maastricht University, PO Box 616, 6200 MD Maastricht, The Netherlands. ²Department of Orthopedic Surgery, Maastricht University Medical Centre Plus, Maastricht, The Netherlands. l.koole@maastrichtuniversity.nl

INTRODUCTION

Vertebroplasty is a minimally invasive procedure to treat or to prevent vertebral compression fractures. There are two major indications: (i) age-related osteoporosis, and (ii), after minimally invasive removal of an osteolytic tumor, which had grown inside the vertebra. In essence, vertebroplasty is the injection of a cement, either into the osteoporotic voids, or into the cavity that is left after tumour removal. During injection, the cement is a soft dough, which is formed by mixing poly(methyl methacrylate) (poly(MMA)) microspheres and MMA. The material hardens *in situ*, and then augments the vertebra. Vertebroplasty cements bear a clear resemblance with bone cements for hip and knee arthroplasty. A major difference, however, is that cements for vertebroplasty must exhibit a much higher level of X-ray contrast. Hence, they contain a large portion of the contrast agent BaSO₄ (up to 30 % by mass, vs. 8 % for hip/ knee bone cements). This affects the physical-mechanical properties of the vertebroplasty cements. The contrast agent influences the flow characteristics of the cement in the dough phase (i.e. between 5 – 12 min after cement mixing). The high content of BaSO₄ may also lead to increased risk for leaching of Ba²⁺ ions *in situ*, which can cause local osteolysis.

Here, we describe a new highly radiopaque bone cement that does not contain BaSO₄. The X-ray contrast is introduced by gold (Au) microparticles; these are incorporated into the PMMA microspheres of the powder phase. The embedded Au particles produce excellent X-ray contrast and favourable rheological characteristics of the cement dough.

EXPERIMENTAL METHODS

PMMA microspheres incorporating Au microparticles were prepared in a suspension polymerization reaction. Inclusion of the Au particles was not trivial; details of the process will be outlined. The PMMA/Au particles are isolated, purified, size-sorted, and mixed with dibenzoyl peroxide. The powder was mixed with MMA; the resulting dough, as well as the hardened cement during were evaluated in several respects.

RESULTS AND DISCUSSION

Figure 1 shows a polished sample of the hardened new cement, observed with backscattered scanning electron microscopy. Poly(MMA) appears black, the gold particles are seen as white spots. Note that the gold particles are located in dispersed circles; these are the microspheres that first formed the powder part of the cement. The dark material around the microspheres is the *in situ* polymerized poly(MMA).

Figure 1. Scanning electron micrograph (backscattered mode) of the gold-containing cement after hardening. The gold particles are seen as white dots in dispersed circles. Bar = 200 micrometer.

Injectability of the doughs of the new cement, and of a commercial counterpart cement (BaSO₄) was studied. A comparison with a commercial cement was made, using fresh frozen human osteoporotic vertebrae. The experiments confirmed that the new cement flows easier through the needle, and penetrates deeper into the pores within the vertebrae. This can be explained by the fact the gold particles are *in* the microspheres, whereas the BaSO₄ crystals are grouped *around* the microspheres.

CONCLUSION

The new gold-containing bone cement exhibits promising properties due to the fact that X-ray contrast agent is incorporated in PMMA microspheres. This leads to improved rheology of the cement dough, and avoidance of contrast leakage. Further studies on this new biomaterial are warranted.

A biomimetic micro-environment, resembling the natural trabecula, is obtained thanks to the Direct laser Writing approach. This structure has been evaluated *in vitro* in terms of bone-like cells differentiation, demonstrating an enhancement of the osteogenesis on the proposed scaffolds.

INTRODUCTION

Several cell behaviors, such as adhesion, survival, proliferation and differentiation depend on the physical and chemical extracellular micro-environment. Different bioinspired approaches have been proposed to artificially recapitulate this microenvironment, in order to regulate cell fate and to foster the appropriate functions *in vitro*.

In the latest years, increasing interest towards the Two-Photon Polymerization (2pp) technique is arising among the scientific community. Particularly, 2pp was found to be an intriguing tool for the fabrication of 3D structures aimed at fostering cell behaviours,¹ and at the investigation of cell-substrate interactions.²

In this work, we propose to recreate *in vitro* the 3D micro-environment of the bone, taking inspiration from the X-ray μ -CT scans of human trabecular bone, in order to improve the osteogenic differentiation of bone progenitor-like cells.

EXPERIMENTAL METHODS

Fabrication of 3D trabecular-like structures through slice-by-slice 2pp technique.

The biocompatible ceramic-like resistOrmocomp was used for the photo-polymerization of the biomimetic structures, by using a Direct Laser Writing (DLW) system (Photonic Professional, Nanoscribe GmbH).

Cell culture and differentiation on the 3D structures and on flat control substrates.

SaOS-2 human osteosarcoma-derived cell line (ATCC HTB-85) was adopted as bone-cell progenitor model. The differentiation protocol consisted in a 4-days treatment with osteogenic factors (10 mM β -glycerophosphate, 100 nM dexamethasone, 50 μ M ascorbic acid). Immunostaining toward Ki-67 (Millipore) was performed to label nuclei of proliferating cells, and OsteoimageTM bone mineralization assay (Lonza) was used to detect the amount of the hydroxyapatite deposits secreted by SaOS-2 cells during the osteogenesis progression. Cells were imaged through an inverted fluorescence microscope (Nikon).

Statistical analysis

Data were analyzed through the non-parametric Kruskal-Wallis test in order to compare the different distributions; p -values < 0.05 were considered significant.

RESULTS AND DISCUSSION

After 4 days since the osteogenesis induction, we observed a decrement of the Ki-67⁺ nuclei of cells differentiating on the artificial trabeculae ($50.0 \pm 6.6\%$) with respect to cells on flat control substrates ($64.5 \pm 4.8\%$, $p < 0.05$), so indicating a promotion of the exit from the cell-cycle when SaOS-2 are differentiated on the trabeculae-like structures.

Furthermore, we detected a remarkable increment of the hydroxyapatite deposits secreted by the SaOS-2 cells differentiated on the trabecular-like structures (84 ± 29 HA deposits, which covered $16 \pm 9.0\%$ of the surface area) compared to control substrates (3.0 ± 1.7 HA deposits, which covered $0.94 \pm 0.34\%$ of an analogous surface area; Figure 1).

Figure 1: nodules of hydroxyapatite deposited during the osteogenic differentiation of SaOS-2 cells grown on flat control substrate (a) and on the 3D artificial trabeculae (b). In green, HA deposits; in blue, nuclei. Scale bar: 100 μ m.

All these results indicate as the presence of the physical micro-environment represented by the 3D bioinspired trabecular-like structures is able enhance the *in vitro* osteogenic differentiation. The observed phenomenon could be triggered by several different factors, such as the 3-dimensionality of the micro-environment, the biomimetic shape of the artificial trabeculae, the high stiffness of the ceramic material and/or by a combination of all of these mechanical cues.

CONCLUSION

Our findings open new perspectives in the exploitation of 2pp as an innovative tool for the design and the fabrication of biomimetic 3D micro-environments able to control cell behavior, with important outcomes in tissue engineering, regenerative medicine, and, more generally, in the study of bio/non-bio interactions.

Understanding material properties of 3D poly(ϵ -caprolactone)-based ternary composite scaffolds responsible for highly improved colonization by Human Bone Marrow Mesenchymal Stem Cells

J. Idaszek^{1*}; A. Bruinink²; J. Rębiś¹; V. Zell²; W. Świąszkowski¹

INTRODUCTION

Fused deposition modeling (FDM) is one of the most popular techniques among the Rapid Prototyping family. FDM is based on extrusion of molten polymer fibres in a layer-by-layer fashion and enables fabrication of scaffolds with precisely controlled architectures. Poly(ϵ -caprolactone), PCL, is a FDA-approved bioresorbable polyester, which due to excellent processability exhibits great compatibility with the FDM technique¹. However, PCL suffers from low stiffness and relatively long degradation rate². In order to overcome those drawbacks we fabricated in our laboratory a series of PCL-based ternary composite scaffolds. Our approach resulted not only in increased mechanical properties and accelerated degradation, but also in highly improved cellular response measured by means of a novel 3D cellular test set-up, namely multicellular spheroids³. The aim of this study was to investigate surface wettability, roughness and energy of the PCL-based composite scaffolds in order to understand relationship between those properties and the improved colonization by cells migrating out of multicellular spheroids.

EXPERIMENTAL METHODS

Porous scaffolds with compositions given in Table 1 were fabricated by means of FDM device (Syseng). Surface roughness (R_a) was measured using optical profilometer (Veeco Wyko 9300). The scans were performed at magnification of 40.5x in a Vertical Scanning Interferometry (VSI) mode. Water contact angle (WCA) was determined using a sessile drop method by means of a goniometer (Contact Angle System OCA, Dataphysics). The surface wettability was measured on solvent cast films. Multicellular spheroids were formed of vitally labelled primary human bone marrow mesenchymal stromal stem cells (HBMC) according to Idaszek *et al.*³. Images of the cultures were taken after 7 days of incubation using a fluorescent microscope (Axio Imager M1, Zeiss).

Table 1. Composition of the prepared materials. TCP- Tricalcium Phosphate; PLGA- Poly(lactide-co-glycolide)

Name	PCL (wt %)	TCP (wt %)	PLGA (wt %)
PCL	100	0	0
PCL-TCP	95	5	0
Ter_25	70	5	25

RESULTS AND DISCUSSION

Both, surface wettability and roughness were strongly influenced by addition of PLGA. The R_a of ternary composite Ter_25 increased by 90% and WCA was reduced by 10°, if compared to neat PCL. Figure 1 depicts WCA plotted against surface area colonized by HBMC. We found a linear relationship between wettability and outgrowth of cells out of multicellular spheroids ($R^2 = 0.9777$). However, the surface colonization was not proportional to the R_a and surface energy. The improved bioacceptance could be a result of increased adsorption of cell adhesion-mediating proteins, which is maximal at surfaces with WCA around 70°⁴.

Figure 1. Surface area colonized by HBMC after 7 days in culture as a function of water contact angle.

CONCLUSION

Surface wettability can be modified by addition of PLGA and has a strong effect on cytocompatibility of PCL-based composites.

The vascularization of porous calcium phosphate ceramics: an in vitro and in vivo study

Ying Chen¹, Xiangdong Zhu¹, Yujiang Fan¹, Xingdong Zhang¹

¹National Engineering Research Center for Biomaterials, Sichuan University, People's Republic of China
constanceyin@sina.com

INTRODUCTION

Bone defect is one of the major diseases threatening human health, and treat for large volume of bone defects is still a challenging clinical problem. Recent studies had confirmed that osteoinductive porous CaP ceramics without addition of any growth factors or cells could have the equivalent repair effect on healing the large bone defects of animals with autologous bone grafts. Angiogenesis is considered essential to fracture healing.

In the present study, we chose the CCD-18Co human fibroblasts (HFs) and human umbilical vein endothelial cells (HUVECs) as cell models, and investigated the effect of various porous CaP ceramics with similar porous structure and different phase composition on proliferation and angiogenic factors secretion of the two types of cells by in vitro cell culture. Also, the role of the conditioned media collected from these cells in enhancing HUVECs proliferation and tubule formation was evaluated. In addition, we selected an intramuscular implantation model in mice, which was used to evaluate ectopic bone formation of porous CaP ceramics in our previous study, to investigate the neovascularization of the ceramics. Meanwhile, temporal gene expressions of the key angiogenic factors of the cells ingrowth into the inner pores of the ceramics were analyzed.

EXPERIMENTAL METHODS

In vitro experiments: Cell lading and culturing, MTT assay, CLSM, in vitro angiogenesis assay, NO staining assay, Quantitative real-time polymerase chain reaction (qRT-PCR).

In vivo experiments: Implantation of the porous ceramics in mouse muscle pouch, SEM, HE, Immunohistochemical Staining Analysis (IHC), Microvessel Density (MVD), Quantitative real-time polymerase chain reaction (qRT-PCR).

RESULTS AND DISCUSSION

Fig. 1 Photomicrographs of HE staining for the decalcified sections of porous CaP ceramics implanted into the thigh muscles of mice. At the 4th week, completely mature blood vessel networks had formed within the ceramics

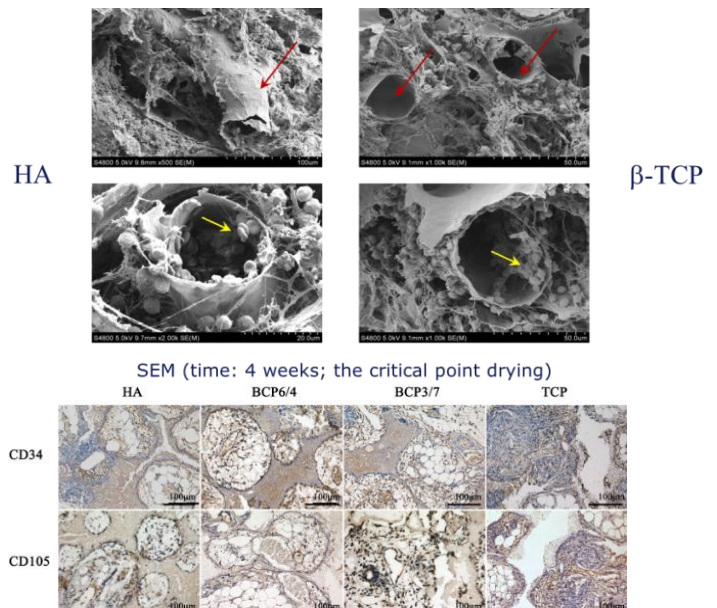

Table Comparison of MVD determined using monoclonal antibodies against CD34 or CD105 in porous CaP ceramics implanted into the thigh muscles of mice

Groups	No. of cases	Microvessel counts (mean \pm SD) using antibodies to	
		CD34	CD105
HA	12	7.58 \pm 2.87	5.67 \pm 3.58
BCP6/4	12	11.67 \pm 3.89	8.91 \pm 3.77
BCP3/7	12	19.58 \pm 4.10*	14.75 \pm 5.37*
TCP	12	15.17 \pm 4.17*	13.83 \pm 4.59*

CONCLUSION

The vascularization of CaPs was related to the factor secretion of HFs and HUVECs. Different chemical compositions of CaPs could lead vascularization to varying levels, among which β -TCP phase was more conducive to the generation of new blood vessels.

INTRODUCTION

A great number of devices are applied in orthopaedics, including surgical intra-operative guides and instrumentations, screening equipment accessories, ranging from hand tables and head supports to cantilevered angiography and full body CT cradles. In this study we present an investigation of the influence of steam sterilization on micromechanical properties. The effect of widely-used steam sterilization multiple processes on the micromechanical properties of the composite, particularly in the interphase region between the polymer matrix and the reinforcing fibers, was studied by nanoindentation.

EXPERIMENTAL METHODS

A composite material was prepared on the basis of ARAMID balanced fabric reinforcement and polydimethylsiloxane (PDMS) matrix. The mechanical properties were measured before sterilization and after 100 sterilization process periods. An autoclave for steam sterilization (134°C, 304 kPa, 10 min) was used for this purpose. After sterilization, a cross-section area of the specimens was polished according to the polishing protocol by Godara et al.¹. The assessment of the influence of multiple sterilization cycles on the mechanical properties of the composites (reduced elastic modulus E_r [GPa]) was studied using the Hysitron TriboIndenter™ TI 950 nanomechanical instrument. For each tested composite sample, indents were applied on three 25x25 µm areas where the fibers were perpendicular to the polished surface as a matrix of 5x5 indents.

RESULTS AND DISCUSSION

Representative reduced elastic modulus–contact depth relationship obtained from the indentation tests (no sterilization treatment) is illustrated in Figure 1.

Figure 1 Some representative indentation responses showing the reduced elastic modulus (E_r) of the composite sample

In this figure, the three different regions (fiber, interphase zone, and bulk matrix) are schematically indicated according to the indentation depth values. The matrix/fiber interphase region was investigated (Figure 2). The zones identified as interphase regions show different mechanical property values after application of the sterilization cycles. The 100 times steam-treated specimens show a trend toward a reduced elastic modulus value, indicating a modification in the properties of the PDMS matrix in this region. This decrease can be estimated to be equal to approx. 30% in comparison with the untreated samples. Nanoindentation analyses verified the findings of an assessment of the impact of multiple sterilization processes on the inner structure of composites carried out by Suchý et al.² at flexural tests.

Figure 2 Mean values of reduced elastic modulus with confidence intervals ($p=0.05$) of investigated regions. * denotes statistically significant differences in the case of comparison of each region before and after sterilization treatment (Mann-Whitney test, $p=0.05$)

CONCLUSION

The results of nanoindentation analysis of an ARAMID/PDMS composite provided an assessment of the influence of multiple sterilization processes on the inner structure of the studied composite. The steam-treated specimens show a trend toward a reduced elastic modulus value in the fiber/matrix interphase region, indicating weakening of the bond between fibers and matrix after application of multiple sterilization cycles.

Fabrication of a Bone Graft Substitute based on a Pre-set Bioactive Glass-Ionomer Cement

Altair Contreras¹, Paul V. Hatton¹, Ian Brook¹, Abigail Pinnock¹ and Cheryl A Miller¹

¹Bioengineering & Health Technologies Research Group, School of Clinical Dentistry, University of Sheffield, UK

INTRODUCTION

Bioactive glasses based on 45S5 have been used as bone graft substitutes with some success¹. However calcium phosphates, dominate the medical market due to their excellent biocompatibility, but they have a complex setting chemistry and are difficult to handle clinically. On the other hand, glass ionomer cement systems are widely known, and a recent patent describes the fabrication of glass ionomer cements (GICs) where the glass component is based on Hench's 45S5 bioactive glass². Therefore, the aim of this research was to fabricate and characterise a granule prototype prepared from the aforementioned bioactive glass ionomer cement (BGIC). If successful, the resulting medical device could potentially combine the excellent biocompatibility of set GICs with the advantages of bioactive glasses, addressing current clinical needs.

EXPERIMENTAL METHODS

Glass based on 45S5 composition was prepared by a melt-quench route. X-ray diffraction (XRD) was used to assess glass formation, and post-melt composition was investigated using X-ray fluorescence (XRF). Scanning Electron Microscopy (SEM) was used to characterise the granules morphology and presence of a porous structure by Micro Computed Tomography (μ CT). Glass frit was processed to obtain particles of $< 45 \mu\text{m}$. Cement granules were prepared by mixing glass, calcium carbonate powder (5% weight), 45k Mw poly(acrylic) acid (Advanced Healthcare Ltd) and an aqueous solution of phosphoric acid (50% w/v). The resultant material was left to age at 37°C . Granules were obtained by grinding and sieving to achieve particle sizes ranging from 0.5 to 1.0 mm, which is commonly used in commercial bone grafting products. The *in vitro* response of MG63 cells cultured on the granules (50 mg and 100 mg) and Tissue Culture Polystyrene was investigated using Presto blue assay.

RESULTS AND DISCUSSION

The amorphous nature of the glasses was confirmed by XRD. It was possible to produce stable granules in media at 37°C under the conditions described above.

XRF showed good correlation between the theoretical and experimental composition values. SEM showed that the obtained granules have irregular shapes and surfaces while μ CT indicated the presence of a porous internal structure. *In vitro* studies showed a reduction in the metabolic activity of cultured cells in the presence of the granules compared to Tissue Culture Polystyrene, possibly due to the rapid release of alkaline ions from the glass.

Figure 1. (a) SEM micrograph and (b) μ CT image of the prototype granules produced from the preset BGIC.

CONCLUSION

It was concluded that it was possible to prepare novel bone graft substitutes based on bioactive glass-ionomer cement technology i.e. using only 45S5 based glass composition in combination with poly(acrylic acid) and a phosphoric acid solution. Future work includes testing with other bioactive glass compositions and application of alternatives fabrication methods to improve granule morphology.

INTRODUCTION

Development of 3D scaffolds for guided tissue regeneration (GTR) is still a major goal in tissue engineering. Rapid prototyping (RP) allows precise fabrication and customization of 3D scaffolds for tissue regeneration.

EXPERIMENTAL METHODS

In this work, novel biphasic scaffolds combining polylactic acid (PLA) and biodegradable CaP glass were made by additive manufacturing, giving 3D structures with pores of $165 \pm 5 \mu\text{m}$, struts of $70 \pm 5 \mu\text{m}$ and having 70% porosity. The aim of the present study was to evaluate the *in vivo* behaviour of these scaffolds in the subcutaneous tissue of mice. Explanted tissue was evaluated by histological analysis and established histomorphometrical methods, focusing on early and late inflammatory responses for up to 30 days of implantation. Polylactic acid (PLA) and biodegradable (PLA/CaP glass) were used as controls.

RESULTS AND DISCUSSION

The results of the study revealed that all materials underwent marked tissue integration. PLA mainly induced mononuclear cells and remained stable over the study period, while the tissue reaction to PLA/CaP glass was predominantly characterized by the presence of TRAP-positive multinucleated giant cells and was associated with a faster material degradation over time. The biphasic group induced a combination of both

above-mentioned tissue reactions. Its PLA-side remained as a stable matrix, while the PLA-CaP glass aspect underwent a comparably faster biodegradation. The present study revealed that biphasic materials could play a key role in GTR, as they combine both stability and biodegradative characteristics.

Emotions	women	Men
----------	-------	-----

CONCLUSION

Materials based on combination of polylactic acid (PLA) and biodegradable CaP could find application particularly in the regeneration of maxillofacial defects, as in these locations materials should prevent soft tissue ingrowth, while acting as osteoconductive matrices for bone regeneration.

Cobalt alloy specific regulation of bone remodelling via HIF: a cause of aseptic orthopaedic implant failure?

Yutong Li, Johannes Staufenberg, Jay Mashari, Divyahline Logitharajah and Gavin Jell

Division of Surgery & Interventional Science, UCL, Royal Free Campus, London, UK, rmhklif@ucl.ac.uk

INTRODUCTION

The biological response to orthopaedic implant wear debris is the principle cause of peri-prosthetic osteolysis and aseptic loosening¹. Cobalt ion (Co^{2+}) containing orthopaedic implants have higher aseptic failure rates (~14% in 7 years) compared to other implant materials such as titanium (~4.1% over 7 years)². We hypothesise that this higher aseptic failure rate is partly due to Co^{2+} causing inflammation and altering bone remodelling dynamics via the hypoxia inducible factor (HIF) pathway. Co^{2+} has been previously reported to stabilise HIF at concentrations present in the peri-prosthetic tissue of failed implants (1-500 μM)³. Here we investigate the effects of the median reported Co^{2+} concentrations present in the peri-prosthetic on osteoclast formation, osteoblast proliferation and macrophage activity.

EXPERIMENTAL METHODS

Clinically relevant concentrations of Co^{2+} , Ti^{4+} , Cr^{3+} and CoCr ions were used in culture over 6 days. Osteoclast (RAW264.7) formation was determined using Tartrate-Resistant Acid Phosphatase (TRAP) assay and Phalloidin fluorescence microscopy. Osteoblast (SaOs-2) proliferation (total DNA) was determined over the same period. Macrophage (RAW264.7) phagocytic activity was determined using fluorescent particles (pHrodoTM Bioparticles[®], Molecular Probes[®]).

RESULTS AND DISCUSSION

Co^{2+} increased ($P<0.001$) osteoclast formation in the absence of osteoclast differentiation factor RANKL (Fig.1), whilst decreasing osteoblast proliferation (Fig.2)

(Fig.1) whilst decreasing osteoblast proliferation (Fig.2) and increasing the phagocytic activity of macrophages ($P<0.001$). Co^{2+} in the presence of RANKL further augmented osteoclast formation compared to RANKL alone (a 300% increase). The decrease in osteoblast proliferation at Co^{2+} 12.5 μM was similar to that observed to osteoblast cultured in 1% O_2 conditions (hypoxia). As Co^{2+} increased there was a further reduction of osteoblast proliferation (25 and 50 μM).

Figure 2. Co^{2+} [above 6.25 μM] and hypoxia (H) reduces osteoblast proliferation in a concentration dependent manner. *= $p<0.05$.

The increased osteoclastogenesis and decreased osteoblast proliferation may contribute to bone resorption leading to aseptic loosening of the implant. Our results showed that Co^{2+} acts via hypoxia pathway corresponding with previous studies⁴. Furthermore, the increase in the phagocytic activity of macrophages in the presence of Co^{2+} may be important in wear particle uptake *in vivo* and the perpetuation of the inflammatory environment present in the peri-prosthetic tissue. Previous studies have shown that Co^{2+} wear debris stabilises HIF-1 α and increases the expression of pro-inflammatory factors *in vitro*⁵ and *in vivo*^{5,6} but this is the first study demonstrating a direct role on bone remodelling. Further studies are currently being completed on confirming the role of HIF in this process using siRNA and HIF-1 α inhibitory chemicals.

CONCLUSION

Co^{2+} ions present in the peri-prosthetic tissue may play an important role in aseptic loosening of CoCr orthopaedic implants by increasing osteoclast formation whilst inhibiting osteoblast via hypoxia pathway. Increased osteolysis promotes aseptic orthopaedic implant failure. These results raise important questions about the use of cobalt in orthopaedic implant manufacturing.

Trimethyl Chitosan-Based Nanoparticles Intracellular Trafficking and Transfection: a Bioimaging Study

Aida Varela-Moreira^{1,2}, Carla Pereira Gomes^{1,3}, Maria Gomez-Lázaro¹, Pedro Miguel Moreno¹, Ana Paula Pêgo^{1,3,4}

¹INEB - Instituto de Engenharia Biomédica, Universidade do Porto, Portugal; ²Faculdade de Medicina, Universidade do Porto, Portugal; ³Faculdade de Engenharia, Universidade do Porto, Portugal; ⁴Instituto de Ciências Biomédicas Abel Salazar, Universidade do Porto, Portugal. aida.moreira@ineb.up.pt

INTRODUCTION

Trimethyl chitosan (TMC) recently emerged as a promising gene delivery vector for biomedical applications. Due to the quaternization of the primary amines, chitosan (CH) acquires a permanent positive charge, thus solubility under physiological conditions (pH 7.4)¹, overcoming its low transfection efficiency. One key issue when using materials for biomedical applications is the biodegradation and the fate of the resulting by-products. CH enzymatic biodegradation occurs between acetylated monomers being the degree of acetylation (DA) the main parameter affecting biodegradation². In this work, we explored the impact of the DA on the enzymatic degradation and biological properties of TMC-based nanoparticles, mainly stability, internalization and transfection efficiency.

EXPERIMENTAL METHODS

TMC with a Mn 43.3 kDa, 11% DA and 30% DQ (degree of quaternization) (TMC₁₁) was used to prepare TMC/DNA complexes with different N/P ratios (moles of quaternized amines/moles of phosphate groups) (1 to 15), in 20 mM HEPES buffer with 5% (w/v) glucose at pH 7.4. CH with similar Mn and DA was used as control. In order to vary the DA, the original TMC was deacetylated and subsequently re-acetylated. To evaluate TMC nanoparticles enzymatic degradation with different DA's, a competition assay previously setup in our team was used³. The influence of the DA on TMC-nanoparticles internalization and intracellular localization was evaluated by Imaging Flow Cytometry (ImageStream^X Amnis, Millipore) at different time-points (0.5h to 24h) on ND7/23 cells. Finally, the impact of nanoparticle biodegradation on transfection efficiency was assessed 72 h post-transfection, using GFP as a reporter gene.

RESULTS AND DISCUSSION

The original TMC₁₁ was successfully deacetylated (DA 2%, TMC₂) and subsequently acetylated (DA 17%, TMC₁₇), with no significant alteration of the polymer molecular weight. TMC-DNA complexes were efficiently prepared, with an average diameter between 160 nm and 200 nm irrespectively of the N/P ratio and polymer DA. The enzymatic degradation profile of the TMC-nanoparticles was found to be in accordance to what is described in the literature for TMC solutions: a higher DA leads to a higher degradation rate of the polymer. Moreover, comparing the degradation profile of TMC₁₁ with CH₁₁, we observed a higher degradation rate of TMC₁₁ nanoparticles despite having the same DA. The internalization efficiency of the prepared nanoparticles was evaluated by imaging flow cytometry. Using this novel technique, we are able to not only determine the % of cells with nanoparticles but also discriminate to which cell compartment the

nanoparticles are associated to, which represents an advantage over the classical flow cytometry-based internalization studies. Over a period of 24 hrs, CH-based nanoparticles are internalized in a steadily fashion. For TMC nanoparticles, 80% of the cells had already internalized nanoparticles after 4h of contact. Although between different TMC's the overall internalization was equal, the % of membrane bound nanoparticles was higher in the TMC₂ nanoparticles, comparing to TMC₁₁ and TMC₁₇. By staining the nuclear DNA with DRAQ5, we were able to evaluate when pDNA (YOYO-1+) co-localized with the cell nucleus. At 0.5h of contact, already 4% of cells were showing co-localization, irrespectively of the DA. A significant difference is seen between TMC's from the 4h time point on, where TMC₁₁ mediated the delivery of a higher quantity of pDNA to the cell nucleus. It was also for this polymer that the highest levels of transfection (% of cells expressing the delivered reporter gene) were observed.

Figure 1- Illustrative images of ND7/23 cells with TMC₁₁ based nanoparticles internalized (N/P 15), after 4h of contact.

A. In blue is defined the mask for the cellular membrane. Plasmid DNA in green (YOYO-1); **B.** Co localization of pDNA (in green) with the nuclear DNA (DRAQ5), in red.

CONCLUSIONS

TMC nanoparticles biodegradation can be positively correlated with the TMC DA. While the % of cells that internalized the nanoparticles is very high for all tested TMC formulations, transfection was found to be significantly affected by the DA of the polymer. The 24 h study of nanoparticle internalization presented herein discloses important data about the process of intracellular trafficking, indicating that biodegradation, hence associated DNA unpacking, is key for the overall transfection process.

Electrospun Polyvinylpyrrolidone Nanocomposites Mesh with Silica-coated Magnetic Nanoparticles

Rebecca Zhiyu Yuan, Jian Ping Fan and Jie Huang*

Department of Mechanical Engineering, University College London, United Kingdom, rebecca.yuan.10@ucl.ac.uk

INTRODUCTION

The use of magnetic nanoparticles (MNPs) for biomedical applications has increased exponentially over the past decade. Iron oxide nanoparticles (IONPs) can be injected intravenously and endocytosed by tumour cells. However, the majority of the NPs are rapidly cleared from the bloodstream by the reticuloendothelial system although surface modifications have been done to improve tumour targeting. IONPs have been encapsulated in a gel matrix; there are concerns of toxic side-effects of organic solvents. Encapsulated electrospun nanofibre web has offered an attractive alternative¹. In this study, a core-shell structure of maghemite ($\gamma\text{-Fe}_2\text{O}_3$) and silica (SiO_2) nanoparticles were synthesised and water soluble polyvinylpyrrolidone (PVP) was used to produce an electrospun nanocomposite mesh.

EXPERIMENTAL METHODS

The maghemite ($\gamma\text{-Fe}_2\text{O}_3$) nanoparticle (NP) core was made by precipitation of iron (III) chloride hexahydrate and, Iron (II) chloride tetrahydrate and ammonium hydroxide and then oxidised with sodium hypochlorite². A sol-gel silica glass from tetraethylorthosilicate (TEOS) was used to coat maghemite NP to obtain a biocompatible protective silica shell, in order to reduce the agglomeration and improve colloidal stability. The microstructure of NPs was examined by transmission electron microscopy (TEM).

MNPs were added into a series of PVP/ethanol solutions (20 to 50 wt. %) to make suspensions for electrospinning (ES). Under ES set up, suspension was infused by a programmable syringe pump (Harvard Apparatus) and subjected to an electrical field by a high voltage generator (Glassman High Voltage Inc.). The flow rates of suspensions (0.2 - 5 $\mu\text{L}/\text{min}$), nozzle diameters (0.68 mm, 0.86 mm and 1.08 mm) and applied voltages (0 - 15 kV) were varied to optimise the formation of nanofibres mesh. The distance between the needle and the collector was set at 10 mm. The microstructure of the nanofibre mesh was examined by scanning electron microscopy (SEM).

RESULTS AND DISCUSSION

Figure 1 shows the microstructure of the $\gamma\text{-Fe}_2\text{O}_3\text{-SiO}_2$ core-shell NPs examined under TEM. The average size of the MNPs was 50 ± 10 nm, coated with silica.

All the PVP solutions were able to produce electrospun nanofibres successfully, where 30 wt. % PVP was found to with minimum beads formation. Processing parameters were then varied to build a nanofibre formation map. As summarised in Table 1, the minimum suitable applied voltage was 8 kV and

suspension flow rate was $2 \mu\text{L}/\text{min}$.

Figure 1. TEM micrographs of the $\gamma\text{-Fe}_2\text{O}_3\text{-SiO}_2$ NPs

Table 1. Summary of the effects of processing parameters on electrospun PVP fibres

Figure 2 shows the microstructure of the PVP nanofibre mesh incorporated with MNPs. The diameter of the electrospun nanofibres was in the range of 200-500 nm.

Figure 2. SEM micrographs of the surface morphology of the PVP nanofibres (A) and incorporated with MNPs (B)

CONCLUSION

Core-shell MNPs- SiO_2 nanoparticles were successfully prepared and incorporated into electrospun PVP nanofibre mesh. The size and morphology of the nanofibres can be controlled by varying polymer concentrations and electrospinning processing parameters. The nanocomposite mesh developed offers great potential in drug delivery and magnetic hyperthermia applications.

dpedreira@ufscar.br

INTRODUCTION

Surface modifications of titanium alloys can be successful techniques to control cells behaviour after implantation surgery¹.

Laser structuring of surface is gaining importance for this application due to avoid contamination and impart micro and nanoscale modifications²⁻⁴. However, the laser irradiation can be detrimental to fatigue properties. To overcome this drawback this study aims to modify the surface of an oxide anodically grown on the surface of Ti-6Al-4V.

Some results of fatigue behaviour will be presented and correlated to the surface modification problems. The expectation is that the laser modification be restricted to the oxide layer to keep fatigue properties of the sample of Fig.1.

Figure1: Sample dimension for fatigue tests.

EXPERIMENTAL METHODS

The process of growth of the oxide can be performed by anodization in phosphate buffer solution and then the oxide can be modified with laser with pulse duration on the order of 500 femtoseconds (ultrafast laser).

The structure obtained will be analyzed by scanning electron microscopy (SEM/EDS) to examine surface morphology, surface characteristics of interest will be underwent by evaluation of fatigue property.

RESULTS AND DISCUSSION

The results will include the oxide thickness before and after surface modification with SEM analysis. Figure 2

shows the morphology of one surface containing some micro to nano features that can favour bone apposition.

Figure 2: surface morphology of an oxide modified by laser irradiation.

CONCLUSION

Fatigue experiments are being carried out. Expectations are based in obtaining fatigue properties not lower than polished surfaces. This can be interesting for this field of biomaterials to control cells activities with surface modification ensuring good fatigue properties.

Fibrin-Hyaluronic Acid Interpenetrating Network Hydrogel with Improved Fibrin Stability

Yu Zhang¹, Philipp Heher², Sujit. Kootala¹, Heinz Redl², Jöns Hilborn¹ and Dmitri Ossipov^{1*}

¹Science for Life Laboratory, Department of Chemistry-Ångström, Uppsala University, Uppsala, Sweden

²Ludwig Boltzmann Institute for Experimental and Clinical Traumatology, Vienna, Austria,
yu.zhang@kemi.uu.se

Introduction

Fibrin hydrogels have been widely used in a variety of tissue engineering (TE) applications because they support cell adhesion, proliferation and stem cell differentiation¹. However, its low mechanical stiffness and rapid degradation before the proper formation of tissue engineered structure are two major disadvantages that limit practical use of fibrin hydrogel as a promising scaffold in TE applications². In this work we constructed fibrin-hyaluronic acid (fibrin-HA) interpenetrating network (IPN) to overcome this problem, in which fibrin hydrogel was combined with an in situ formed disulfide cross-linked hyaluronic acid (HA) hydrogel.

EXPERIMENTAL METHODS

HA-thiol (HA-SH) and HA-pyridinyldithio (HA-SSPy) derivatives were synthesized according to our previously published protocol³. Fibrinogen and thrombin (Tissucol Kit, 1.0 mL, two-component fibrin sealant) were from Baxter AG, Vienna, Austria.

Preparation of 2%Fibrin-1%HA IPN hydrogel: 75 μ L of 8% (w/v) fibrinogen was mixed with 75 μ L of 2% (w/v) HA-SSPy solution; 75 μ L of thrombin (4U/L) was mixed with 2% (w/v) HA-SH solution; mixture of fibrinogen/HA-SSPy was mixed with solution of thrombin/HA-SH and then transferred into a syringe module to form a hydrogel.

RESULTS AND DISCUSSION

In this study, we have reported preparation of an IPN hydrogel composed of fibrin and orthogonally reactive formed hyaluronic acid network which improved fibrin stability (Figure 1). Fibrin-HA IPN was formed as a result of thiol-disulfide cross-linking reaction between HA-SH and HA-SSPy chains as well as simultaneous and orthogonal thrombin-induced conversion of fibrinogen.

Fig. 1. Fibrin-HA IPN by simultaneous and orthogonal enzymatic and disulfide networking

Electron microscopy studies showed fibrillar structure of formed IPN (Figure 2a), indicating formation of fibrin. In comparison, when thrombin was omitted from the gel preparation, the resulting structure (Figure 2b)

showed similar structure of pure HA hydrogel, indicating that fibrinogenesis did not compromise disulfide cross linking between HA-SH and HA-SSPy. During the degradation study, fibrin hydrogels got dissolved during incubation in PBS for a week while fibrin-HA IPN hydrogels kept shape, revealing the support of interpenetrating HA network to fibrin hydrogel.

Fig. 2. SEM images of (a) 2%Fibrin-1%HA IPN (b) 1%Fibrinogen-1%HA (c) Fibrin hydrogels

Pure HA hydrogel was poor at cell adhesion. Here we confirmed that fibrin-HA IPN hydrogels supported proliferation of encapsulated osteoblasts analogously to fibrin hydrogels (Figure 3).

Fig. 3. Morphology of osteoblasts encapsulated for 8 days in fibrin, fibrin-HA IPN, and HA hydrogels (live cells stained green).

CONCLUSION

Fibrin-HA IPN hydrogels were formed through thrombin-induced polymerization of fibrin monomers and disulfide cross-linked hyaluronic acid and showed improved stability over analogous fibrin hydrogel while retaining the ability to support proliferation of encapsulated osteoblasts as pure fibrin hydrogel did. The result suggests that fibrin-HA IPN hydrogel is a potential scaffold in tissue engineering application.

Effect of Preconditioning on 70S30C Bioactive Glass Foam Structure and Protein Adsorption

Gowsihan Poologasundarampillai^{1*}, Peter D Lee², Dave Clark³, Julian R Jones^{1*}

^{1*}Department of Materials, Imperial College, UK, gowshp@gmail.com

INTRODUCTION

Bioactive glasses have great potential as template scaffolds for bone regeneration¹. They bond to bone, degrade in the body and release ions which stimulate bone regeneration. Sol-gel derived porous bioactive glass scaffolds with 70 mol% SiO₂ and 30 mol% CaO (70S30C) have an interconnected macroporous network achieving compressive strengths similar to human trabecular bone². *In vivo* studies have shown that a preconditioning (PC) treatment (3 days in cell culture media) is required for bone regeneration in a rat tibial defect models³. Also, poor bone ingrowth and inflammation was found for non-preconditioned (dry) sol-gel foams³. The aims of this investigation are to understand the effect of PC on the scaffold chemistry and structure and link it to protein adsorption and bone formation.

EXPERIMENTAL METHODS – Determination of Structural changes

Bioactive glass foams were produced by air foaming a sol-gel solution containing H₂O, HNO₃, tetraethyl orthosilicate and Ca(NO₃)₂. The foams were aged, dried and stabilised to 700 °C. These were then cut to thin slices of 5x5x0.8 mm³ and some were PC in cell culture media α -MEM for 3 days. The samples were then analysed using synchrotron x-ray tomography (S μ CT on the Diamond I13), SEM, XRD and FTIR. To dynamically study the influence of PC on the bioactive glass serum containing α -MEM was perfused through both dry and PC samples. The pH and ion concentration of the media was measured as a function of time for up to 4 hours. Following perfusion with media the foams were imaged on S μ CT and SEM. XRD and FTIR were also performed.

Protein adsorption was studied using a bioreactor to flow protein containing phosphate buffered solution (PBS) through the dry and PC bioactive glass foams. Fluorescently labelled sera proteins albumin, fibrinogen and globulin at a concentration of 0.1 mg ml⁻¹ were flowed through at 0.3 ml min⁻¹ for 30 minutes to investigate the kinetics of protein adsorption on the bioactive glass surface and their relative intensities. Multiphoton confocal imaging was performed at the Harwell Octopus facility.

RESULTS AND DISCUSSION

Preconditioning of the bioactive foams produced a calcium rich precipitate within the pores and walls of the porous bioactive glass foams (Figure 1). The precipitates were identified to be either calcite or amorphous calcium carbonate (ACC) depending on the location of the precipitate in relation to the pore network. Calcite was found to precipitate within the larger pores while ACC was often found within smaller and closed pores.

Fig.1 Synchrotron μ CT images (a,b) and (c) SEM image of a PC bioactive glass foam showing the CaCO₃ precipitates. Inset of b shows μ CT slice of a dry foam.

Preferential protein adsorption was observed (Fig. 2). Adsorption plateau was attained for the dry foams within 5 minutes of flow indicating monolayer adsorption. On the dry foams fibrinogen was found to adsorb on the surface regions of the pores while albumin was found to adsorb throughout the bioactive glass foams (Fig. 2a). After PC (Fig. 2b), even after 30 minutes of flow the adsorption intensity of fibrinogen and globulin continued to increase, indicating multilayer adsorption. Additionally, fibrinogen was found to preferentially adsorb on the calcium carbonate precipitates.

Fig.2 Fluorescence images of (a) dry and (b) PC bioactive foams after flowing sera proteins through for 30 minutes. Scale bar 100 μ m.

The results indicate that the preconditioning treatment has a significant influence on the structure, composition and properties of the bioactive glasses foams hence they both behave differently *in vivo*.

CONCLUSION

Sol-gel bioactive glass 70S30C when preconditioned in α -MEM forms a CaCO₃ precipitate which has significant influence on the *in vivo* performance of the material.

INTRODUCTION

Bioactive glasses with the ability to bond to both soft and hard tissue and to promote bone growth have been well documented^{1,2}, since several studies have reported these properties for a number of sol-gel produced materials in vitro as well as in vivo^{2,3}. New studies over the introduction of various metallic ions when synthesizing bioactive glasses report that in small amounts, when used, could prove beneficiary⁴. Specifically, the addition of Sr has been proposed to show beneficial effects on bone cells and bone formation in vivo^{5,6} whereas the addition of Zn ion shows anti-inflammatory effects and stimulates bone formation in vitro by activating protein synthesis in osteoblasts⁷. The aim of this work was to successfully synthesize and characterize two sol-gel systems, 60S10Zn (SiO₂ 60, CaO 30, ZnO 10 in wt %) and 60S10Sr (SiO₂ 60, CaO 30, SrO 10 in wt %) in order to evaluate their bioactive behaviour.

EXPERIMENTAL METHODS

Sol-gel derived bioactive glasses (Table 1) were produced as described in literature⁸, pulverized in a hydraulic press and sieved to particle size under 40µm.

a/a	SiO ₂ (%wt)	CaO (%wt)	SrO (%wt)	ZnO (%wt)
60S10Sr	60	30	10	---
60S10Zn	60	30	---	10

"Table 1 show the composition of the synthesized materials".

The sieved powders of the bioactive glasses were then soaked in SBF solution for various immersion times with renewal conditions, as proposed by Zhong and Greenspan⁹. The amount of powder immersed in SBF solution was determined by the ratio 1ml:1.5mg as indicated by Kokubo *et al*¹⁰. The characterization of the samples before and after immersion in SBF was conducted using Fourier Transform Infrared (FTIR) Spectroscopy using a Perkin-Elmer Spectrometer Spectrum 1000 in MIR region, Scanning Electron microscopy with associated energy dispersive spectroscopic analysis (SEM-EDS) and X-Ray Diffractometry (XRD) using a Philips (PW1710) diffractometer with Ni-filtered CuKα wave radiation. Differential thermal and thermogravimetric analysis were performed with a Setaram thermogravimetric-differential thermal analyzer SETSYS 16/18-TG-DTA (1400 °C rod), with heating and cooling rates 10 °C/min - in nitrogen atmosphere - and furnace cooling, respectively.

RESULTS AND DISCUSSION

Both synthesized materials presented the characteristic FTIR bands of silicate glasses which are; a broad band at 900-1100 cm⁻¹ assigned to the Si-O stretching mode and a band at 490 cm⁻¹ assigned to the Si-O-Si bending one¹¹. After immersion, the identification of an amorphous Ca-P phase was revealed on the surface of the Zn-containing samples and apatite formation on the surface of the Sr-containing samples, by both FTIR spectra and XRD patterns after 5 days. EDS analysis confirms these findings.

CONCLUSION

Strontium and Zinc containing bioactive glasses have been successfully synthesized via the sol-gel method. It was possible to acquire the stabilization temperature through Differential thermal and thermogravimetric analysis. In vitro bioactivity tests showed that apatite formation was possible on the surface of Strontium-containing bioactive glass while only a Ca-P phase was developed on the surface of the Zinc-containing bioactive glass. Future work is planned in order to evaluate the behavior of the bioactive glasses when in contact with cells and the investigation of their possible application for dental tissue regeneration in scaffolds fabrication.

Mechanical Stabilisation of Non-Toxic Collagen Fibres for Tendon Repair

Anna Soroushanova, India Sweeny, Abhay Pandit, Dimitrios Zeugolis

Network of Excellence for Functional Biomaterials (NFB), National University of Ireland, Galway, Ireland,
a.soroushanova1@nuigalway.ie

Introduction

Tissue grafts are commonly used for tendon repair, however they lack mechanical stability and often associated with donor morbidity. Therefore, development of novel scaffolds with increased stability is required. Crosslinking the collagen fibres could potentially increase the mechanical properties and strength of the scaffolds. However, based on previous studies, cross-linkers such as GTA are cytotoxic for tenocytes and therefore alternative cross-linkers are required². We hypothesise that StarPEG crosslinking of collagen fibres will optimally stabilise collagen tendon scaffold, providing sufficient mechanical stability and maintain tenocyte function, and promote tendon regeneration *in vivo*.

Experimental Methods

Collagen fibres were extruded using an established protocol¹. Fibres were cross-linked with 4 arm StarPEG. GTA and EDC/NHS cross-linked fibres were used as negative control and non-cross-linked fibres were used as a baseline control. Hydrothermal stability was tested by differential scanning calorimetry (DSC). Mechanical properties were assessed by tensile testing. Enzymatic degradation was assessed by collagenase assay and levels of free amines assessed by ninhydrin. Fibres were arranged into bundles and subsequently pre-incubated in complete media for 24 hours. Human tenocytes (passage 2-3) were seeded onto collagen fibre bundles at concentration of 10×10^3 cells/cm². Media changes were performed every other day. At 3, 7, 14, 21, 28 day time points *in vitro*, Rhodamine Phalloidin and DAPI staining were used to assess the alignment, elongation and morphology of cells on fibre bundles and alamarBlue was used to assess metabolic activity. Tenocyte markers including decorin, scleraxis, tenomodulin and tenascin-C were assessed using immunocytochemistry and gene analysis. SEM was used to examine the structure of the fibres.

Results

Tensile testing and DSC showed an increase in mechanical and thermal properties compared to the non-cross-linked collagen fibres. Over time the collagen fibre bundles degraded into small fragments as assessed by collagenase assay. Over time the collagen fibre bundles degraded into small fragments as assessed by collagenase assay. Ninhydrin showed a low level of free amines in the

StarPEG cross-linked fibred compared to the controls. Collagen fibre structure was seen with SEM. Elongation of tenocytes on collagen fibre bundles was observed, with a steady increase until the 28th day time point. Tenocytes aligned in parallel orientation along on the StarPEG collagen fibre bundles as seen in figure 1. Immunocytochemistry and gene analysis showed the expression of tenogenic markers specific to tenocytes.

Fig.1 (A) (B) Human tenocytes stained with DAPI and Rhodamine Phalloidin demonstrating cellular alignment along fibre direction

Discussion and Conclusion

StarPEG crosslinking provided collagen fibres with sufficient mechanical properties and stability for use as a tendon graft substitute compared to non-cross-linked tendon fibres. *In vitro* assessment of tenocytes showed proliferation and alignment on StarPEG collagen fibres, indicating tenocyte function was not compromised compared to GTA and EDAC-HCL. PCR results showed expression of tenogenic markers specific to tendon. Ongoing and future *in vivo* work is a sheep Achilles tendon model.

Cell Osteogenic Function Enhancement and Selective Apoptosis by Hydroxyapatite Nanoparticles

Fangzhu Qing, Zhe Wang, Yanfei Tan and Xingdong Zhang*

National Engineering Research Center for Biomaterials, Sichuan University, P. R. China, prww@qq.com

INTRODUCTION

Because of the similarity in composition to bone minerals, calcium phosphates, notably hydroxyapatite [$\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$, HA], were widely used as bioactive materials for bone repair. Specially, HA was demonstrated to present the biological function of broad anti-cancer activity^{1, 2}. And studies revealed that HA nanoparticles (HA-NPs) could induce apoptosis to many kinds of tumor cells. Meanwhile, some researches reported that HA-NPs could promote the proliferations of normal cells³. Considering the broad application of osteogenic function, HA-NPs functions of both promotion on osteogenic function and selective apoptosis to tumor cells had newly potential of nano materials. But up to now, little researches referred to thus selective biofunction. Hence, in the present work, the biological effects of the HA-NPs to both osteosarcoma cells MG63 and normal osteoblasts were examined in details. Especially, emphasis was laid on observations of the genes expressions not only related to apoptotic process, but also to the osteogenic function.

EXPERIMENTAL METHODS

The dispersive HA-NPs with ~50 nm were prepared via hydrothermal process. Phase composition of the prepared HA-NPs was assessed by X-ray diffraction (XRD) and morphology of HA-NPs was observed by field emission scanning electron microscopy (FE-SEM) (Fig. 1A, B). Osteosarcoma cells MG63 were employed as tumor cells and osteoblasts isolated from small specimens of trabecular bone as normal cells. The MG63 cells and osteoblasts were cultured with the HA-NPs solutions at the concentration of 0, 25, 100, 250, and 500 $\mu\text{g/mL}$, respectively. The cell viability of those two kinds of cells was tested by MTT (3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyl tetrazolium bromide) assay and fluorescent staining assay. Ultrastructure changes of the cells were observed under transmission electron microscopy (TEM). Gene expressions of markers in cell apoptosis and osteogenic function were monitored via Quantitative Real-Time Polymerase Chain Reaction (qRT-PCR).

RESULTS AND DISCUSSION

According to the MTT assay and fluorescent staining assay, HA-NPs inhibited the growth of MG63 cells in a time and concentration dependent manner, but supported proliferation of the osteoblasts. The entrance of HA-NPs to both two kinds of cells was confirmed by TEM observations. The particles could enter the nucleus and distributed in the nucleus of the MG63 cells, while no particles were observed in the nucleus of osteoblasts. The deformation of nucleus and whole cell of MG63 indicated apoptosis emerged when treated with HA-NPs (Fig. 1C, D). HA-NPs exhibited no toxicity and induced apoptosis to osteoblasts. As

markers of cell apoptosis, Caspase-8, Caspase-9 and Caspase-3 of MG63 cells in all treated groups were high expressed in different concentration of HA-NPs, indicating that the apoptosis of MG63 cells developed from both intrinsic and extrinsic signal pathway. As markers of cell osteogenic function, gene expressions of ALP, Collagen type I (Col I), osteocalcin (OCN), BMP-2, osterix and Runx2 were analyzed. In both two kinds of cells, HA-NPs did not inhibit the gene expressions of ALP, Col I and OCN; BMP-2 and osterix in both cells were upregulated after treatment for 24 hours; Runx2 was significantly stimulated to a greater extent in MG63 and maintained a relatively high level in osteoblasts. These results proved that HA-NPs could upregulate the osteogenic function relative genes expressions of both MG63 and osteoblasts.

Figure 1. (A) XRD patterns and (B) SEM of HA-NPs; Fluorescent images of MG63 cells (C) untreated and (D) treated with 100 $\mu\text{g/mL}$ HA-NPs after 1 day's exposure which was stained with DAPI.

CONCLUSION

The results proved that HA-NPs have selective affections to cells, with promotion to MG63 apoptosis and osteoblasts proliferation. Furthermore, HA-NPs can enhance osteogenic function in both cells.

Low Temperature Aqueous Precipitation of Nanocrystalline Hydroxyapatite Containing Strontium and Magnesium for Biomedical Application

Kristine Salma-Ancane^{1*}, Liga Stipniece¹, and Liga Berzina-Cimdina²

^{1*}Rudolfs Cimdins Riga Biomaterials Innovation and Development Centre, Riga Technical University, Latvia,

²Institute of General Chemical Engineering, Riga Technical University, Latvia, kristine.salma-ancane@rtu.lv

INTRODUCTION

Over the last decade, hydroxyapatite (HAp) has been of special interest to dentistry, the orthopedic industry and nanomedicine because of their excellent performance¹. It is established that nanosized and nanocrystalline HAp can mimic the dimensions of mineral component of calcified tissues^{1,2}. The major inorganic component of bone mineral is a biological apatite, which can be defined as a non-stoichiometric, carbonated, ion-substituted and calcium deficient HAp (CDHAp)^{1,3}. The non-stoichiometry of biological apatites arises from the incorporation of foreign ions, either into the crystal lattice or adsorbed onto the surface^{3,4}. Substituting ions present in native hard tissues such as Sr, Mg, and Zn into HAp structure can lead to advantageous effects on biomaterial physic-chemical properties which directly influence bioactivity on living system⁴. In order to investigate the influence of Sr and Mg incorporation on the physico-chemical properties of nanocrystalline HAp we have prepared compositions of pure, Sr- and Mg-substituted HA by a low temperature aqueous precipitation.

EXPERIMENTAL METHODS

A series of Sr-substituted, Mg-substituted and pure HAp were synthesized using an aqueous precipitation method under identical experimental conditions. The synthesis was carried out on a 10 g scale. In this synthesis, CaO, H₃PO₄, MgO and SrO (all of analytical grade) were applied as sources of Ca, P, Mg and Sr, respectively. The added amounts of Mg and Sr sources were 0.0, 1.0, 2.0 and 3.0 wt.% in respect to Ca source, respectively. The baker with Ca(OH)₂ or Sr(OH)₂/Ca(OH)₂ or Mg(OH)₂/Ca(OH)₂ suspension was placed in an ice-salt bath and intensively stirred at 400 rpm. The 2M H₃PO₄ solution was rapidly added to the beaker in drop-wise. The temperature of the synthesis media was kept at 0°C and the pH adjusted to 10. The final synthesis solution was stirred for 10 min. The filtered precipitate was centrifuged, stored in a freezer at -24°C for 24 h and finally dried at 40°C for 24 h. The phase, molecular and chemical composition, crystallite size and morphology, specific surface area (SSA) of synthesized powders were assessed by X-ray diffraction (XRD), Fourier transform infrared spectroscopy (FT-IR), scanning electron microscopy - energy dispersive spectroscopy (SEM-EDS) and Brunauer-Emmett-Teller (BET) method with N₂ adsorption.

RESULTS AND DISCUSSION

XRD patterns of as-synthesized powders show the formation of single poorly crystalline hydroxyapatite phase. The major peaks indicate the nanocrystalline form. No other secondary phases were identified. The

peaks in the XRD patterns of Sr- and Mg-substituted HAp are identical to the XRD pattern of pure HAp. As Sr and Mg concentration increases, the XRD peaks of the samples become broader, indicating lower crystallinity and crystallite size. These results were confirmed by the SSA measurements. Evaluation by BET shows that SSA values of as-synthesized powders increased with increasing of Sr and Mg content in samples. Respectively, as-synthesized pure and Mg-substituted HAp reach SSA between 164 and 185 m²/g. The levels of Sr and Mg substitution in HAp structure were measured by SEM-EDS and all expected elemental peaks were identified including Sr and Mg suggesting that substitution elements were incorporated into the synthesized HAp. The amount of Sr and Mg increases with increase in the amount of Sr and Mg added in the synthesis media. Consequently, Mg-substituted samples contain 0.30, 0.50, 1.14. wt% of Mg. The major functional groups including [PO₄] and [CO₃] were identified by FT-IR. The broad band of adsorbed water was observed for all samples. A major characteristic of nanocrystalline carbonated HAp is the presence of the ν₃ bands of [CO₃] groups observed between 1460 cm⁻¹ and 1470 cm⁻¹ and ν₂ band at 871 cm⁻¹. This is due to the substitution of [PO₄] groups by [CO₃] species.

CONCLUSION

A series of nanocrystalline carbonated Sr-, Mg-substituted and pure hydroxyapatite powders were synthesized by low temperature aqueous precipitation method. Experimental results show that the addition of small amounts of Sr and Mg (from 1 to 3 wt%) can induce a remarkable effect on the physico-chemical properties such as crystallinity, crystallite size, specific surface area of nanocrystalline hydroxyapatite.

INTRODUCTION

Bone morphogenic protein (BMP-2) is a registered drug for the treatment of certain defined bone defects (1). These therapeutic approaches are cost intensive and require high dosages of the protein. We could recently show that osteogenic effects of BMP-2 on the osteogenic differentiation of human adipose tissue stromal cells (hASC) could be improved when the BMP-2 antagonist chordin is silenced by a single treatment with siRNA against chordin in a non-viral approach (2). However, improvement regarding late osteogenic markers, such as mineral accumulation, showed donor dependencies and depended on rapidly differentiating cells. We therefore hypothesize that sustained silencing of BMP-2 antagonists such as chordin by controlled release of siRNA improves osteogenic differentiation and eventually bone formation. In this study, we set up a controlled release system for nucleotides involving poly(caprolactone) (PCL) and gelatine with the aim to eventually generate a scaffold system as an implant for controlled release of siRNA. Here, we show the effects of siRNA content and gelatine amount as well as ratios between nucleotide and gelatine to engineer promising controlled release profiles. To this end, PCL, gelatine and pDNA were processed to film-like discs. Nucleic acid was encapsulated in a gelatine matrix and coated in a freeze drying step on the PCL microparticles in order to stabilize the nucleotide and allow for homogeneous distribution in such discs.

EXPERIMENTAL METHODS

ASCs silencing and differentiation: ASCs had been isolated from liposuction aspirates of different donors. Cells were transfected with siRNA against chordin and noggin using liposomal or poly(ethyleneimin) strategies. Next day, the transfection medium was replaced by osteogenic medium with and w/o 100 ng/ml BMP-2 (BOM and OM). Gene expression of chordin was determined by qPCR. ALP activity and matrix mineralization as early and late osteogenic markers, respectively, were quantified.

Biomaterials: PCL particles were generated from PCL pellets by precipitation. Prior to lyophilization up to 7.5% of gelatin (type A, 140 bloom) along with up to 5 µg plasmid DNA were added to obtain drug loaded particles. Disc were formed by hydraulic compression of weighted aliquots as a model for scaffold based drug delivery system.

Release study: The discs were placed in 24 well plates and 0.5 ml of PBS were added. The released DNA was quantified with the Pico green assay over a period of one month and normalized to samples from discs

containing the same amount of gelatin without nucleotide.

RESULTS AND DISCUSSION

Gene expression assay on ASCs treated with siRNA against noggin and chordin showed significant silencing of noggin and chordin on day 4, whereas no significant effect on BMP-2 gene expression were observed. ASCs that were silenced for either chordin or noggin, showed enhanced noggin expression when treated with 100 ng/ml BMP-2 after two weeks of differentiation. This may explain why late osteogenic markers showed stronger variability in response to siRNA treatment than earlier markers.

The release of pDNA from PCL discs was prolonged for up to one month. pDNA release between 5 and 100 % was found depending on the gelatin content and the pDNA loading of the discs. In general, we found a positive correlation of the released amount with gelatin content of the disc. 5-7.5% of gelatin effectively suppressed burst release effects and modulated the release efficacy. Beside the gelatin content, the amount of nucleic acid per disc does also influenced the release. With 5 µg pDNA we found significantly lower release than with 1 and 2.5 µg. We hypothesize that a certain ratio of pDNA and gelatin is required for reasonable pDNA release. Further investigations on optimal composition are ongoing. For the envisioned scaffold based siRNA delivery strategy, a controlled release of siRNA over one month is assumed to improve osteogenic differentiation of ASCs and bone formation to a greater extent than BMP-2 alone.

CONCLUSION

Suppression of BMP-2 antagonists in BMP-2 treated ASCs is able to induce osteogenic differentiation. A single treatment with siRNA against these antagonists may not suffice for longer term stimulation of osteogenic differentiation. We show a promising system for siRNA release that may allow to overcome the problem of silencing BMP-2 antagonists over a longer period of time with the aim to stably induce bone formation for a reasonable time.

INTRODUCTION

Ti6Al4V alloy is one of the most commonly used metallic materials in the manufacture of orthopedic implants, due to its optimal mechanical properties and excellent biocompatibility. However, it fails to show bioactivity, which is very important for the bone tissue integration of the implants. Therefore, the Ti6Al4V implant surfaces are typically coated with hydroxyapatite.

On the other hand, pure hydroxyapatite coatings on metallic biomaterials are lack of features, such as preventing the formation and recurrence of cancer and reducing the risk of infection at the implant site unless they are functionalized with some ions. In this sense, selenium ions are attractive candidates because the functions of the selenium in the body include regulating metabolism, improving immunity, enhancing reproductive performance and preventing cancer¹. The main aim of this study is to obtain a selenium doped hydroxyapatite coating on Ti6Al4V plates.

EXPERIMENTAL METHODS

Ti6Al4V plates with the dimensions of 20×20×2 mm³ were abraded and pretreated with 5M NaOH at 80°C for 3 days and exposed to a temperature of 600°C for 1 hour. The plates were coated in conventional² and 0.15 mM selenate ion added 1.5×SBF at 37°C for 14 days. Pure and selenium doped coatings was observed by field-emission scanning electron microscopy (FE-SEM, Quanta 400F). The coatings were also examined by Fourier-transform infrared spectroscopy (FTIR, Bruker IFS 66/S) in the range 4000–400 cm⁻¹. X-ray diffraction (XRD, Rigaku Ultima-IV) was performed with Cu-K α radiation at 40 kV and 30 mA. Cell viability tests were performed by using normal human osteoblasts (hFOB 1.19) and osteosarcoma cells (Saos-2). Anti-bacterial efficacy of the coated plates was determined by seeding *Staphylococcus epidermidis* bacteria onto the plates. After 3 days of incubation period, the bacteria attached on the plates were collected by vortexing and the numbers were determined by using a spectrophotometry (Thermo Scientific, Multiscan GO).

RESULTS AND DISCUSSION

From SEM micrographs, it was observed that the entire surface was successfully coated with a calcium phosphate layer after 14 days in both solutions. The coating obtained from the selenate ion added 1.5×SBF exhibited the standard hydroxyapatite XRD peaks, as the coatings obtained from the normal 1.5×SBF. There

were also no significant differences observed in the FTIR spectra.

From the results of the cell viability tests, it was shown that by adding 5×10⁻⁸g selenium into 1.1ml of the cell culture media it is possible to inhibit the growth of Saos-2 cells while promoting the growth of hFOB 1.19 cells. However, from Figure 1, it can be said that the Saos-2 cells attached firmly and spread on the the both types of coatings following the surface topography.

Figure 1. The SEM images (2000×) of the Saos-2 cells incubated for 7 days on the coating in normal 1.5×SBF for 14 days (left) and the coating in selenate added 1.5×SBF for 14 days (right). Arrows indicate cell extensions.

From, bacterial attachment and proliferation tests, it was seen that the number of *S. epidermidis* bacteria that were attached on coatings obtained from the selenate added 1.5×SBF and normal 1.5×SBF was very low.

CONCLUSION

Based on the results obtained in this study, it can be concluded that selenium can inhibit the growth of osteosarcoma cells and offers a promising solution for eliminating bacterial attachment but further studies are needed to determine the structural changes of hydroxyapatite after selenium doping.

Microfluidic Neuronal Circuitry – Towards Therapies for Huntington's Disease

Munyaradzi Kamudzandu^{1,2}, Paul Roach² and Rosemary A. Fricker¹

Institute for Science and Technology in Medicine, Keele University, ¹Huxley Building, Keele, Staffordshire, UK, ²Guy Hilton Research Centre, Stoke on Trent, UK

INTRODUCTION

Huntington's disease (HD) damages a circuitry of neurons in the brain resulting in involuntary movements and cognitive impairment¹. Microfluidic devices can be used to replicate the circuitry *in vitro*, to model the disease process and provide a high throughput system for testing neuroprotective therapies².

EXPERIMENTAL METHODS

A 5-compartment microfluidic device template was designed using AutoCAD. A master was then fabricated using the template via a process of photolithography. Microfluidic devices were fabricated via soft-lithography; polydimethylsiloxane (PDMS) polymer was cast onto a master and allowed to cure for approximately 1 h at 60°C. Devices were pre-coated with poly-D-lysine (PDL) and laminin prior to cell culture. Different types of dissociated rat central nervous system (CNS) cells were cultured for 14 - 21 days. Cells were examined for electrophysiology properties using patch clamp and calcium imaging.

RESULTS AND DISCUSSION

Fig 1: AutoCAD template design for microfluidic device, A. Compartments in different colors are separated by tapered microgrooves (black). 5-compartment device silicon master, B. PDMS microfluidic device with 5 compartments in different colors, C and PDMS, soft-lithography fabricated grooves, tapered (left to right) D.

Fig 2: Calcium oscillations. A and B show Z-axis profile of mean intensity through a stack (ImageJ) for a cortical and LGE neuron, respectively. Rise and fall of intensity equals neuron depolarization.

Fig 3: Patch clamp performed on cortical neuron. Depolarization and hyper-polarization spikes after current injection, A. Spontaneous firing observed after 1000ms, since no current injection was applied when spike was observed, B.

A compartmentalized microfluidic device (Fig 1) was fabricated and provides a platform for developing cultured neuronal networks. Different types of neurons can be cultured and connectivity is established via tapered microgrooves (Fig 1D). Calcium oscillations, using Fluo4 dye, were observed for unconnected cortical and lateral ganglionic eminence (LGE) neurons (Fig 2). Spontaneous firing was observed for cortical neurons using patch clamp (Fig 3).

CONCLUSION

Calcium imaging and patch clamp provide ways of measuring connectivity within a cultured neuronal network. Continuing work will involve more calcium imaging, viral transfection for tracing/imaging generation of action potentials across compartments as well as use of microelectrode arrays (MEAs) for studying extracellular electrical activity of networks.

Nanoscale Analyses of *Parawixia bistrata* Synthetic Spider Silk Fibres

Valquíria A Michalczechen-Lacerda^{1,2*}, Giovanni R Vianna², André M Murad², Luciano P Silva², Elíbio L Rech²

¹Department of Cell Biology/ Institute of Biology, University of Brasília, Brazil, * kira21bio@gmail.com

INTRODUCTION

Spider silks are remarkable natural polymers and, with advances in genetic engineering, it is possible to produce synthetic silks based on recombinant proteins obtained from heterologous hosts even at large-scale. The core repetitive domain is a block copolymer-like arrangement, where amino acids sequence can result in a protein with unique biomechanical properties. Different protein sequences may result in new types of spider silks-based biomaterials. They also display biocompatibility and a slow rate of degradation, making synthetic spider silks promising candidates as biomaterials for tissue engineering, guided tissue repair, cosmetic products and industrial materials. The aim of the present study was to characterize synthetic *P. bistrata* MaSp2 fibres, for surface topography, viscoelasticity, roughness, Young's Modulus, separation and interacting forces using atomic force microscopy (AFM) image analyses and force spectroscopy experiments.

EXPERIMENTAL METHODS

A silk monomer gene from *P. bistrata* major ampullate 2 (MaSp2) was designed (DNA2.0). The 16 mer plasmid was constructed using a "head to tail" cloning strategy¹. All plasmids were confirmed by DNA sequencing. The 54 kDa protein containing a histag was induced at *Escherichia coli* BL21(DE03) with 1 mM isopropyl- β -D-thiogalactopyranoside (IPTG) for 4 hours, at 37°C, 200 rpm, in LB medium. After immobilized metal affinity chromatography (IMAC) purification, protein was dialyzed against distilled water, lyophilized and dissolved into 95% hexafluoroisopropanol (HFIP) + 5% formic acid. The fibers were wet spun by a pump syringe and extruded in 100% isopropanol coagulation bath. A total of 20 fibers with 1 cm length were separated in two groups: control (10 fibres) and isopropanol 80% treatment with 1 \times stretch (10 fibres). Surface and force spectroscopy analyses were performed by AFM under ambient conditions on a SFM-9600 instrument (Shimadzu, Kyoto, Japan) as previously described². Statistical significance was determined by student t test using the software Assistat 7.7 Beta (Assistat, Campina Grande, Brazil).

RESULTS AND DISCUSSION

The fibres presented inhomogeneous topographical characteristics. At least 2-4 different areas of each fibre were analysed. All groups presented a similar general pattern for Rz (maximum height), Rzjs (10 points mean roughness based on the five highest peaks and lowest valleys in the entire sampling length), Rp (maximum peaks and lowest valleys) presenting no difference between control and isopropanol groups. However, Ra

(arithmetic average roughness), Rq (root-mean-square roughness), Rv (maximum valley depth) analysis showed a decreased for isopropanol treatment compared to control group ($P < 0.05$).

For the fibre force spectroscopy measurements there were no difference between control group and isopropanol treatment for detachment force (comprised adhesive forces), Young's Modulus (local elasticity), maximum load force and energy dissipated during the analyses. Only the snap-in, which illustrate the attractive force resulting from the primary surface interactions of the fibre with the tip, showed an increase for the isopropanol treatment group ($P < 0.01$).

The isopropanol-treated group did not differ significantly from the control group as expected. It is known that alcohols might be responsible for induction β -sheet formation. In a previous work², isopropanol seems to result in a better fibre formation than using methanol for post-spinning treatments, and they also found a decrease for Rv parameter². Other studies have shown inferior mechanical properties for synthetic fibres from recombinant protein with low molecular mass compared to natural fibres. However, synthetic fibres can increase its mechanical quality as a natural fibres as long as the monomers and protein molecular mass are increased³. Synthetic spider silk fibre with high molecular mass as native one (300 kDa) needs to be measured with this technology.

CONCLUSION

The synthetic fibres presented irregular surface, elasticity and strength. This biomaterial depends on their molecular organizations which are not completed even after extrusion. Different bath coagulation and a treatment post-spinning still needs to be optimized for the production of synthetic fibres with quality similar to natural dragline silk fibre. Analyses by AFM are a reliable method to qualitatively describe the mechanical properties of silk fibres.

INTRODUCTION

New developments have shown that titanium (Ti) implants with interconnected porous structure improves osseointegration because it provides space for anchoring bone cells and for vascular and bone tissue ingrowth¹. As Ti does not exhibit osteoinduction, calcium phosphate (CaP) bioactive coatings on Ti surfaces have been studied².

In this work, a biomimetic methodology consisted in a simplified solution (SS) with calcium (Ca) and phosphorus (P) ions, was used in order to deposit CaP coatings on Ti substrates by a simple and fast technique³. The main objective of the work was to assess the composition and biocompatibility by *in vitro* testing of CaP coatings on Ti substrates precipitated from SS solution.

EXPERIMENTAL METHODS

Porous Ti samples produced by powder metallurgy (C-PTi) and dense commercially pure Ti sheets (C-DTi), both ASTM F67-grade 2, were used as control substrates. The samples were chemically treated with 5 mol/L NaOH solution in ultrasonic bath, for 2 hours at room temperature and heat treated at 200°C/2h in a chamber furnace in air, for enhancing surface bioactivity. Then they were immersed for 10 days in the SS solution, prepared with pH 7.0, resulting in the following ionic concentration (10^{-3} mol/L): 2.0 (Na^+), 2.5 (Ca^{2+}), 5.0 (Cl^-), 1.0 (HPO_4^{2-}). Coated samples were named as PTi and DTi. Fourier Transform Infrared Spectroscopy (FTIR), Scanning Electron Microscopy (SEM/EDS) and X-Ray Photoelectron Spectroscopy (XPS) were used for characterization. The rapidly mineralizing UMR-106 cell line was used to assess matrix mineralization by alizarin red-S staining and extraction at days 7, 10 and 14.

RESULTS AND DISCUSSION

Figure 1a shows the SEM topographic view of C-PTi substrate without CaP coating, with $61.38 \pm 0.04\%$ average porosity and large interconnected macropores. Figure 1b displays a CaP coating with network microstructure on PTi substrate, as confirmed by FTIR and XPS analyses.

Figure 2 depicts the results of UMR-106 cultures. All Ti substrates supported the development of the osteoblastic phenotype. However, the porous substrates showed the highest alizarin red-S values, especially for those coated with CaP.

Figure 1: SEM images of C-PTi sample without CaP coating (a) and PTi with CaP coating (b).

Figure 2: Alizarin red-S extraction of UMR-106 cell cultures grown on C-DTi, DTi, C-PTi and PTi substrates for 7, 10 and 14 days.

CONCLUSION

CaP coatings were deposited on porous and dense Ti substrates, as indicated by SEM/EDS, FTIR and XPS analyses. *In vitro* testing revealed that all Ti substrates were able to support the development of the osteoblastic phenotype, but the porous Ti exhibited the greater osteogenic potential. In addition, the effect of CaP coating was more pronounced for the porous group.

Synthesis and Characterization of Novel Chitosan Hydrogels for Biomedical Applications

Krzysztof Pazdan*, Kinga Pielichowska*, Jan Chłopek,

AGH University of Science and Technology,
Faculty of Materials Science and Ceramics,
Department of Biomaterials,
Al. Mickiewicza 30, 30-059 Kraków, Poland
*e-mail: kpazdan@agh.edu.pl, kingapie@agh.edu.pl

INTRODUCTION

Biodegradable materials for drug delivery and bone tissue engineering have recently been intensively investigated, but there are still a lot of problems concerning their bioactivity, biocompatibility, drug release profile etc.

The most promising materials are composites based on natural polysaccharides such as chitosan. Its properties like bioactivity, biodegradability, non-toxicity etc. make them one of the most promising material for biomedical application. Referring to some studies, chitosan hydrogels could promote the proliferation and osteogenesis, but only with moderate swelling ratio of material. However, the most common organic cross-linker for chitosan is glutar aldehyde which causes adverse effect on living organisms. In this work, Laponite® was used to cross-link hydrogel and to improve bioactivity of the composite.

EXPERIMENTAL METHODS

Selected type of Laponite® and two chitosan types with different molecular weight - 100,000-300,000 and 600,000-800,000 purchased by Acros Organics were used. Synthesis was performed at room temperature or at 50°C and under mechanical stirring or using sonication. In synthesis process chitosan was dissolved in 2% aqua solution of acetic acid. All samples had the same content - 3% of chitosan and 7.5% of Laponite®. They were also precipitated as a beads to 5% solution of tripolyphosphate ions to achieve ionic gelation chitosan phase. Preliminary bioactivity assessment was performed using Kokubo method and surfaces of the samples were analyzed by SEM. The obtained samples were also investigated by means of XRD, FTIR and DSC methods.

RESULTS AND DISCUSSION

Results of DSC investigations of all chitosan/Laponite composites are presented in Fig. 1. The obtained results suggest that the reaction conditions significantly influenced on material properties. DSC results show that increase temperature of reaction up to 50°C (samples with 'c' index in sample name) or sonication ('u' index) leads to changes in thermal properties of the samples in comparison to samples obtained at room temperature ('z' index).

Fig. 1. DSC curves of low molecular weight chitosan/Laponite composites.

CONCLUSION

Using Laponite as a cross-linker, glutar aldehyde was eliminated. Obtained samples showed different thermal properties, depending on the reaction conditions. However, results for samples obtained using sonication treatment were similar to thermal characteristics of samples obtained at higher temperature. Moreover results of *in vitro* investigations show potential bioactivity of the chitosan/Laponite composites - the formation of an apatite layer on the samples surface during incubation in SBF was observed.

Silver Nanoparticles Modified Titanium for Medical Implants

Barbara Szaraniec¹, Magdalena Oćwieja², Marta Kujda² and Bartosz Piec¹

¹ Department of Biomaterials, Faculty of Materials Science and Ceramics,
AGH – University of Science and Technology, Poland szaran@agh.edu.pl

² Jerzy Haber Institute of Catalysis and Surface Chemistry,
Polish Academy of Sciences, Poland

INTRODUCTION

Titanium and its alloys are the most widely used engineering materials for implants in dental and bone surgery due to their good mechanical properties and biocompatibility. In literature there are reports of serious infections - both acute and delayed ones - caused by titanium. These cases must be treated with care, as bone infections can be very dangerous to health and difficult to treat. One approach is to design implants to be bactericidal. Introduction of silver nanoparticles into materials can provide them with antibacterial and antiviral functions, thanks to silver's antimicrobial properties [1,2] and long period of activity [3].

EXPERIMENTAL METHODS

Bulk and porous cylinder-shaped titanium specimens (11 mm in diameter and 4 mm tall) were manufactured by powder metallurgy. Titanium powder (Atlantic Equipment Engineers, USA) was mixed with porogen (ammonium bicarbonate, Chempur) at 70/30 and 50/50 weight ratio. The amount of porogen determined the final porosity: $30 \pm 5\%$ and $53 \pm 4\%$ [4,5]. Isostatically pressed cylindrical die stampings were thermally treated at 1200°C under vacuum conditions.

Using the defined silver particle suspension (15nm), studies of adsorption on titanium modified by poly(allylamine hydrochloride) (PAH) were carried out [6]. The coverage of adsorbed particles was directly determined by AFM (atomic force microscopy) and SEM (scanning electron microscopy) imaging. Antibacterial activities of silver nanoparticles modified titanium against *Escherichia coli* (K12) were tested. Zones of inhibition of *E. coli* around titanium disks were determined by a disk-diffusion method in Mueller Hinton broth + 1,5% agar. Inhibition zones were observed after 12h lawn growth of *E. coli* cells at 37°C . As a reference sample untreated titanium sinters were used.

RESULTS AND DISCUSSION

AFM and SEM analysis (fig.1) indicate that the surface coverage of silver particles was about $38 \pm 5\%$ and they formed uniform monolayer.

Figure 1 SEM (a) and AFM (b) images of titanium surface with silver nanoparticles.

Modified sinters exhibit different antibacterial activity, dependantly on their porosity (tab.1.). Greater porosity is connected with greater surface area and larger number of silver nanoparticles. Therefore, antibacterial effect is the most noticeable for sinters with 50% porosity.

Table 1 Zone and area inhibition for initial and modified titanium

material	zone of inhibition [mm]	area of inhibition [mm ²]
Ti	0	0
Ti/PAH/nAg	3	132
Ti30/PAH/nAg	4	189
Ti50/PAH/nAg	7	396

(Ti-untreated bulk titanium, Ti/PAH/nAg – modified bulk titanium, Ti30/PAH/nAg and Ti50/PAH/nAg – modified porous titanium with porosity 30% and 50%, respectively)

CONCLUSION

The measurements suggest that it is feasible to produce uniform silver particle monolayers of desired coverage in the self-assembly process of particles.

Both bulk and porous titanium modified by silver nanoparticles using that method, exhibit bactericidal effect. They are promising materials for medical implants. Using such materials like can make medical procedures more successful and safer even among high-risk patients.

² Nanotechnology and Advanced Materials Department, Materials and Energy Research Center (MERC), Iran

INTRODUCTION

Damage to the nervous system is devastating to patients and although methods such as nerve autografts and allografts have been developed, they have limitations such as shortage of donor nerves or rejection by the body's immune system¹. In recent years, engineered materials for the regeneration of the nerve tissue have been proposed. These engineered materials must possess balanced characteristics in terms of biocompatibility, biodegradability, mechanical properties, surface properties, and permeability². To this end, composites of natural and synthetic polymers are designed. It is also desirable to mimic the structure of the extracellular matrix (ECM) which has a fibrous structure. One common method for the synthesis of nanometer fibers is electrispinning³. Ghasemi et al.⁴ electrospan poly(ϵ - caprolactone) or PCL and gelatin and showed that although the 50:50 ratio of PCL/gelatin has good wettability, it lacks mechanical integrity compared to the PCL/gelatin 70:30 nanofibers.

Recently carbon nanomaterials such as graphene have gained much attention due to their unique properties. Graphene is a 2-D sheet of sp^2 bonded carbons with high Young's modulus and good electrical conductivity⁵. Graphene oxide (GO) is the oxidized form of graphene which has carboxyl and carbonyl groups on the edges, and epoxide and hydroxyl functional groups on its basal plane. Due to these functional groups, GO is hydrophilic. In this work we utilize GO as nanofiller for 70:30 PCL/gelatin electrospun scaffolds and report the morphology and biocompatibility of these structures towards neural cells.

EXPERIMENTAL METHODS

Graphene oxide was prepared through a modified Hummer's method⁶. In a typical procedure, graphite powder (0.5 g) and $NaNO_3$ (0.5 g) were added to H_2SO_4 (23 mL). Mixture was stirred at 0°C and $KMnO_4$ (3 g) was gradually added. The temperature was raised to 35°C and stirred for 24 hours. Afterwards DI water (140 mL) and H_2O_2 (3 mL) were added until gas evolution ceased. The mixture was allowed to rest for 1 day. The supernatant was removed and the remaining particles were washed and centrifuged with HCl (1M) and water to remove remaining salts and acids. The aqueous solution of graphite oxide was ultrasonicated for 1 hour to achieve GO dispersion. This solution was dried at 40°C to yield the solid form of graphene oxide. Two dispersions of 0.5 wt% and 1 wt% of GO were prepared in dimethylformamide (DMF) solvent via ultrasonication. PCL and gelatin were added to these solutions with a weight ratio of 70:30, and a

total concentration of 5 wt%. A control solution containing only PCL and gelatin was also prepared. These solutions were electrospun with mass flow rate of 0.6 mL/h with an applied voltage of 12 kV.

The chemical properties of the synthesized GO nanosheets were characterized by FT-IR. XRD was used to show interlayer spacing of the sheets. AFM and TEM analyses were performed to determine sheet thickness and morphology respectively. Morphology, fiber diameter, and porosity of the scaffolds were determined by SEM images. Mechanical properties of the scaffolds were also determined. In order to observe neural biocompatibility of the samples, PC 12 cells were proliferated for 2 days. Cell viability was determined by MTT assay.

RESULTS AND DISCUSSION

FTIR and XRD analyses confirmed successful formation of GO nanosheets. Also, TEM images (shown on the right) showed the sheet like structure of these nanoparticles.

SEM images of the scaffolds exhibited the desirable morphology for nerve regeneration. Moreover, mechanical properties of the scaffold was enhanced using GO as a nanofiller. Biocompatibility of these scaffolds was confirmed by the viability of neural cells.

The enhanced mechanical properties can be attributed to the addition of GO nanoparticles and their ability to bond with PCL and gelatin through functional groups such as the hydroxyl and carboxyl groups.

CONCLUSION

Addition of GO as a nanofiller not only enhances the mechanical properties of the scaffolds, but also can make the scaffolds less hydrophobic due to its hydrophilic nature; hence making the scaffold suitable for nerve regeneration applications.

katy.nazemi@yahoo.com

INTRODUCTION

In the recent years, so much attention has been paid to nanocomposites for using in tissue engineering. Many of composites are currently has been used as scaffolds for biomedical applications¹. In bone tissue engineering, scaffolds served as the matrices of tissue formation plays a pivotal role and should be highly porous, required surface property that promotes cell adhesion, proliferation and differentiation, desirable mechanical properties, non-cytotoxicity and osteoconductivity. Currently, composites of polymers and ceramics are being developed with the aim to increase the mechanical scaffold stability and to improve tissue interaction².

In this study, we synthesized a bioactive glass 58S using sol-gel method. Then, investigate the mechanical behavior of the samples by using mechanical compressive test.

EXPERIMENTAL METHODS

The bioactive glass 58S powder (60% SiO₂, 4% P₂O₅, and 36% CaO) (mol%) has been synthesized via sol-gel method. For the preparation of each scaffold samples, 250 mg chitosan dissolved in 1% acetic acid solution. Different percentages of bioactive glass 58S were added into the chitosan solutions and stirred for 12 h. Next, 62.5 mg of PLGA has been dissolved in 3 mL of dichloromethane, and then added into the dispersing phases [0% (S1), 0.5% (S2), 1% (S3), 1.5% (S4), 2% (S5) of bioactive glass 58S] under moderate magnetic stirring³.

RESULTS AND DISCUSSION

The microstructures of the cross-section of the typical prepared scaffolds have been observed with SEM, shown in Fig. 1.

Fig.1. Low magnification SEM micrograph of the prepared scaffold, sample S3

The prepared scaffolds have been tested to determine the effects of increasing bioactive glass 58S on the mechanical properties. Fig. 2. shows the data obtained

from mechanical compressive tests of the samples, and compares them with natural cancellous bone. In our study, the results represented that E and σ both increased progressively by further addition of bioactive glass 58S. It is worth mentioning that σ and E of the samples containing higher amounts of bioactive glass 58S have been in the range of cancellous bone.

Fig.2. the mechanical properties of the scaffolds from compression tests compared with cancellous bone

CONCLUSION

In conclusion, the elastic modulus of the scaffolds was comparative to the natural cancellous bone and also by increasing weight percentage of bioactive glass 58S the mechanical strength increased.

INTRODUCTION

In the field of orthopedics and traumatology, the improvement of implant materials plays a crucial role for the patient's quality of life. Newly developed biodegradable materials have the potential to provide enhanced mechanical properties and reduce the need for implant removal surgery. The initial evaluation of newly designed materials in vitro to predict the outcome in vivo is strongly desired. Therefore, to approach the in vivo situation we established co-culture conditions for primary human mesenchymal stem cells (hMSCs) and monocytes (MCs) to address the bone remodelling process. Our aim of this study was the evaluation of the osteoclastogenesis of monocytes in consequence to the interaction and cross talk with hMSCs without any differentiation factors by media supplementation.

EXPERIMENTAL METHODS

Human monocytes were isolated of buffy coats and were characterized by FACS analysis, histochemical staining and differentiation studies.

For co-culture experiments, hMSCs were seeded either on tissue culture plates (TCPS) or on bovine cortical bone slices. Two set ups were considered: proliferative media and the induction of the osteogenic differentiation for 14 days. Subsequently, monocytes were seeded on top of the pre-cultured hMSCs and were evaluated after another 14 days for an osteoclastic phenotype by immunofluorescence staining and REM analysis.

RESULTS & DISCUSSION

MCs were successfully differentiated to osteoclasts by media supplementation including RANKL and M-CSF (Fig. 1 D). Co-culture of hMSCs and MCs led to the expression of an osteoclastic phenotype after 14 days (Fig. 1 B). Cathepsin K, VNR and Actin/Vinculin were

expressed and analyzed by immunofluorescence staining revealing multinucleated cells within the co-culture set up.

Fig. 1 Development of culture conditions for a successful co-culture of osteoblasts and osteoclasts. (A) VNR staining of co-cultured hMSCs and monocytes (B) osteogenic differentiated hMSCs (C) and differentiated monocytes (D).

The co-culture of hMSCs and hMCs leads to an osteoclastic phenotype after 14 days. The interaction of both cell types is therefore sufficient to generate osteoclast like cells.

CONCLUSION

The bone remodelling process can be simulated in vitro by using monocytes and mesenchymal stem cells. However, the activity of the osteoclasts must be further investigated e.g. by the detection of resorption pits in order to test efficiently the degradation potential of newly designed materials. The co-culture could further be transferred into a three-dimensional setting to consider the influence of a multilayer culture.

INTRODUCTION

The peripheral nervous system in small injuries has an intrinsic ability to regenerate itself under the appropriate conditions. In human, axon regeneration occurs in a very low rate, approximately about 2-5 mm/day. Surgical techniques like autograft, allograft and xenograft have been used for treating transection injuries in peripheral nerves and autologous nerve grafting became a golden standard technique compared to other methods. However, it has disadvantages such as limited availability of donor sites¹. Therefore, developing artificial nerve grafts has become a great challenge in tissue engineering. It has been widely recognized that advanced materials including carbon-based nanomaterials could be considered as promising candidates for applications in regenerative medicine due to their unique physical, chemical and biological properties. Graphene is a two-dimensional carbon nanostructure arranged in a hexagonal network. Due to its unique properties like flexibility, electrical conductivity, high strength, stiffness, and biocompatibility, it has become a very attractive biomaterial in recent years. Graphene oxide (GO) is a nanomaterial containing epoxide, carboxyl and hydroxyl functional groups. The presence of functional groups on the surfaces of scaffolds play a key role in cell adhesion, proliferation, migration and has particular effect for aligning neural cells². Electrophoretic deposition (EPD) is an electrochemical method which is based on two stages. First an electric field is applied between two electrodes, then in the second stage the particles deposit to form a relatively compact film³. The intrinsic negative charge of GO make it suitable for this purpose.

Poly(ϵ -caprolactone) (PCL) has been widely used for the reconstruction of various tissues, but it lacks functional groups on its surface which results in poor cells adhesion. In addition electrospun nanofibers are known to be suitable scaffolds for neural tissue engineering applications and modification of the substrates often provides better environments for neurite outgrowth⁴. Our study is aimed at coating GO on a PCL/gelatin scaffold for nerve tissue engineering and investigating the effect of this coating on the mechanical properties and bioactivity of the scaffolds.

EXPERIMENTAL METHODS

1. Synthesis of GO

Natural graphite powder (particle diameter of ≤ 20 μm , Sigma Aldrich) was utilized to produce graphite oxide suspension by modified Hummer's method⁵. Graphene oxide nanosheets were obtained by ultrasonication of the graphite oxide suspension at frequency of 40 KHz and power of 150 watt for 1 h.

2. Preparation of electrospun scaffold

PCL/DMF and gelatin/DMF solutions were prepared separately under continuous stirring for 2 h. Then they were mixed to obtain a solution with 70:30 PCL/gelatin ratio. A voltage of $1\text{kV}\cdot\text{cm}^{-1}$ and a flow rate of 0.5 ml h^{-1} were applied for 6 h to prepare the scaffold.

3. Coating the scaffold via EPD

EPD was done by using two electrodes which were connected to a DC voltage source with the scaffold situated at the center of the EPD cell.

4. Neural cell culture on the scaffold

In order to investigate the effect of the prepared scaffold on nerve cell viability, PC 12 cells were seeded onto the coated PCL/gelatin nanofiber scaffold and MTT assay was executed.

RESULTS AND DISCUSSION

Water solubility of GO

and the presence of functional groups on its surface caused a homogeneous coating on the PCL/gelatin scaffold and made it more hydrophilic; which in turn provides a significantly better substrate for protein absorption. The results indicate that GO was successfully synthesized as it is shown in the XRD test below. The results are also confirmed by TEM, FT-IR and SEM analyses. Presence of the GO layer on the PCL/gelatin scaffold provides a biocompatible and nanostructured surface topography that improves cell viability.

CONCLUSION

An improvement in the bioactivity of the PCL/gelatin nanofibrous scaffold is observed in the presence of GO coating. This method can be used for other tissue engineering scaffolds to functionally customise the final characteristics.

Morphometry of bone tissue around endossal implantation of Hap/TCP granules and autologous mesenchymal cells in rabbits with experimental osteoporosis

Aleksandrs Grishulonoks¹, Vita Zalite², Inese Cakstina³, Arvids Jakovlevs⁴, Andrejs Skagers¹

¹Department of Oral and maxillofacial surgery, Riga Stradins University, Latvia, ²Rudolfs Cimdins Centre for innovations and development of Biomaterials, Riga Technical University, ³Laboratory of Biodosimetry and bioanalytical methods, Faculty of Biology, University of Latvia, ⁴Department of Pathology Riga Stradins University, or_aleksandrs.gr@gmail.com

INTRODUCTION

The current trend is the biologisation of non-organic bioceramic material to be close to natural living bone and the replacement of bone grafting by bioceramics saturated with growth factors or/and potential cells^{1,2,3}. As scaffold biphasic calcium phosphate bioceramics is evident⁴.

EXPERIMENTAL METHODS

Synthetic porous HAP ceramics Hap/TCP 90/10 with open porosity 61 % produced in Rudolfs Cimdins Biomaterials Innovations and Development Centre were used. Granules have macroporous structure with pore size 50 – 450 µm. All samples were sintered at 1150°C for 2 hours. Purity of hydroxyapatite phase was investigated using X-ray diffractometry and Fourier transform infrared spectroscopy. With permission of Latvian Food and Veterinary Administration on 10 Californian rabbits under general anesthesia with Dormicum and Ketamine experimental osteoporosis by ovariectomy and 8 weeks intramusculary metilprednisolone 1 mg/kg was developed. During the same surgery fat tissue from *omentum majus* were collected in tubes (Sarstedt) with physiological solution and heparin. Samples were then washed with PBS and treated with Collagenase type XI for 2 - 5 h in at 37°C. Cell pellet was seeded in tissue culture flasks in DMEM/20%FBS, soaked in 100%FBS for 2 h. lets and DMEM/10%FBS was added. Samples were incubated at 37°C, 5% CO₂ for one day. Before implantation samples were washed with PBS twice. Under local anesthesia with 1% Lidocaine and 1 mg Dormicum intramusculary implants loaded with cells on one side and pure Hap/TCP on other side in rabbit lower jaw hole were inserted. Samples were taken out after three and six months, histologic specimens stained with Hem/eoz and Masson trichrome in light microscope were evaluated. Image Pro+ morphometry was performed.

RESULTS AND DISCUSSION

Essential osseointegration of Hap/TCP granules in jaw bone was estimated. No signs of inflammation were detected.

Morphometric evaluation obtained average osseointegrated trabecular bone width only with Hap/TCP (90/10) granules - 271 mkm, trabecular bone width with granules and mesenchymal autologous cells 236mkm (p=0,107); cortical bone width only with Hap/TCP (90/10) granules 739 mkm, cortical bone

width with granules and mesenchymal autologous cells 753 mkm (p=0,341).

CONCLUSION

Morphometric measurement of osteoporotic bone osseointegrated with Hap / TCP (90/10) granules implanted in rabbit lower jaw with and without autologous mesenchymal cells after six month observation period was without statistically significant morphological differences.

A Study On 45S5 Bioglass® Foam Dissolution

V. Melli¹, L.-P. Lefebvre², L. Altomare¹, L. De Nardo¹

¹Dipartimento di Chimica, Materiali e Ingegneria Chimica G. Natta, Politecnico di Milano, Italia

²National Research Council Canada, Boucherville, Canada, virginia.melli@mail.polimi.it

INTRODUCTION

The production of 45S5 Bioglass®-resorbable scaffolds for bone substitution has been strongly limited by the effects of thermal treatment on microstructure. [1] Several studies demonstrated that despite a glass ceramic structure, obtained scaffolds still maintain bioactivity, and ability to dissolve; however, a reduction in the kinetic of formation of HA in SBF solutions is in general reported. [2] Moreover questions related to the ability of crystalline phase to dissolve remained unanswered; ion release analysis displayed a plateau suggesting a stop in dissolution. [3] The presence of insoluble phases, that might provoke an inflammatory reaction if released in the form of particulate, cannot be excluded. [4]

The aim of the work is to understand behavior of glass ceramic scaffolds, made of 45S5 Bioglass® through a powder metallurgy process, in water.

EXPERIMENTAL METHOD

6 samples were immersed, in DI H₂O pH 4.5 at 80°C, 40°C and 20°C. H₂O was replaced every day ("D") in the three temperature conditions, kept static ("S") or stirring ("St") at 20 °C. For the first 28 days other samples were soaked in SBF+TRIS pH 7.4, replaced every 3 days, at 37 °C. Weight reduction was measured every 4 days after drying. In "epoxy test" a sample was embedded in epoxy resin and a polished surface was exposed to H₂O replaced every day at 80 °C. Scaffolds have been analyzed via SEM, XRD and micro-CT in order to elucidate the dissolution kinetic of the obtained glass ceramic scaffold.

RESULTS AND DISCUSSION

XRD pattern showed that the scaffold contains crystalline phases [5], with main crystalline phase Na₂Ca₂Si₃O₉ and a smaller amount of CaNaPO₄.

Fig.1: Weight reduction of bioglass foam sample in water and SBF solution.

As shown in fig.1, the weight reduction of sample immersed in water is linear with time in all the studied conditions. Raising temperature the slope of dissolution lines is increased. "D" condition at 20 °C has no effect on the dissolution rate probably because the process is still far from equilibrium after 24 h of dissolution. Otherwise, stirring solution provides a very fast

dissolution kinetic being all the surface area involved in the reaction. All this results are in contrast to the behavior in SBF solution, where the dissolution appears fast in the first 14 days but after the weight is again increased with the growth of the bioactive CaP layer thickness.

The linear dissolution trend suggests the absence of insoluble phases. On the contrary, CaP coating has a passive effect lowering dramatically the dissolution kinetic. The fast initial dissolution of bioglass in SBF could be ascribed to the effect of a higher solution pH, that can increase the dissolution product of the silica network. [3,6]

After dissolution in water the microstructural changing (e.g. the crystallites decomposition) observed in the case of SBF soaked samples [7], is no more evident and the scaffold maintained the same crystalline phase content after 16 days of dissolution.

Fig.2: Section view of the dissolved polished surface of an epoxy embedded bioglass foam sample after 28 days.

The epoxy tests showed that different part of the foam can follow different dissolution kinetics resulting eventually in an homogeneous reduction of the bioglass foam height with respect to the epoxy surface. (fig.2) These observations suggested a heterogeneous dissolution due to the different dissolution kinetics.

CONCLUSIONS

Crystalline bioglass foam showed the ability to completely dissolve in water although with different kinetics. The macro dissolution behavior is homogeneous. Ongoing test are aiming to assess if insoluble micrometric crystallites are released or not in the bulk solution.

Biocompatibility of Poly High Internal Phase Emulsion Scaffolds prepared using Stereolithography

Atra Malayeri^{*1,2}, Ilida Ortega¹, Frederik Claeysens², Colin Sherborne², Neil R Cameron³, Paul V. Hatton¹

¹School of Clinical Dentistry and ²Kroto Research Institute, University of Sheffield, UK and ³Department of Chemistry and Biophysical Science Institute, Durham University, UK. dtpl1am@sheffield.ac.uk

INTRODUCTION

Complex bone defects in the head and face would benefit significantly from the use of custom-shaped devices or scaffolds that stimulated tissue regeneration after implantation. Despite some promising data, resorbable polymeric biomaterials have not yet been optimised for preparation of custom structures using contemporary advanced manufacturing methods. Poly high internal phase emulsions (PolyHIPEs) have been reported to provide structures with interconnected micropores that have the potential to enhance biocompatibility. Despite their promise, only a limited volume of work has been reported on the biocompatibility of PolyHIPEs prepared using 2-ethylhexyl acrylate and isoboronyl acrylate, and only recently the fabrication of simple 3D structures via stereolithography has been reported¹. The aim of this study was therefore to evaluate the biocompatibility of this polyHIPE system using cultured bone cells, and to manufacture more complex “woodpile” three-dimensional scaffolds using stereolithography.

EXPERIMENTAL METHODS

Simple polyHIPE disks (approximately 1 cm diameter) based on 2-ethylhexyl acrylate and isoboronyl acrylate were fabricated. Some disks were further modified by plasma polymerization using acrylic acid to form a poly (acrylic acid) surface. The microporosity of these was studied using scanning electron microscopy (SEM). The *in vitro* response of MG63 osteosarcoma cells to both untreated and plasma treated scaffolds was investigated using SEM and MTT assay for up to 7 days culture. More complex 3D “woodpile” structures were prepared using the same polyHIPE materials and stereolithography. The structure of these was also investigated using SEM.

RESULTS AND DISCUSSION

Simple polyHIPE disks were shown to have a high degree of microporosity using SEM (Figure 1a). Cultured MG63 cells actively colonised the surface of these materials and remained viable for up to 7 days, as demonstrated by SEM (Figure 1b) and MTT assay. In all micrographs the open-cellular porous morphology was very evident. MTT assay further suggested that although cells were viable on all PolyHIPE disks, respiratory activity appeared to be greatest on acrylic acid plasma coated materials at all time points (1, 3 and 7 days). More complex “woodpile” PolyHIPE scaffolds were then fabricated via stereolithography (Figure 2).

Figure 1. Scanning electron photomicrographs of the surfaces of a simple polyHIPE disc prepared by UV polymerisation (a) prior to tissue culture and (b) after 7 days of culture of MG63 bone cells.

Figure 2. Scanning electron photomicrographs of basic “woodpile” structures formed from polyHIPE using stereolithography at (a) low and (b) higher magnification.

This data showed that the polyHIPE biomaterial reported here were both biocompatible in a bone cell culture model, and it was possible to manufacture more complex 3D structures to provide both macro- and microporous architecture in the same scaffold or device. Further work is continuing on these materials and other promising polyHIPEs including novel materials based on poly (ϵ -caprolactone) polyHIPEs.

CONCLUSION

It was concluded the acrylate-based PolyHIPEs described here supported the growth of bone cells *in vitro*, and that plasma polymerisation appeared to further improve cell response. Using stereolithography, it was possible to prepare even more complex 3D scaffolds or devices that have great potential for tissue engineered craniofacial surgery.

Implantable hybrid composite for reducing inflammation in age related macular degeneration

E. Chinarro¹, L. Pires², Ana P. Pêgo^{2,3,4} and B. Moreno¹

¹Instituto de Cerámica y Vidrio, CSIC, Madrid, Spain, ²INEB – Instituto de Engenharia Biomédica, Universidade do Porto, Porto, Portugal, ³FEUP - Faculdade de Engenharia da Universidade do Porto, Porto, Portugal, ⁴ICBAS – Instituto de Ciências Biomédicas Abel Salazar, Universidade do Porto, Porto, Portugal, martin@icv.csic.es

INTRODUCTION

Age-related macular degeneration (AMD) advances causing a gradual loss of central vision and the deterioration of the macula. From all the phenomena that contribute to extra cellular ageing, the imbalance between the synthesis and the elimination of reactive oxygen species (ROS) is one of the most relevant. In addition, the innate immune system, particularly the phagocytes and the complement system, are involved in the progression of the disease. The insertion of an implant with potential anti-inflammatory activity is a reliable therapy, however the materials choice is a key parameter for its success. Our aim is to develop a new class of hybrid biomaterials based on the union of polymethyl methacrylate (PMMA) and a ceramic material, titanium dioxide (TiO₂). The hybrid design should present a built-in bioactivity able to modulate the extracellular microenvironment and connective tissue of the eye in order to prevent and control those inflammatory processes that occur during the progression of the disease. To reach this goal, the synthesis and characterization of hybrids based on PMMA-TiO₂ is described evaluating its ROS scavenging activity by two different methods SIN-1 and DPPH.

EXPERIMENTAL METHODS

TiO₂ nanopowders were used after its calcination at 600 °C in air. These processed powders were mixed with previously purified commercial PMMA. With this aim purified PMMA was dissolved in THF and then mixed with a TiO₂ suspended in THF as well. Membranes were processed through two different techniques: casting and spin-coating. With the aim of having the TiO₂ powders exposed in the surface of the membrane, the films obtained were treated with acetone. Moreover, the films have been prepared by deposition of TiO₂ powders (with xerography) onto the PMMA membrane. Morphological characterization of the membranes has been done. The ROS scavenging capacity of the different membranes was addressed by generating chemically ROS using two methods: 1,1-diphenyl-2-picryl-hydrazyl (DPPH) and 3-morpholinocarbonylhydrazine hydrochloride (SIN-1).

RESULTS AND DISCUSSION

Characterization of the casted membranes showed that TiO₂ powders sediment during the processing, creating a TiO₂ concentration gradient but avoiding the exposure of the powders (Figure 1, B). After the etching with acetone it was clearly observed how the TiO₂ agglomerates are present in the surface of the membrane, but remained anchored to the polymer phase (Figure 1, C). The membrane prepared by spreading TiO₂ powders on the surface of a just-casted PMMA film shows TiO₂ clearly exposed in the surface,

although the dispersion of the powder was less homogeneous than in the previous case.

In this study, we addressed the ROS scavenging capacity of different membranes with chemical assays using artificial ROS. The results show that although PMMA itself reduces the ROS created, its mixture with TiO₂ calcined at 600°C enhances the concentration of ROS depleted.

Figure 1: SEM of the membranes obtained. A) PMMA membrane prepared by casting, B) PMMA/TiO₂ membrane prepared by casting, C) PMMA/TiO₂ membrane prepared by casting after etching with acetone; and D) and E) Spin coating films prepared from PMMA solutions (5% (w/v), dimethylformamide) containing TiO₂ particles (5% (w/v)).

At present we are extending the work to spin coating films. We were able to prepare thin PMMA films over coverglass where TiO₂ is deposited afterwards. We have to test the supported films with the chemical assays described above to evaluate the ROS scavenging activity of this material and to relate it with the degree of TiO₂ exposure.

CONCLUSION

Taken together, these results suggest that the synthesis and processing of PMMA/TiO₂ hybrids has been successfully approached. Moreover, the surface treatment of the membranes with acetone allowed enhancing the degree of TiO₂ exposed and able to react in the chemical assays carried out. It was found that PMMA itself showed a mild ROS scavenging activity that was improved in the hybrids prepared with the TiO₂ powder calcined at 600°C.

Hypoxia inducible factor-1 α (HIF-1 α) stabilization for enhanced cell and tissue construct survival

Wai Ho, Barry Fuller and Gavin Jell

Division of Surgery and Interventional Science, University College London, Royal Free Hampstead Hospital, wai.ho.12@ucl.ac.uk

INTRODUCTION

Cell and tissue construct survival following implantation is low due to stresses association with storage and when implanted, low oxygen and nutrient supply. Strategies to increase cell survival following implantation would enhance cell therapy efficacy and promote tissue construct integration. Cell or tissue construct survival may be artificially increased by stabilising HIF-1 α through the use of HIF stabilising mimetics, in normoxic conditions prior to implantation or storage. Stabilising HIF in normoxia may activate a number of pro-survival factors whilst preventing the oxidative stress associated with hypoxia-reoxygenation reperfusion injury¹.

EXPERIMENTAL METHODS

Osteoblast (SaOS-2), Keratinocytes (HaCaT) and Fibroblast cells (HDFa) were preconditioned in either untreated media (control group), or media treated with a range of hypoxia mimicking agents (Co²⁺, DFX (1mM), DMOG (1mM) and Hypoxia Bioactive Glass in conditioned media² (which has 2 Mol % Cobalt incorporated in the glass network)) in normoxia or hypoxia incubator for 24 hours. Following cryopreservation cell survival was determined using haemocytometer and Trypan Blue assay prior to cell recovery being determined by cell proliferation (day 1, 3 and 7) in a hypoxia incubator (1%O₂, 95%N and 5%CO₂), with a total DNA assay (Hoechst staining).

Abbreviations: DFX = Deferoxamine mesylate; DMOG = Dimethylxalylglycine;

RESULTS AND DISCUSSION

Cells preconditioned with hypoxia mimetics showed higher proliferation rates when cultured in hypoxia incubator for 7 days following resuscitation (Fig. 1). Furthermore, cells preconditioned with hypoxia mimetics or in low oxygen level appeared have higher metabolic activity on resuscitation, which may due to hypoxia adaption to oxygen independent metabolism during preconditioning (Fig. 2).

Figure 1. Cell Proliferation and Survival. Preconditioned cell with cobalt ion and 2% Cobalt ion in BG have higher cell recovery. **P<0.01 vs. normoxia.

Figure 2. Metabolic Activity. Cells preconditioned with hypoxia mimetics and low oxygen level has higher metabolic activity following resuscitation. **P<0.01 vs. normoxia)

These results have demonstrated that preconditioned cells in hypoxia mimetic agents may increase the survival of cells in adverse conditions (e.g. low nutrient and nutrient). Current Studies are underway to understand the pro-survival factors expressed in HIF stabilised cells.

CONCLUSION

Preconditioning cells with HIF mimetics can increase cell proliferation and viability in adverse environments. The incorporation of HIF mimetics into tissue scaffolds may provide a means to increase cell survival following implantation.

Practical fixation issues of multifunctional bioresorbable miniplates for osteotomies

Karol Gryń¹, Anna Morawska-Chochół¹, Barbara Szaraniec¹, Magdalena Ziabka², Jan Chłopek¹

INTRODUCTION

In literature there are many biomaterial concepts describing a range of biodegradable polymers and composites used for trauma surgeries [1]. Apart from the benefits of rigid fixation and the advantage of biodegradation [2], the general conclusion shows the main drawbacks as well. Miniplates made of biodegradable polymers or composites are characterised by relatively low mechanical properties, when compared to e.g. titanium or stainless steel [3]. Moreover, as their degradation process continues, mechanical parameters of the implant decrease [4]. Thus, the application of such devices is limited only for osseosynthesis in non-loaded areas of bones or in hybrid systems. In a hybrid system the internal plate is fixed to the pieces of the broken bone to keep them in position, whilst a combined metal stabilizer (usually an external one) bears higher loads [5].

In our research we wanted to find out which factors downgrade the mechanical properties of implants during the degradation process.

To verify this query we prepared different types of materials and various shapes of miniplates. Their mechanical properties were determined. Complimentary mechanical tests concerning simulated work conditions (including proper fixation, biological fluids presence and higher temperature of the environment (37°C)) were assessed.

EXPERIMENTAL METHODS

The present study uses bioresorbable polylactide acid (PLA) (Ingeo 3051D by NatureWorks) and composites of PLA with bioceramic additives: hydroxyapatite (HAP) (nGimat) and tricalcium-phosphate (TCP) (SigmaAldrich). For the sake of this research, three different materials were used to manufacture miniplates: pure PLA, PLA/7% wtTCP, PLA/7% wtTCP/0,3wt%HAP. Injection moulding was applied to fabricate different shapes of miniplates (*I,H,T,Y*) (165-175°C). The samples were mechanically tested (Zwick 1435). Static and dynamic research was carried out along with fatigue (cyclic uniaxial tensile strain and creep). The maximum torque that can be applied to the fixation screw was measured (PolTorque PRO) and the maximum load a miniplate can bear was determined. Two types of screws were used: with countersunk head and pan head. This test revealed also information about stability and durability of the fixation. To verify the influence of degradation processes on mechanical stability additional mechanical testing in simulated work conditions was conducted. The samples were tested in two manners of proceedings: a) after 2 and 6 weeks incubation in

simulated body fluids and Ringer's solution at 37°C; b) implants were placed in the chamber filled with Ringer's solution at 37°C and tested "in situ". The material's microstructure was observed using SEM.

RESULTS AND DISCUSSION

Bioceramic additives (TCP and HAP) not only modified bioactivity and the implants osseointegration (proved in our previous research) but also changed their mechanical behaviour from rigid to more plastic. Hence, the composite miniplates didn't crack/snap instantly when a force or a torque was applied (fixation). Moreover, they displayed higher creep and fatigue resistance than the miniplates made of pure PLA. It can be stated that composite miniplates are more reliable then. On the other hand, bioactive additives increase the rate of degradation and - as a consequence - the mechanical properties decrease. Another factor that negatively influenced durability of the implant was the shape of a fixing screw head (and matching hole in the miniplates). When countersunk head screws were used adverse circumferential tensile stress appeared around miniplate holes.

CONCLUSION

The results of this study show that not only material, geometry of the implant and the testing conditions are crucial but also the way the implant is fixed. As we know more about the subtle factors changing implants' mechanical behaviour during their degradation, we are one step closer to tailoring mechanical characteristics of bioresorbable implants to the actual need of a healing bone tissue referring to Wolff's law. Hence what at the beginning was seen as a drawback does not necessarily need to be one.

Dynamic Surfaces for Stem Cell Differentiation and Retention of Stem Cell Phenotype

Laura E. McNamara^{1*}, Jemma N. Roberts^{1,2}, Jugal Sahoo², Karl V. Burgess³, Jake Hay¹, Hilary Anderson¹, Richard O.C. Oreffo⁴, Rein Ulijn² and Matthew J. Dalby¹

⁴Department of Bone and Joint Research, University of Southampton, UK

INTRODUCTION

The ability to have ‘on demand’ control over the fate of stem cells would have great benefit for the supply of both stem cells and mature cell types for research and clinical applications. Although some topographical and chemically patterned surfaces have been fabricated that are capable of enhancing the retention of stem cell character or promoting differentiation [1], the ability to trigger a change from stem cell retention to maturation on the same substrate would be highly advantageous to facilitate the expansion of stem cells prior to differentiation. In this study, an enzyme-cleavable surface chemistry was utilised to modulate stem cell fate by concealing or exposing adhesive –RGD groups.

EXPERIMENTAL METHODS

Surface chemistry synthesis: Peptide-modified glass surfaces were produced on glass coverslips, which either presented a cell adhesive –RGD sequence, or had the –RGD sequence masked with an adjacent –Fmoc or –PEG blocking group attached to an elastase-cleavable linker. Glass controls and –RGE, –RGD, and –PEG presenting surfaces were used as controls. At least 3 surfaces were examined per experiment.

Cell culture: Mesenchymal stem cells (MSCs; Stro-1+ selected) were cultured on the peptide surfaces in the presence (‘switched’) or absence (‘unswitched’) of elastase (which could cleave off the –Fmoc or –PEG blocking groups).

Immunostaining/focal adhesion (FA) quantification: Cells were stained for the stem cell marker Stro-1+, and markers of differentiation such as osteopontin and osteocalcin. FAs were also immunostained, imaged using a fluorescence microscope and quantified using ImageJ.

Metabolomic analysis: Solvent-extracted metabolites were analysed using an Orbitrap Exactive mass spectrometer. Metabolite analysis was performed using in-house software and Ingenuity Pathways Analysis to assess the likely functional significance of the differentially abundant metabolites and analyse potential interactions between metabolites.

RESULTS AND DISCUSSION

Stem cells cultured on the lower adhesion ‘unswitched’ surfaces had greater retention of the stem cell marker Stro-1+ than cells cultured on glass controls after 2 and 4 weeks of culture. On the ‘switched’ surfaces, and control –RGD substrates, where the –RGD sites were exposed and higher cytoskeletal tension was promoted, there were quantitative distinctions in the size of focal adhesions, and bone differentiation was stimulated. The

bone markers osteocalcin and osteopontin were enriched on the switched substrates.

Most interestingly, the metabolic profile of stem cells cultured on the ‘unswitched’ –Fmoc terminated surfaces was distinct from that of the cells on the ‘switched’ substrates. MSCs cultured on the unswitched substrate were enriched for unsaturated lipids, which were depleted on the switched surfaces (Figure 1).

Figure 1: Relative abundance of lipid metabolites on unswitched (–RGD concealed), enzymatically switched (–RGD exposed) and glass control surfaces. Red indicates highest abundance and blue indicates lowest abundance. Note the relative enrichment of unsaturated lipid metabolites on the unswitched surface relative to the glass control, versus depletion on the switched surfaces.

Enrichment of unsaturated metabolites has previously been associated with stem cell plasticity [2]. Cells cultured on the switched surfaces had depleted levels of these metabolites, consistent with a more metabolically active, differentiating phenotype.

CONCLUSION

The ‘unswitched’ –RGD surfaces were more effective at retaining stem cell character, and MSCs cultured on these surfaces were metabolically distinct from those on the ‘switched’ surfaces. The switched surfaces were effective at modulating FAs and promoting osteogenic differentiation. This system offers great potential for the retention of stem cell characteristics prior to the controlled induction of differentiation.

Cytotoxicity control of SiC nanoparticles introduced into polyelectrolyte multilayer films

Aldona Mzyk¹, Roman Major¹, Bogusław Major¹

¹Institute of Metallurgy and Materials Science, Polish Academy of Sciences, Poland
aldonamzyk@gmail.com

INTRODUCTION

Nowadays, biosensors technology development is directed toward improvement of sensing devices biocompatibility. Polyelectrolyte multilayer film (PEM) seems to be appropriate for electrode coverage and semiconducting nanoparticles localization in order to create controllable polymer – nanoparticles tridimensional network. However, control of nanoparticles release from films and in a consequence their cytotoxicity is still a challenge. In this study we demonstrated that cytotoxicity of silicon carbide (SiC) nanoparticles introduced by physical vapour deposition (PVD) method into poly-L-lysine/hyaluronic acid (PLL/HA) or poly-L-lysine/alginate acid (PLL/ALG) films could be controlled by chemical cross-linking of coating.

EXPERIMENTAL METHODS

Multilayer (48 bilayers) polyelectrolyte films were prepared by “layer by layer” method on the silicon substrate. Coatings were cross-linked by mixture of 100 mM N-hydrosulfosuccinimide (NHS) and 260 mM, 400 mM or 800 mM 1-ethyl-3-(3-dimethylamino-propyl)carbodiimide (EDC) respectively. For the comparison various concentrations of the second cross-linker, genipin (1 mM, 10 mM or 50 mM) were tested. Nanoparticles were introduced to films by PVD, in 5-10s ongoing process. At first topography observations were done using Scanning Electron Microscopy technique (SEM) on Quanta 200 3D. Microstructure characterization was performed using Transmission Electron Microscopy technique (TEM), on cross-section by the Tecnai G² F20 (200kV) FEG. Potential cytotoxic effect of coatings was determined according to the ISO 10993-5 2009 standards.

RESULTS AND DISCUSSION

Analysis of nanoparticles distribution has shown aggregate-like structure formation in each type of investigated polyelectrolyte films. Nanoparticles have penetrated polymer coating and have formed a phase directly on the substrate (Fig. 1). Only a small number was anchored in the polymer multilayer. Nanoparticles phase composition revealed silicon carbide presence. We supposed that such charged molecules interact with polymer films in varying degrees depend on multilayer cross-linking state. The biological verification considered cytotoxicity of coatings modified by SiC nanoparticles has shown changes dependent on type of applied polyelectrolytes, cross-linker type and cross-linking rate. It was noticed that PLL/HA affected cells viability much more than PLL/ALG polyelectrolytes.

It has placed probably due to higher rate of swelling and release of polymer chains from PLL/HA. Multilayers cross-linked by NHS/EDC were more cytotoxic than the same non-cross-linked films. Moreover it was found that genipin cross-linker had lower necrotic effect than NHS/EDC. This might be a result of specificity and differences in cross-linking action mechanism of applied reagents. Cytotoxicity of NHS/EDC cross-linker was mentioned by Va'zquez et al. as a result of toxic unreacted amounts of applied reagents or reaction side products¹. The most important observation comes from this studies is that SiC nanoparticles could cause cytotoxic effect. Contrary, in literature silicon carbide was considered as a highly biocompatible material. However, up to date only a few toxicological data were available^{2,3}.

Fig. 1. Cross section TEM analysis of the SiC nanoparticles introduced into porous polymer coatings.

CONCLUSION

This studies present that SiC cubic nanoparticles could affect cellular viability. Among tested cross-linkers, genipin seems to be more suitable for nanocomposite properties control due to lower cytotoxicity and more effective stabilization of polymer – nanoparticle interaction.

INTRODUCTION

Titanium and titanium alloys are widely used in orthopaedic and dental implants. Early osseointegration is affected by surface characteristics and modification of the surface via plasma electrolytic oxidation (PEO), which is considered to be more conducive to cell attachment, spreading and proliferation of osteoblast-like cells [1]. A recent study using transcriptional profiling of cells during osseointegration revealed that several mechanisms, including inflammatory responses, play a significant role in the wound healing process related to osseointegration [2]. Therefore, the inflammatory process is an important factor which should be taking into consideration when evaluating implant materials. The aim of this study was to determine the effect of PEO surface modification of titanium and titanium alloy, on the inflammatory response and osteoblast growth and mineralisation.

EXPERIMENTAL METHODS

Ti13Nb13Zr and commercially pure titanium (cpTi) discs were selected for this study. PEO was conducted in a 10 kW KeroniteTM rig using the initial current density of 20 A·dm⁻² and using 0.05 M Na₃PO₄ electrolyte. The chemistry and surface morphology of the coatings were studied using XRD and SEM. Inflammatory responses were evaluated using human neutrophils and monocytes, purified by dextran sedimentation and discontinuous plasma-Percoll gradients, for up to 6 and 48 hours, respectively. Human foetal osteoblast cells ((Public Health England Culture Collections) were cultured on the materials for 29 days. To investigate inflammatory responses, pro-inflammatory tumour necrosis factor-alpha (TNF-α) a multifunctional cytokine with pro-apoptotic properties and anti-inflammatory interleukin-10 (IL-10) a potent deactivator of monocyte pro-inflammatory cytokine synthesis, were measured using paired antibody ELISA kits (R&D Systems). The metabolic activity of the foetal osteoblasts was monitored using alamarBlue (AbDSerotec); collagen release was determined by immunoblotting and mineralization using the OsteoImage kit (Lonza).

RESULTS AND DISCUSSION

Porous TiO₂ coatings with varying anatase-to-rutile phase proportions were produced on the surfaces of Ti13Nb13Zr and cpTi discs (Figure 1 A & B). In this study the cytokine production wasn't surface related. However all surfaces induced higher TNF-α at early time points and lower at later time points for both

neutrophils and monocytes studies. Furthermore there was no surface related difference in early release of IL-10 and the low released levels of IL-10 and TNF-α with no significant differences when exposed to PEO-treated and untreated titanium alloy or cpTi discs were evaluated. The change in metabolic activity with time was not significantly different between cell cultures on the different surfaces. However, mineral nodule formation was more apparent on the PEO-treated surfaces after 29 days (Figure 1 C & D).

Figure 1. SEM surface morphology of Ti13Nb13Zr (A) and cpTi (B) discs after 30 minutes of PEO coating and mineral nodule formation (C and D) (green fluorescence) after 29 days of human foetal osteoblast culture on Ti13Nb13Zr and cpTi discs.

CONCLUSION

Modification of Ti-alloy materials using PEO increased mineral formation with no adverse effects on the metabolic activity of human foetal osteoblasts. There was a low level release of TNF-α from both neutrophils and monocytes, which *in vivo* may contribute to wound healing; however, no difference was seen between PEO treated and untreated titanium surfaces.

Development of new bioactive phosphate-based glasses and study of the particle size effects on osteoblasts response for bone implant applications

Martin Stefanic, Xiang Zhang

Lucideon Ltd., Stoke-on-Trent, United Kindom

martin.stefanic@lucideon.com

INTRODUCTION

Phosphate based glasses (P-glasses) have many attractive properties for biomedical applications, such as an ability to completely dissolve in the body and the fact that their composition can be tailored across a wide range to give glasses with versatile properties [1]. P-glasses studied so far as bone implants were mainly too soluble for clinical applications. Therefore our aim was to develop and characterize more stable P-glasses with the composition (in mol.%): $40\text{P}_2\text{O}_5\text{-}25\text{-CaO-}5\text{Na}_2\text{O-(}30\text{-x)MgO-xSrO}$ ($x=0, 1, 5, 10$) and to study the influence of strontium content on the physico-chemical and biological properties of glasses.

Furthermore, we will report on the effects of glass particle size ($<1\text{ }\mu\text{m}$ vs $25\text{-}38\text{ }\mu\text{m}$) on the response of osteoblasts.

EXPERIMENTAL METHODS

Four P-glasses at compositions shown in Table 1 were prepared via melt-quenching route using $\text{NH}_4\text{H}_2\text{PO}_4$, Ca(OH)_2 , MgOH_2 , Na_2CO_3 and SrCO_3 as starting materials. The composition and structure of the prepared glasses was studied using XRD, XRF and FTIR.

Table 1. Composition of the studied P-glasses (mol.%).

Abbreviation	P_2O_5	CaO	Na_2O	MgO	SrO
P-glass_0Sr	40	25	5	30	0
P-glass_1Sr	40	25	5	29	1
P-glass_5Sr	40	25	5	25	5
P-glass_10Sr	40	25	5	20	10

Dissolution test. Dissolution of prepared glasses was tested in distilled water and in PBS with pH 7.4.

In vitro bioactivity in a simulated body (SBF). The in vitro bioactivity of phosphate glasses was evaluated by immersing 0.3 g of glass granules ($250\text{-}500\text{ }\mu\text{m}$) in 30 ml of SBF solution for various periods of time.

Effects of glass particle size on the cell response. For this study, dense P-glass/alginate hybrid membranes were prepared. In the composites P-glass particles were exposed on the surface of membranes and were not covered with a polymer. Two different size ranges of P-glass were investigated and compared, i.e. a) $<1\text{ }\mu\text{m}$ and b) $25\text{-}38\text{ }\mu\text{m}$. Sub-micron glass particles were obtained by milling the glass frit using a high-energy planetary ball mill (Retsch, Germany). An amount of P-glass particles in the composite membranes was optimized using an image analysis programme (SPIPTM, Image Metrology A/S, Denmark), such that the total surface

area of the glass in a membrane exposed to the cell medium was in the same range for both the sub-micron and micron-size glass particles.

RESULTS AND DISCUSSION

XRD analyses of the prepared glasses showed that all the glasses were amorphous. Figure 1 (left) shows degradation profiles obtained for the investigated P-glass formulations. Test of bioactivity in a simulated body fluid showed that a bone-like apatite layer precipitated on all the studied P-glasses after 7 days of immersion, indicating that investigated P-glasses have a bone-forming capacity (Figure 1(right)). Figure 2 shows SEM images of P-glass/Alginate membranes with submicron- and micron-sized P-glass particles.

Figure 1. Left) degradation profiles of studied P-glasses in PBS. Right) SEM image of the P-glass_0Sr granule after 7 days of immersion in SBF.

Figure 2. SEM images of the P-glass/alginate hybrid membranes with (left) $<1\text{ }\mu\text{m}$ and (right) $25\text{-}38\text{ }\mu\text{m}$ size particles.

CONCLUSION

Amorphous P-glasses in the system $40\text{P}_2\text{O}_5\text{-}25\text{-CaO-}5\text{Na}_2\text{O-(}30\text{-x)MgO-xSrO}$ were successfully prepared via the melt-quenching route. P-glass with 5 mol.% of SrO showed the highest stability in PBS. According to the SBF test, all the P-glasses studied are bioactive and possess bone-forming capacity.

Backside wear in fixed-bearing total knee arthroplasty : the effect of liner locking mechanism and surface roughness of tibial tray

Łukasz Łapaj¹, Jacek Markuszewski¹, Justyna Wendland², Adrian Mróz², Jacek Kruczyński¹

¹Department of General Orthopaedics, Musculoskeletal Oncology and Trauma Surgery, Poznan University of Medical Sciences, Poland, esperal@tlen.pl

^{2*}Metal Forming Institute, Poznan, Poland

INTRODUCTION

Backside wear of polyethylene (PE) inlays in fixed-bearing total knee replacement (TKR) generates high number of wear debris, but is poorly studied in modern plants with improved locking mechanisms [1]. That is why we decided to perform a retrieval studies of contemporary TKRs

EXPERIMENTAL METHODS

This study included five types of implants, retrieved after a minimum of 12 months (14-71) : three models with a peripheral locking rim and two models with a dove-tail locking mechanism occupying part of the circumference (Table 1)

Implant model (group name)	Alloy, mean Ra ¹	Locking mech. type	Nr. of inlays
Stryker Triathlon (Triath)	CoCrMo 5,61 µm	Periph. rim	15
Aesculap Search (Srch)	CoCrMo 0,81 µm	Periph. rim	9
DePuy PFC Sigma (PFC)	TiAlV 0,61 µm	Periprh. rim	13
Zimmer Nex-Gen (NGen)	TiAlV 0,34 µm	dovetail	11
S&N ² Genesis II (Gen2)	TiAlV 0,11 µm	dovetail	9

Table 1. Implants included in the study, (1) mean Ra – mean surface roughness (2) Smith & Nephew

Wear of bearing surface and back side of retrieved inlays was examined in 10 sectors under a light microscope. Seven modes of wear were analysed and quantified according to the Hood scale [2]: surface deformation, pitting, embedded third bodies, pitting, scratching, burnishing (polishing), abrasion and delamination. Damage of inlays caused by backside wear was also evaluated using scanning electron microscopy (SEM). Roughness of tibial tray was evaluated using a contact profilometer.

RESULTS AND DISCUSSION

We found no differences between wear scores on the articulating surface in all group, they did not correlate with backside wear scores in all groups as well. Backside wear scores the NGen group was significantly higher compared to other implants ($P < 0,001$ Wilcoxon test; Fig. 1). Lowest wear rates were found in implants from both Ti and CoCr alloys and peripheral locking rim.

Fig. 1 – Hood wear scores of bearing surface and backside of retrieved implants

SEM analysis demonstrated different wear modes in implants with dovetail mechanism and peripheral rim. The first group demonstrated signs of gross rotational instability, with severe abrasion with an arch-shaped pattern and delaminated PE (Fig 2a). In one design we observed severe extrusion of PE into screw holes of the tibial tray (Fig 2b). Inlays from trays with peripheral rim presented two types of wear : flattening of machining marks (Fig 2c) or protrusion of the material caused by the rough surface (Fig 2d).

Fig. 1 SEM analysis of retrieved inlays (bars indicate 500 µm – a,b,c and 300µm –d)

CONCLUSION

This study demonstrates that backside wear is still a problem in modern TKR. Our findings suggest that it is predominantly affected by type of locking mechanism (with peripheral rim performing better), to a lesser extent by surface roughness of the tibial component, while material type does not seem to play an important role.

INTRODUCTION

In the histologic assessment of biomaterials and their tissue response frozen sections are used in common practice. It is believed to best preserve the material by this method. In tissue preparation for paraffin sectioning alcohol series and xylol are used for dehydration. The chemicals could cause the disappearance of the material out of the section. On the other hand, the effect of rapid freezing on tissues and materials is not well investigated the applicability of frozen sections is greatly restricted for immunohistological staining – an important method to evaluate various tissue reactions like inflammation. For this reason, in the present pilot study, frozen and paraffin sections of dermal wound dressing materials were compared.

EXPERIMENTAL METHODS

In house pigs dermal lesions were performed and treated with natural degradable collagen-based wound dressing materials. Five punch biopsies were taken and of each one frozen and one paraffin section was performed. The samples were then compared regarding specimen quality, the preservation of the material, the preservation of the section and the quality of margins.

RESULTS AND DISCUSSION

In both paraffin and frozen sections material or residuals of material were present. In frozen sections the material appeared more densely whereas in the paraffin samples the material remnants were fluffy in most parts. However, in the frozen sections the material including surrounding tissue was often broke out of the sample, implying a loss of a part of the sample. These findings could be explained by the different processing methods. While in frozen sections the freezing causes stiffness of the material and tissue leading to preservation without greater chemical alteration. The cutting process then may lead to an avulsion of the material and the surrounding connected tissue including the loss of a part of the sample. Within histological processing in paraffin

sectioning the sample is exposed to several chemicals which lead to a dissolving of the material which can explain the fluffy structure of the material in the present study. The dissolving leads to a soft liberation without avulsion and loss of surrounding tissue or parts of the sample. Therefore, the material-tissue-interaction is better preserved in paraffin than in frozen sections. In preserved material-tissue areas gaps were present between the material and the tissue in the frozen sections. In contrast, in the paraffin samples the material-tissue-junction was well-preserved. Also, with both methods a loss of tissue was present, but the samples of paraffin sections contained more undamaged tissue and less tissue loss compared to frozen sections. Margins were sharp in paraffin sections, whereas the margins in the frozen sections were rather blurry.

CONCLUSION

Paraffin sections are not inferior to frozen sections to histologically evaluate material implants. If it is regardless whether paraffin or frozen sections are taken regarding the possibility of histological evaluation, clearly paraffin sections should be performed. The reason is the enlarged methodical possibility by e.g. producing histological stains which play a major role to help evaluate various tissue reactions like inflammation. A further important aspect is the far more easy way of storage of material for paraffin sections compared to frozen sections. To store frozen material is expansive, sophisticated and bears the risk of material loss if e.g. the fridge breaks or power failure occurs. Tissue treated with paraffin, by contrast, is easy and cheap to store and sections are easy to reproduce since the slice is always cut from the same surface.

Altogether, paraffin sections are as good as frozen sections and should then be the preferred method since tissue is easier to store and the diagnostic spectrum is broadened e. g. by the possibility of immunohistological staining.

Composition-Property Relationships for Gallium-Borate Glasses

INTRODUCTION: Various glass systems have become increasingly attractive and have been used in areas, such as oncology (localized radiotherapy) and bone regeneration¹. These glasses may be compositionally engineered to provide for an appropriate host response in a number of applications². Boron based glasses in particular have displayed variable degradation rates which can be subject to intermediate ion additions³. The loading of these systems with therapeutically relevant ions is increasingly considered in the literature and as demonstrated promising early results. Within this study, gallium (Ga) was incorporated (0-10mol%) into 70mol% B₂O₃ glasses and the composition-property relationship of each was evaluated. Ga was chosen as it possess certain characteristics which may enable it to interact with cellular processes and important proteins, specifically those related to the cellular uptake of iron. Ga has shown promising results in the areas of metabolic bone disease, cancer & infectious disease⁴.

EXPERIMENTAL METHODS: Six glass compositions (Table 1) were melt-quenched, ground, then sieved to a particle size distribution of 45-150µm. The glass transition temperature (T_g) of each glass was determined by means of Differential Scanning Calorimetry (DSC). Volume & density measurements were obtained by a helium pycnometer. B³⁺, Sr²⁺, Na⁺ & Ga³⁺ release dissolution characteristics were determined for each composition via ICP-OES for specimens incubated under simulated physiological conditions for up to 30 days.

Table 1: Mole fraction compositions of Ga-B glass compositions.

Glass Designation	B2O3	SrCO3	Na2CO3	Ga2O3
B100	0.7	0.2	0.1	0
GB200	0.7	0.2	0.8	0.2
GB201	0.7	0.2	0.6	0.4
GB202	0.7	0.2	0.4	0.6
GB203	0.7	0.2	0.2	0.8
GB204	0.7	0.2	0	1

RESULTS AND DISCUSSION

Figure 1: Density (g/cm³) for each composition (based on Ga₂O₃ mol. Fraction)

Fig. 1 and 2 illustrate that the compositional alterations (0-10mol% Ga₂O₃)

Figure 2: T_g for each glass composition (based on La₂O₃ mol. Fraction)

Figure 3: Ga³⁺ release (30 day) as a function of glass composition (Ga₂O₃ mol. Fraction).

had a pronounced effect on density and T_g, with a sharp increase occurring at 10mol% Ga₂O₃. Fig. 3 illustrates Ga³⁺ ion release after 30 days; ion release increased with increasing Ga₂O₃ content, however a maximum was reached at 8mol% Ga₂O₃, after which a decline in ion release was observed. Na⁺ showed a direct linear relationship with compositional alterations (decreasing additions of Na₂O). B⁺ & Sr²⁺ release appeared consistently high, increasing at 4 & 6mol% Ga₂O₃. B atoms can coordinate with both 3 and 4 oxygen (O₂) atoms forming triangular or tetrahedral structural units. The presence of additional O₂ atoms may instigate a conversion in the coordination number which can ultimately stabilize the B network.

CONCLUSION: The ability to compositionally engineer glass networks has resulted in their growth in popularity, specifically in the field of biomedical engineering. Ga₂O₃ was successfully incorporated into the 70mol% B₂O₃ network at varying additions (0-10mol%) and consequently the composition-property relationships of each was evaluated. The data obtained demonstrates increases in density and T_g along with distinct decreases in the release levels of each component ion (at 10mol% Ga₂O₃), indicating stabilization of the B₂O₃ network. These results support the proposal to further optimize these networks and Ga³⁺ release.

INTRODUCTION

This study reports on hydroxyapatite (HA) coatings and HA-based coatings doped with silicate ions [1-3].

EXPERIMENTAL METHODS

Plates of Ti grade 4 were used as substrates. The targets consisted of a powder of stoichiometric HA and silicate-containing HA (Si-HA) $\text{Ca}_{10}(\text{PO}_4)_6 \cdot x(\text{SiO}_4)_x(\text{OH})_{2-x}$ ($x=0.5$ and 1.72) were used. Thin nanostructured calcium phosphate (CaP)-based coatings were deposited by RF-magnetron sputtering with a power of 30-290 W, a negative substrate bias up to 100 V, and a pressure of 0.1 Pa [1]. As-deposited thin CaP coatings (up to 1 μm thick) were characterized by EDX, ESEM, XRD, IR spectroscopy, and pull off test. The primary dental pulp stem cells (DPSCs) and NCTC murine fibroblasts (clone L929, ATCC CCL1) were used to study the biocompatibility of the uncoated Ti substrates and deposited CaP-based thin films.

RESULTS AND DISCUSSION

As-deposited CaP-based coatings were dense and pore-free, and their composition was close to that of the precursor target composition. The chemical and phase composition as well as thickness and structure can be varied by adjusting the deposition control parameters. A low RF-power density ($0.1\text{--}0.5 \text{ W cm}^{-2}$) resulted in amorphous or low crystalline CaP-coating structure, and an increase in RF-power level ($>0.5 \text{ W cm}^{-2}$) induced the crystallization of the coating. The mineral in the coatings consisted of HA; all observed X-ray diffraction peaks matched the ICCD 9-432 card (HA). The four strongest peaks assigned to HA were observed at 25.8° (002), 31.7° (211), 32.2° (112), and 32.9° (300) (Cu K α radiation; 1.54 \AA). The (002) peak dominated the diffraction pattern, indicating a preferred c-axis crystallographic orientation. Its intensity increased with deposition time, i.e. film thickness. With an increase in the substrate bias voltage from 0 to -100 V , the intensity of the (002) peak gradually decreased. The XRD peak width of the coatings deposited at a negative bias voltage was broader than that deposited at zero bias, which indicates the presence of smaller crystals or smaller grain size. These differences in grain size were in good agreement with the data obtained by scanning electron microscopy. The XRD pattern of the coating at

different negative bias revealed a halo located at 32° typical for a nanostructured material. The negative substrate bias allowed us to vary the Ca/P ratio from 1.53 to 4. The adhesion strength of the coatings was higher than 40 MPa. Based on the biological assays it was concluded that low-crystalline HA coatings with the thicknesses 170, 250 and 440 nm stimulated cells to attach, proliferate and form mineralized nodules on the surface compared to uncoated Ti substrates. The absence of cytotoxicity of CaP coatings was shown *in vitro* assays using primary dental pulp stem cells and mouse fibroblast NCTC clone L929 cells. No suppression of metabolic activity of cells was observed. No significant effect of CaP coating thickness on cells behavior was found.

CONCLUSION

The results presented in this study showed that RF-magnetron sputtering allowed us to prepare CaP-based coatings with different structure and stoichiometry. These characteristics can be controlled by the deposition parameters. Based on the obtained results we suggest that RF-magnetron sputter-deposited HA-based coatings are prospective for clinical application, e.g. in stomatology or craniofacial medicine, where the initial material surface porosity for a further bone in growth should be preserved. It is suggested that the actual geometric and physical properties of the CaP coating must be important regulators in attachment and migration of the cells.

INTRODUCTION

Titanium (Ti) is widely used in both orthopaedic and dental fields due to their good mechanical properties, high corrosion resistance, and biocompatibility. Micro-arc oxidation (MAO) is a useful surface treatment based on electrochemical reactions under high voltage in a specific electrolyte. MAO treatment can easily alter the surface properties of metals and is also effective to improve the bioactivity of Ti. Our previous study revealed that certain amounts of extra elements presented in the electrolyte are incorporated in the porous oxide layer during the MAO process. Therefore, in this study, MAO treatment was performed on Ti in silver (Ag)-containing solution. The incorporation of Ag in the porous oxide layer can lead the slight release of Ag ions and the improvement of antibacterial property after implantation in a living body. The surface layer of MAO-treated Ti was characterized by surface analyses. The behavior of the Ag-ion release from the oxide layer was also evaluated by immersing in a simulated body fluid. ICP-AES was performed to determine the concentration of Ag ions in the fluid.

EXPERIMENTAL METHODS

A commercially pure Ti rod was sliced to make disk-shaped specimens with 8 mm in diameter and 1.5 mm in thickness. The surfaces of the disks were grinded with up to #800 grid SiC abrasive papers followed by ultrasonic cleaning in acetone and ethanol. The specimen was fixed in a polytetrafluoroethylene holder that allows exposing to an electrolyte only the specimen surface (7.0 mm in diameter). A Type-304 stainless steel plate was used as a counter electrode. The electrolyte for MAO treatment was 0.1-mol L⁻¹ calcium glycerophosphate, 0.15-mol L⁻¹ magnesium acetate, and 0-10 mmol L⁻¹ silver nitrate. After pouring the electrolyte into the electrochemical cell, positive voltage was applied for 8-10 min. The surface morphologies and compositions of the specimens were analyzed using a scanning electron microscope with an energy-dispersive X-ray spectroscopy (SEM/EDS). X-ray diffraction (XRD) was also performed with a diffractometer to identify the crystal structure of the oxide layer. 0.9mass% NaCl solution was used as a simulated body fluid to evaluate the Ag ion release from the MAO-treated specimen. The solution was replaced every 7 d to simulate the refreshment of the body fluid inside a living body. ICP-AES was used to measure the concentration of the Ag ions in the solution.

RESULTS AND DISCUSSION

The specimen after MAO treatment shows porous oxide layer on its surface (Fig.1). The morphology of the porous oxide layer was not changed by the presence of

Ag ions in the electrolyte. However, the voltage was not fully raised when the Ag concentration of the electrolyte exceeded 5 mmol L⁻¹ so that it was unable to form the oxide layer. The EDS results showed that Ag was incorporated in the oxide layer.

Fig. 1 Porous oxide layer containing Ag formed on Ti after MAO treatment

Figure 2 shows Ag-ion release from the oxide layer during the immersion in simulated body fluid (0.9mass%NaCl aqueous solution). Although the release rate of Ag ion was decreased at the initial stage of the immersion, it was stabilized at a certain value around 5 mg·m⁻²/week. It was confirmed that the incorporated Ag was gradually released from the oxide layer to the environment for long period.

Fig. 2 Change in the Ag-ion release rate from the oxide layers to the simulated body fluid

CONCLUSION

We succeeded to make the Ag-containing porous oxide layer on Ti by MAO treatment. Ag ions were properly released from the sample when it was immersed in a simulated body fluid. Thus, this technique is useful to develop novel biomaterials having both bioactive and antibacterial properties.

Imaging the structure, dissolution, and bone ingrowth into Bioactive Glass scaffolds

INTRODUCTION

The success of Bioactive Glass (BG) has been dominated by its controlled chemical degradation in biological systems where it can be applied as a powdered glass inserted into a defect sites, locally stimulating bone regrowth. However, for applications such as repair of long bone defects, a scaffold structure is required to guide growth and ideally provide strength. For over 15 years a number of groups have been producing Bioactive Glass scaffolds, using a range of techniques from sol gel foaming to 3D printing. This development has required not only significant advances in materials processing and chemistry, but also concomitant developments in 3D imaging and image quantification techniques. In this study the developments both in imaging techniques, and quantification techniques, are first reviewed and then the current state of the art laboratory and synchrotron techniques are applied to optimise BG scaffold chemistry and morphology.

Quantification of 3D scaffold architecture is critical in its matching the design criteria to act as both a guide and a stimulus for bone regeneration *in vitro* and then *in vivo* as defined by Jones, Ehrenfried and Hench [1]: a suitable interconnected porous network is important as the pore size and more importantly the interconnect size must be large enough to enable cell migration, fluid exchange and eventually bone ingrowth and vascularisation. Features such as interconnect diameter for vascularised bone ingrowth can now be automatically quantified and plotted using X-ray micro computed tomography (μ CT), as shown in Fig. 1. [2,3]

Figure 1. Quantification of a 70S30C sol gel scaffold (A&B) and Actifuse (C) with the distribution of interconnect sizes plotted (D).

EXPERIMENTAL METHODS

Laboratory and synchrotron μ CT was used to image the initial structures and ex vivo bone ingrowth into sol gel and 3D printed BG structures. Both commercial and in house code was then applied to quantify the structures, bone in growth, and scaffold dissolution, allowing a

quantitative comparison of the efficacy of different morphologies and compositions of glasses.

RESULTS AND DISCUSSION

The influence different pre-treatments of a 70S30C scaffold were compared to commercially available products such as Actifuse porous granules, as qualitatively assessed in Midha *et al.* [4]. Using quantitative μ CT quantitative measures of bone ingrowth were obtained. First a model joint was developed (Fig. 2a) and then registered in 3D to ex vivo scans at different time points (Fig. 2b).

The results show that with an effective pretreatment, there is excellent bone regeneration using a 70S30C scaffold (Fig. 2c,d) comparable to Actifuse (Fig. 2g,h), but without the presence of growth across the marrow cavity that occurs under these conditions when Actifuse is used. Without pretreatment ingrowth into the 70S30C scaffold is poor (Fig. 2e,f)

Figure 2. A 'model' joint was developed via statistical averaging (a,b) and then used to quantify the bone in growth into (c,d) 70S30C scaffold pre-conditioned by immersion into media for 3 days; (e,f) 70S30C scaffold with no preconditioning; and (g,h) Actifuse granules in autologous blood.

CONCLUSION

The use of laboratory and synchrotron μ CT allows not only the initial structures of Bioactive Glass scaffolds to be quantified, but also the time dependent in growth of bone, providing effective feedback for the optimisation of both BG chemistry and scaffold morphology.

INTRODUCTION

Angiogenesis is the physiological process involving the growth of new blood vessels from pre-existing ones. It is a critical process not only during normal development, but also in pathologic situations, where inadequate vascular evolution contributes to health complications. Angiogenesis is predominantly regulated by local factors that promote or inhibit neovascularization like e.g. AcSDKP (N-acetyl-seryl-aspartyl-lysyl-proline, acetyl-N-Ser-Asp-Lys-Pro)¹ isolated originally from fetal calf bone marrow.

Figure 1. Structure of N-acetyl-Ser-Asp-Lys-Pro

It has been shown that AcSDKP acts as a mediator of angiogenesis which occurs both during embryonic development and in postnatal life. AcSDKP can be used as biologically active supplement in number of different biomaterials². That is why its support in angiogenesis process has been investigated. Because of using ionizing radiation as a method of choice for sterilization, its influence on tetrapeptide has been also studied.

EXPERIMENTAL METHODS

In this work hydrogel matrixes containing polyvinylpyrrolidone – PVP, poly(ethylene glycol) – PEG, agar and tetrapeptide were synthesized using EB-irradiation (25 kGy, 4μs, 50 Hz). Release kinetics of active substance from the hydrogel dressings by high performance liquid chromatography – HPLC and gel swelling kinetics by the gravimetric method were

investigated. The equilibrium swelling degree of hydrogels and gel fraction content were determined. Changes in gene expression of human endothelial cells EA.hy926 (CRL-2922™ ATCC) induced by hydrogel matrix containing AcSDKP were studied using Human Angiogenesis Oligo GEArray System (SABiosciences). Cells were grown, in the presence of hydrogel with AcSDKP, to 80% of confluence. Total RNA was then isolated from the cells. cRNA was obtained in PCR reaction, then it was amplified and labeled with biotin-16-dUTP. The synthesized molecular probe (biotined cRNA) was used for 12 hours of hybridization with oligonucleotide fragments immobilized on microarrays. Chemiluminescent reaction was triggered by an addition of CDP-Star (1,2-dioxetane). Gene expression was determined by the spot darkness analysis on X-ray film (Kodak) by using ImageQuant 300 and ImageQuant TL 8.0 software (GE Healthcare).

RESULTS AND DISCUSSION

It was observed that the amount of active substance released from hydrogel matrix into water at 25 °C reaches the level of 55 - 80% after 6 h. Furthermore, swelling degree of hydrogel matrix in water rises with the amount of active substance and achieves the equilibrium after 160 h swelling. Gel fraction of matrix decreases with increasing amount of AcSDKP. Contact of endothelial cells with hydrogel matrix containing AcSDKP results in a higher level of changes in expression of genes responsible for angiogenesis.

CONCLUSION

Hydrogel based matrix containing acetyl-N-Ser-Asp-Lys-Pro activating angiogenesis process can be synthesized using EB-irradiation technique.

INTRODUCTION

The initial acceptance or rejection of a biomaterial is controlled by the interface of a material surface with the biological environment. Variations in substratum surface properties such as chemistry, topography, surface energy, etc., affect cell–biomaterial interfacial characteristics, potentially influencing cellular functions.¹ Biological response can be controlled by biomimetic approaches by patterning methods and selective chemical modification schemes.² A cell that comes into contact with a biomaterial will detect the surface chemistry to find suitable sites for adhesion, growth and maturation. Additionally, the 3D topographical environment is also important for cellular response.

We investigated cell–nanotopographic substrata interactions by using cells cultured on polymer-demixed nanotopographies. The nanofabrication system employed involves demixing of two immiscible polymers. The shape of the features is controlled by varying the composition of the polymer mixture. These surfaces were used to evaluate the biological response of mesenchymal stem cells (MSCs). Furthermore, to assess the effect of nanotopography versus surface chemistry, similar topographies with varying polymer combinations were investigated.

EXPERIMENTAL METHODS

In this study, we investigated six different polymer combinations of poly(methyl methacrylate) (PMMA), poly (lactic acid) (PLA), polystyrene (PS) and polycaprolactone (PCL) to produce polymer demixed thin films with varying nanotopographies. Control surfaces were produced using 100% of each of the polymers and each combination set was assessed at 3 different ratios (25:75, 50:50 and 75:25). The topography of each sample was assessed by AFM, while surface chemistry was analysed by FTIR and wettability by contact angle microscopy. Following MSC culture and seeding onto each sample, analysis of cell proliferation, morphology and differentiation by immunostaining (using osteocalcin, collagen II and adiponectin markers) was performed at 7, 14 and 28 days.

RESULTS AND DISCUSSION

The polymer demixed surfaces were predominantly made up of either nanoislands and protrusions or nanopits. Each polymer combination showed a preference for either the substrate or air interface. In the case of PMMA:PS, demixed films from blend solutions with a greater PS dose displayed pitted topographies whereas those with a higher proportion of PMMA were

largely made up of nanoscale protrusions. Such variation was also demonstrated in the PS:PLA group, with PS seemingly preferring the substrate interface and PLA the air interface; this produced pits when the proportion of PS was higher and islands and protrusions when the PLA dose increased. In both cases, higher doses of PMMA and PLA produced an island-dominant topography. Fittingly, the PMMA:PLA group, exhibited topographies that were all made up of interconnecting protrusions, which are even more apparent as the PLA dose increases. PCL appeared to prefer the substrate interface much more than both PMMA and PS. This is because as the proportion of PCL fell and PMMA/PS increased, the surface changed from a predominantly pitted surface to an island-dominant surface. The PCL:PLA group however produced topographies that were all relatively similar; this could be because the surface energies of these two polymers are similar. Representative images of the PS:PLA polymer combination is given in Figure 1.

Figure 1: AFM topographical images of PS:PLA films

Cell–substrata interactions were studied by using MSCs cultured on polymer-demixed nanotopographies. The results confirm that both physical and chemical characteristics can influence cell behaviour, specifically in terms of proliferation and differentiation. Cell proliferation was similar on the different samples studied at 7, 14 and 28 days. The morphology of the samples showed a shift from a fibroblast-like MSC morphology at 7 days, to a much more spindle-like morphology by 28 days.

CONCLUSION

Spin cast blends of displayed either nanoislands or nanopits depending on the ratio of the polymer used. It is hypothesized that the pits are a result of an incomplete dewetting process of a polymer blend. Cells not only prefer nanotopographies, but the underlying chemistry also plays a significant role on differentiation.

Role of Gallium doped phosphate-based glasses in the Management of Periodontitis

Bernadette Lackey¹, Rohan Sahdev¹, Quentin Nunes², Tahera Ansari³, Susan Higham¹, David Fernig⁴, Sabeel Valappil^{1*}

^{1*} Department of Health Services Research, University of Liverpool, UK, S.Valappil@liv.ac.uk

⁴ Department of Structural and Chemical Biology, University of Liverpool, UK

INTRODUCTION

This study aimed at evaluating the potential role of gallium, which is incorporated in controlled delivery agent phosphate-based glasses (PBGs)¹, for the management of periodontitis. Periodontitis describes a group of inflammatory diseases of the gingiva and supporting structures of the periodontium. They are initiated by the accumulation of plaque bacteria such as the putative periodontal pathogen *Prophyromonas gingivalis*, but the host immune response is the major contributing factor for destruction of periodontal tissues. Proteins that bind to heparin (HBPs) play important roles in health and disease and interact with each other via networks known as 'heparin interactomes'².

EXPERIMENTAL METHODS

In silico analyses using published datasets were used to construct a putative HBPs using online database resource 'Search Tool for the Retrieval of Interacting Genes' (STRING). *In vitro* study investigated the effect of gallium on matrix metalloproteinase (MMP-2) activity using MMP assay kit. Antibacterial assay of gallium was conducted using disc diffusion assay on *P. gingivalis* ATCC33277. *In vivo* biocompatibility of gallium was evaluated in rats as subcutaneous implants. Student's t-test was used to compare the mean values using GraphPad software (San Diego, CA, USA). P values < 0.05 were considered statistically significant.

RESULTS AND DISCUSSION

In silico analyses using published datasets revealed 25 up-regulated and 23 down-regulated HBPs in periodontitis. *In vitro* study of gallium on MMP-2, which is part of the HBP interactome in periodontitis confirmed that gallium ions released from Ga-PBGs inhibited MMP-2 activity significantly in water (p=0.03) and artificial saliva (p=0.003) media. Antibacterial assay of gallium displayed activity against *P. gingivalis* (22 ± 0.5mm compared with controls 0mm). *In vivo* biocompatibility of gallium evaluated in rats showed a non-toxic and foreign body response after two weeks of implantation (Fig 1).

The network analysis indicates that MMP-2 is an important player in the putative HBP interactome and a potential target for antibacterial gallium in the management of periodontitis. It was reported that the antibacterial effect of gallium was marked in an iron-controlled medium¹ hence Ga-PBG would be more effective in humans, where iron is sequestered by iron-

binding complexes to maintain an extremely low concentration of free iron.

Fig 1. Digital image of two glass discs after two week subcutaneous implantation in SD rats (a). Histological H&E stained sections following two week post implantation showing the biological response of (b) C-PBG (×40), (c) and (d) Ga-PBG (×40). Key: 1; Ga-PBG disc, 2; C-PBG disc, 3; darken area of the capsule shows signs of increased inflammatory cells and 4; lymphoid aggregates (collection of lymphocytes).

CONCLUSION

The results indicate that gallium ions might act on multiple targets of biological mechanisms underlying periodontal disease. Moreover, Ga-PBGs are biocompatible in a rat model evaluated after two weeks of implantation. The findings warrant further investigation into optimisation of gallium release from glass composition that will have important clinical implications in the future treatment and management of periodontal disease.

Antibacterial TiO₂ nanotubes incorporated with silver nanoparticles

Zhijun Guo and Li Zhang*

Research Center for Nano-biomaterials, Sichuan University, China,

*corresponding author: zhangli9111@126.com

INTRODUCTION

Titanium implants are widely used clinically, however, implant associated infection remains one of the most complications. So it is important to attain long-term ability to combat bacterial colonization on the implant¹. Due to the high surface-area-to-volume ratio, TiO₂ nanotubes (Ti-NT) are promising bioactive coating that can induce direct bone-implant bonding with enhanced host defense and serve as carriers for silver particles which is one of most popular antibacterial agents with benefits of lower resistant strains and no-cytotoxicity at suitable doses²⁻³. In this work, we attempt to fabricate silver-incorporated TiO₂ nanotubes. And investigate whether the samples indeed possess long-term antibacterial capability by *S. aureus* and *E. coli*.

EXPERIMENTAL METHODS

The Ti foils (10×10×1mm³) were polished by SiC sandpapers and soaked in mixed acid to remove the oxidation layer and ultrasonically cleaned by acetone, ethanol and deionized water. Afterwards, Ti foil served as the anode electrode and a graphite as counter in ethylene glycol electrolyte containing 0.5wt% NH₄F and 5 vol% deionized water. After anodization, the samples were soaked in AgNO₃ solutions with different concentration (0.5, 1, 1.5 and 2M) for 2 hours. Afterwards, they were cleaned with deionized water, dried, and irradiated with UV light for 2 hours. The samples were denoted as NT-Ag0.5, NT-Ag1.0, NT-Ag1.5, NT-Ag2.0.

RESULTS AND DISCUSSION

Fig.1 (a) SEM images of TiO₂ nanotubes anodized for 5h at 40V in 0.5% NH₄F ethylene glycol and (b) high magnification of a TiO₂-NTs formed by anodization of a Ti foil at 40 V for 5 h, which is a optimized anodization conditions, have a typical inner diameter of about 130 nm, outer diameter of 160 nm and length of about 2.8μm. (Fig.1). TiO₂-NTs perpendicular to the substrate and separated from each other, were open at the top and closed at the bottom.

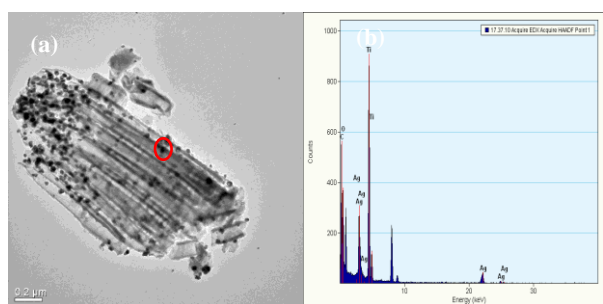

Fig.2 TEM images (a) and EDS (b) of Ag-incorporated TiO₂ nanotubes

The TEM image acquired from the nanotubes taken from NT-Ag0.5 shown in Fig.2. Careful inspection of Fig.2 reveals the Ag nanoparticles incorporated into the nanotubes tightly. The diameter of the Ag nanoparticles varies from 15 to 80 nm, which is related to AgNO₃ concentration. The Ag nanoparticles attached mainly to the inner wall of TiO₂ nanotubes, but also outer side walls and on top edges. The silver particles (black dots) are distributed homogenously in the TiO₂ nanotube layer. EDS analysis further confirms that the random black dots in Fig.2 is Ag nanoparticles.

a: control, b: NT-Ag0.5, c: NT-Ag1.0, d: NT-Ag1.5, e: NT-Ag2.0

Fig.3 photos of bacteriostatic annulus of samples

As shown in Fig.3, the bacteria and samples are cultured together to determine the bacteriostatic effect from zone of inhibition. The results indicated that all silver-loaded Ti-NTs reduced the proliferation of bacterial. In comparison, no zone of inhibition was seen around NT-0.0. Besides, the NT-Ag 1.5 and NT-2.0 have a wider zone of inhibition than other groups. NT-1.5 have high Ag-loaded efficacy than that of NT-2.0, indicating that it is a best choice to realize a better long-term antibacterial effect.

CONCLUSION

In summary, Ag nanoparticles are incorporated into TiO₂ nanotubes on Ti implants using a simple procedure involving AgNO₃ solution immersion and UV irradiation. The Ag nanoparticles adhere strongly to the inner walls of TiO₂ nanotubes, and the size and loaded dose of Ag nanoparticles can be regulated by adjusting the AgNO₃ concentration and immersion time.

The antimicrobial activity of NT-Ag were evaluated by *S. aureus* and *E. coli*. The results indicated that the Ag-loaded TiO₂ nanotubes could prevent the bacteria from adhering to the NT walls dramatically. Thus, the Ti implant with a series of treatment will have excellent antibacterial and osseointegrative abilities and have a great potential to be used in the field of hard tissue repair.

Bone Nodule Formation by Osteoblast-Like Cells Incubated with a Novel Silane Modification of Glass

Sandra Fawcett¹, Nicholas Rhodes¹, John Hunt¹, and Judith Curran²

¹ Clinical Engineering, UKCTE, Department of Musculoskeletal Biology, Institute of Ageing & Chronic Disease, University of Liverpool, UK

INTRODUCTION

Modification to biomaterial surface chemistry has been shown to be a useful tool for controlling cell response. More specifically, enriching substrates with groups that are prevalent in the extracellular matrix, *e.g.* $-NH_2$ (amine) can be used as a technique for enhancing the osteogenicity of a biomaterial¹. Whilst this research shows potential, results achieved to date have been variable due to the lack of consideration of the material induced responses at the sub-micron scale. In this work primary human osteoblast-like cells were isolated from human bone and seeded onto a range of $-NH_2$ -modified glass substrates. We fabricated $-NH_2$ -modified substrates with controlled chemical group distribution, surface energy and nanotopography. The optimal combination of these material factors was constructed to produce highly osteoconductive substrates.

EXPERIMENTAL METHODS

A range of $-NH_2$ -silane modified substrates were produced. The exact mechanism of material production is currently undergoing patent protection. All substrates were characterised using a ninhydrin assay (for amine concentration), water contact angle (surface energy), scanning electron microscopy (surface morphology) and atomic force microscopy (nanotopography).

Human osteoblasts (hOBs) were isolated from primary human trabecular bone. When the primary-derived cells had formed a monolayer, cells were trypsinised and seeded onto modified materials (50,000 cells / ml medium in a 24 well culture plate, 1 ml / well) and incubated in basic DMEM media with no exogenous growth factors, for 7, 14 and 28 days. Samples were then fixed and stained using Von Kossa's stain for mineralisation and visualised using light microscopy. In parallel cell-material interactions and formation of matrix was also qualitatively assessed using SEM (Zeiss/Leo 1550). Nodule formation was monitored and size and number were recorded for each test substrate using image analysis software. Quantitative evaluation of the mRNA expression of collagen I, osteopontin, osteocalcin, osteonectin, Cbfa1 and sclerostin was performed using real time polymerase chain reaction (qRT-PCR). All targets were normalised to β -actin and up-regulation of genes of interest calculated using the $\Delta\Delta C_t$ method. For all measurements of nodule size and qRT-PCR expression, a total of 4 repeats were carried out and differences in expression determined by ANOVA.

RESULTS AND DISCUSSION

Viable cell adhesion and general maintenance of the osteogenic phenotype was maintained on all $-NH_2$ -

modified substrates throughout the test period, although changes in $-NH_2$ modification affected the levels of expression observed in a modification-dependant manner. Bone nodules were formed on amine modified substrates with significantly smaller peak heights (sub 20nm) compared with other modified substrates, after 7 days. This material factor was the only significant difference between all tested amine-modified substrates.

Figure 1 Bone nodule formation by hOBs on sub-20nm peak height amine modifications (right), compared to untreated glass control (left)

There was no significant difference in overall amine concentration or surface energy on all $-NH_2$ -modified substrates tested within the study.

In addition the expression of sclerostin, marker of an osteocyte phenotype, was present on the sub 20nm peak heights after 14 days, but not present on the $-NH_2$ -modified substrates that had an average peak height greater than 20nm. Substrates that had a peak height greater than 100nm did not support nodule formation. Instead, cells cultured on these substrates were flattened and formed a cohesive monolayer, and maintained mRNA profiles that were suggestive of maintenance of the osteoblast phenotype. The expression of osteogenic markers on the surfaces with peak height greater than 100nm was smaller than the other test substrates.

CONCLUSION

Enrichment of a substrate surface with $-NH_2$ modifications is a valid tool for producing cell contacting materials that are osteoconductive. In order to enhance the osteogenic nature of these substrates and control the subtle switches from osteoblast to osteocyte and develop materials that induce matrix remodelling, we must combine changes in surface chemistry with a controlled nanotopography.

INTRODUCTION

Pure Mg and Mg alloys show great potential for application as biomaterial due to their special properties such as light weight, biodegradability, strength under load and the natural decay in the period of 3-4 months in vivo condition which is a perfect time for the integration of bone tissue¹. The number of biomedical applications with porous surfaces in micro scale is increasing especially in orthopedic applications. Micro-porous surfaces improve the integration between implant and bone and increase new bone formation². Porous surfaces also allow to control corrosion rate of an implant by manipulating the porosity. Previous studies showed that both micro-pores and micro-structures are responsible for the adherence of bone cells on implant surface and the acceleration of healing process^{3,4}. Therefore, it is assumed that a micro-textured and porous Mg alloy implant with an achievable porosity can enhance bone attachment and corrosion resistance.

In this study, different surface texture characteristics of AZ91D alloy were studied for the first time.

EXPERIMENTAL METHODS

AZ91D Mg, powders (Grain size: 10% < 50.4 µm, 50% < 177.6 µm and 90% < 614.1µm) were compacted by a Dartec Universal testing machine under different compaction pressures (150 and 200 MPa) at 100 and 150°C. Compacted implants are sintered at temperatures of 380 and 420°C at different periods (40, 60, 120 and 150 >mins) (Table 1). The goal is to determine acceptable windows of pressure, temperature and time to produce Mg implants with acceptable levels of porosity and strength for further biocompatibility and biodegradability tests.

No.	Mold Type	Load (kN)	Load Rate (kN/s)	Compaction Temp. (°C)	Sintering Temp. (°C)	Sintering Time (min)
1	#	360	4	150	420	60
2	#	360	4	300	420	60
3	#	360	4	300	420	120
4	O	360	4	300	420	120
5	O	480	4	300	380	150
6	#	480	4	300	380	150
7	#	480	4	150	420	40
8	O	480	4	150	420	40
9	W	480	4	150	420	120
10	#	480	4	150	420	60

"Table 1 shows experiment conditions."

XRD was used to investigate the presence and amount of the phases of the samples. XRD was performed on Also, the morphology of powder and specimens was investigated by SEM. The density and pore size of the implant were measured by Archimedes and Mercury porosimetry methods, respectively. Electrochemical tests were carried out to measure the electrical

conductivity in Hank's solution, DMEM and DMEM +10%FBS.

RESULTS AND DISCUSSION

The results show that compaction load has a significant effect on the attainable porosity level. Porosity of samples decreases with increasing compaction pressure. During trial experiments, sufficient bonding between particles could not be achieved when metal powders were compacted at temperatures below 100°C. It was also proved that the mold surface type has no significant effect on porosity. Image processing results were highly matched with mercury porosimetry results. The other conclusion from SEM images was that we were able to manufacture a porous surface, which have patterned or smooth surface features. No significant difference was observed between micro-hardness values after sintering in temperatures below eutectic temperature.

"Figure 1 show a) the SEM images of compacted powders; b) porosimetry results"

CONCLUSION

The main purpose of this investigation was to verify the feasibility of manufacturing porous structure of AZ91D alloy with micro surface features.

In summary, porosity can be controlled by manipulating the experiment parameters. The compaction temperature should also be higher than 100 °C in order to achieve strong bonding between particles. Moreover, de-inserting problems generally occur at compaction temperatures below 100 °C. Also, there was no oxidation problem because the working temperatures were relatively low at compaction stage. However, sufficient gas flow should be provided to prevent oxidation of magnesium during heat treatment process. And there is a need for obtaining uniform particles to get better results from image processing technique.

Nerve Tissue Engineering Using Blends of Polyhydroxyalkanoates

L.R. Lizarraga-Valderrama and Ipsita Roy*

Faculty of Science and Technology, University of Westminster, United Kingdom royi@wmin.ac.uk

INTRODUCTION

Peripheral nerve injury (PNI) affects 2.8% of trauma patients, many of whom suffer life-long disability. For injuries consisting of gaps of more than 5mm the treatment is most commonly attempted using autologous nerve graft repair. This treatment has various limitations including donor site morbidity, scar tissue invasion, lack of donor nerves, inadequate return of function and aberrant regeneration¹. Currently, there are several clinically approved artificial nerve guidance conduits (NGCs) made from various biomaterials that have overcome some of the limitations of nerve autografts. The drawbacks of using NGCs include the difficulty in their application surgically, their tendency to trigger immune responses, to induce scar tissue and to release compounds that are detrimental to the regeneration process¹.

Polyhydroxyalkanoates (PHAs), linear polyesters synthesized by a variety of bacterial species are potential materials to be used in the manufacturing of nerve guidance conduits to assist axonal regeneration. Properties such as: controllable surface erosion; variability in material properties, lower acidity of by-products after degradation and longer stability compared to their synthetic counterparts are of special interest in this field. Currently, poly-3-hydroxybutyrate P(3HB) would appear to be only type of PHA that has been explored for use in nerve regeneration. P(3HB) conduits have been shown to repair nerve gaps of 10mm and 40mm in rat sciatic nerves and rabbit peroneal nerves respectively^{2, 3}. The main objective of this project is to develop an advanced nerve conduit made from PHAs that have never been used before in nerve tissue engineering, such as mcl-PHAs and blends of mcl-PHA with scl-PHA. A key objective will be to determine the ideal mcl/scl PHA blend ratio that provides the desired physical properties and degradation rate for optimal nerve regeneration. This will then be used to produce a range of conduit structures

EXPERIMENTAL METHODS

Short chain length (scl) and medium chain length (mcl) PHAs were produced through bacterial fermentation at shaken flask and fermenter level. The polymers were extracted by using the chloroform-hypochlorite dispersion method and purified by using organic solvents. Chemical structure confirmation was carried out using FTIR, GC-MS, ¹³C and ¹H NMR. Different films made from neat PHAs and PHA blends in various ratios were fabricated using the solvent casting method. DMA was used to measure the mechanical properties of the polymers and the blends. To evaluate the hydrophobicity of the films, contact angle studies were carried-out. The thermal properties of the polymers and

films were analysed by using DSC. Surface study of each polymer was performed using scanning electron microscopy (SEM) and white light interferometry study. The *in vitro* cell culture studies were carried-out on the pure PHA films and their blends using NG108-15 neuronal cells.

RESULTS AND DISCUSSION

Chemical characterization. FTIR, ¹³C and ¹H NMR

The typical bands of the ester carbonyl group (C=O) and C-O stretching of mcl- and scl-PHAs confirmed the chemical nature of the polymers. The carbonyl bands were detected at 1727.15 cm⁻¹ for mcl-PHAs and at 1719.02 cm⁻¹ for scl-PHAs. The C-O stretching bands for mcl- and scl-PHAs were 1160.22 and 1180.14 cm⁻¹ respectively. The corresponding spectra of ¹³C and ¹H NMR of both PHAs (data not shown) verified the chemical structure of these polymers.

DMA, DSC and water contact angle

Young's modulus (E values), elongation at break and tensile strength of the different blends are shown in the Table 1. The results show that Young's modulus values increase as the content of scl-PHA increases in the blend film.

Table 1

Film	E' (MPa)	Tensile strength (MPa)	% Strain
mcl/scl PHA (75:25)	1.06	0.58	91.9
mcl/scl PHA (50:50)	93.44 ± 7.04	15.71 ± 2	48.80 ± 2.37
mcl/scl PHA (25:75)	144.12 ± 6.84	19.40 ± 2.96	39.62 ± 4.54

The mechanical properties of the blend mcl/scl-PHA (75:25) are similar to those found in acellular peripheral nerve suggesting that this blend could be a good base material for the manufacture of NGCs. DSC results (not shown) of blends suggested lack of homogeneity. Water contact angle of the blends (75:25), (50:50) and (25:75) were 95.02 ± 1.24, 84.40 ± 0.50 and 77.83 ± 3.05 ° respectively. As the content of mcl-PHA increased, the hydrophobicity increased because of the longer aliphatic chains present in these polymers.

CONCLUSION

PHA blends have varying properties, which can be tailored to obtain PHA-based materials suitable for nerve tissue engineering.

INTRODUCTION

Iron oxide nanoparticles attracted the interest of researchers working in nanotechnology due to potential biomedical applications, amongst others, in drug and gene delivery, magnetic resonance imaging (MRI) and hyperthermia¹⁻⁶. However, these nanoparticles should be easily dispersible, colloidal stable and biocompatible⁴. For this purpose, various polymers such as dextran, poly(lactic acid), poly(ethylene glycol), chitosan, poly(vinyl alcohol), polyaniline and polyethyleneimine (PEI) have been successfully coated on the surface of iron oxides.

In this paper, we describe a new approach to synthesize hybrid nanostructures based on Fe_3O_4 and PEI.

EXPERIMENTAL METHODS

Organic-inorganic hybrid nanostructures were synthesized using hydrothermal method in high pressure and low temperature conditions. Predictive studies concerning interaction of iron oxides with PEI were performed based on computational models. Composition of PEI based hybrids was carried out via FT-IR spectroscopy. The morphology and size of the inorganic particles were characterized with HRTEM analysis. Stable aqueous colloidal suspensions were prepared for in vitro measurements

The biocompatibility of this suspension was evaluated by interaction with mouse bone marrow-derived mesenchymal stem cells (MSC) in culture. The viability, proliferation and morphology of cells in the presence of nanohybrid were followed by MTT assay and phase-contrast microscopy.

RESULTS AND DISCUSSION

HRTEM micrograph presented in the figure below demonstrates the existence of crystalline planes with Miller indexes (220) and (400) corresponding to Fe_3O_4 . Crystallite sizes range between 2.5 and 7 nm. All structures were biocompatible with cells in vitro, in terms of supporting proliferation in complete medium (DMEM supplemented with 10% MSC qualified FBS). Interestingly, the sample having Fe_3O_4 :PEI=1:2 induced a change in MSC morphology resembling brown fat cell specific lipid. Further studies are needed to determine whether vacuoles appeared inside the cells are lipid

loaded and cells are directed towards differentiation into adipose cells.

CONCLUSION

New hybrid nanostructures based on polyethyleneimine and iron oxides were obtained, consisting of small crystallite of magnetite entrapped in organic phase. Biological interaction of these hybrid nanomaterials with MSC cells in vitro showed no cytotoxic effect and preservation of the cells morphology. Surprisingly, one sample having Fe_3O_4 :PEI=1:2 induced a change in MSC morphology and might be promising for their differentiation into adipose cells.

Regulation of Sclerostin Expression by ATP and PTH at Different Stages of Human Bone Development

Osman M Azuraiddi, Peter J Wilson, Nicholas P Rhodes and James A Gallagher

Department of Musculoskeletal Biology, Institute of Ageing and Chronic Disease, University of Liverpool L69 3GA, UK, Moht-Azuraidi.Osman@liv.ac.uk

INTRODUCTION

Sclerostin is a glycoprotein expressed by the SOST gene in osteoblast and osteocyte lineage cells¹. Sclerostin has anti-anabolic effects on bone formation through the inhibition of the WNT signalling pathway². The WNT signalling pathway is thought to be a major regulator of bone modelling and remodelling. Precise understanding and modulation of the WNT pathway should result in better control of the bone healing response³. Administration of Parathyroid hormone (PTH) in osteoporosis treatments has been shown to stimulate fracture healing⁴. However, in clinical trials, PTH has been shown to contribute only a limited improvement to bone healing in humans⁵. Consequently, there is much interest in sclerostin as a potential therapeutic target for applications in bone regeneration and healing. The aim of this study was to determine how SOST expression is regulated by ATP and PTH at different stages of osteoblastic development.

EXPERIMENTAL METHODS

We investigated the effect of ATP and PTH on the expression of sclerostin in three human osteosarcoma cell lines representing different stages of osteoblast differentiation, MG-63 the least differentiated, TE-85 intermediate and SaOS-2 the most mature. All cell lines were grown in DMEM + 10% FCS in 6 wells plate until 90% confluent. Cells were serum deprived for 48 hours with serum-free DMEM before treatment. Cells were treated with 10 μ M ATP, 10ng/ml PTH and 10 μ M ATP + 10ng/ml PTH respectively and incubated at 37°C for 17 hours. mRNA was extracted and reverse transcribed to cDNA. Expression of specific sclerostin was monitored by qRT-PCR using an iCycler iQ. Results were analysed using a Kruskal-Wallis test and Mann-Whitney with Bonferroni Correction.

RESULTS AND DISCUSSION

The gene expression profile in the three cells lines was consistent with the previously reported differentiation status. In control/untreated cells, SaOS-2 cells had the highest expression of sclerostin ($p < 0.05$) compared to MG63 and TE85 (Figure 1). Expression of sclerostin was intermediate in TE85 cells but significantly higher than MG63 ($p < 0.05$). One of the most striking differences between the cell lines was the expression of sclerostin in MG-63 cells, which was barely detectable, and that in SaOS-2 cells which was abundantly expressed. Sclerostin transcripts were present in TE85 cells but at an order of magnitude less than in SaOS-2 cells. In both TE85 and SaOS-2 cells, treatment with 10 μ M ATP, 10ng/ml PTH and 10 μ M ATP + 10ng/ml PTH caused a decrease in the expression of sclerostin.

However, the inhibition of sclerostin was not significant ($p > 0.05$) in all treatments in both cell lines compared to the control group.

Figure 1 Relative expression of sclerostin in response to ATP and PTH treatments in MG63, TE85 and SaOS-2 cells

CONCLUSION

The results reinforce previous reports on the relative differentiation status of these commonly used osteoblastic cell models. The robust expression of sclerostin in SaOS-2 confirms that this cell line represents a mature stage of the osteoblast / osteocyte lineage. However, the findings of this study show that inhibition of sclerostin by ATP and PTH occurred at all stages of bone development. Better understanding of the regulation of sclerostin should contribute to the development of new therapeutic approaches to the regeneration of bone in degenerative diseases, trauma and surgery and metabolic bone conditions.

Hemocompatible Biomaterial Based on Fibrin Coatings

Ondřej Kaplan, Tomáš Riedel, Milan Houska, and Eduard Brynda

Department of Biomaterials and Bioanalogous Systems/ Institute of Macromolecular Chemistry, Academy of Sciences of the Czech Republic, v.v.i., Czech Republic, kaplan@imc.cas.cz

INTRODUCTION

Various biomaterials have been synthesized for the manufacture of blood vessels prostheses and cardiovascular implants such as stents or aortic valves. However, no synthetic material has been capable of substituting the active functions of blood vessel endothelium. Thus, surface modifications are searched which could prevent an acute thrombus formation and encourage the subsequent endothelialisation on the cardiovascular implants.

Recently developed technique¹ has allowed us to coat materials, e.g. glass, nitinol, polystyrene, poly(ethyleneterephthalate), poly(lactide), poly(caprolactone), poly(hydroxyethyl methacrylate), and collagen, with fibrin networks growing from their surfaces. The coatings promoted the in vitro formation of confluent layers of vessel endothelium cells seeded on their surfaces². In the presented work we reached a decrease in thrombogenicity after coating glass surface with fibrin networks and immobilized heparin.

EXPERIMENTAL METHODS

Fibrin network was prepared on a glass surface by catalytic action of surface-attached thrombin on ambient fibrinogen solution². The fibrin structures were observed by SEM, AFM and confocal microscopy. The anticoagulant effect of the coating was characterized by the measurement of coagulation time after the recalcification of human blood plasma.

RESULTS AND DISCUSSION

Thickness of the surface fibrin gels was controlled within a range from 20 nm to 180 µm. The coagulation time of the recalcified human blood plasma increased from several minutes to couple of hours after coating of the surface with fibrin gel containing immobilized heparin depending on the gel thickness and heparin content.

CONCLUSION

The coatings can be applied on objects of various shape, structure, and materials. Potentially, they can encourage the endothelialisation of vessel prostheses lumen and other cardiovascular implants before thrombi are formed on their surface.

Inflammation-modulating biomaterial impacts neutrophil-monocyte juxacrine and paracrine regulation

Hannah Caitlin Cohen,¹ Tyler Jacob Lieberthal,² W. John Kao (PI, wjkao@wisc.edu)^{1,2}

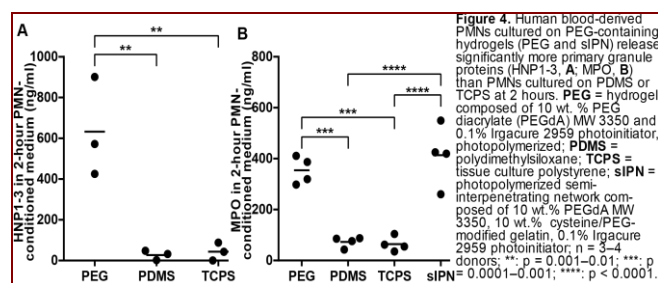

¹Pharmaceutical Sciences Division, School of Pharmacy, University of Wisconsin-Madison, Madison, Wisconsin 53705

²Department of Biomedical Engineering, University of Wisconsin-Madison, Madison, Wisconsin 53705

Statement of Purpose: The extend and the duration of the host inflammatory response have a predictive impact on wound healing outcome and material biocompatibility. Material-mediated polymorphonuclear leukocyte (PMN) and monocyte/macrophage (MC) paracrine and juxacrine regulation is not well understood. A mechanistic understanding of this will result in novel material engineering strategies.

Methods: Whole blood was collected from human donors and PMN and MC were isolated using a gradient method.² PEG hydrogels, PDMS and gelatin-PEG hydrogels were prepared as previously described,^{3,4} and cultured with PMN and/or MC with or without Src or PI3K γ inhibitors. Cellular viability, MPO as a primary granule marker and MMP-9 as a tertiary granule marker were measured. PMN conditioned medium was utilized to study the effect on MC migration in a Boyden chamber and cytokine expression. Experiments were repeated for four donors.

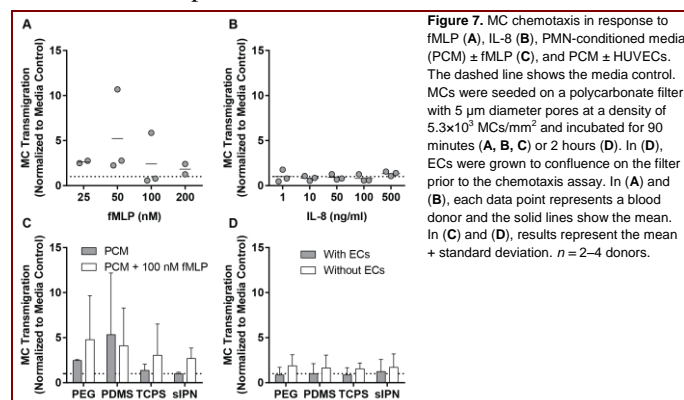

Results: There were no significant differences in adherent viable or necrotic cell densities among biomaterials. PEG-containing hydrogels had significantly higher MPO expression where MMP9 levels were comparable. Src was ubiquitously important for degranulation but PI3K γ dependent pathway was crucial only in PMN primary granule degranulation mediated by PEG and gelatin-PEG hydrogels.

To determine the downstream effect of PMN degranulation on MC function, MC were treated with material-specific PMN conditioned medium. We found that PMN-MC paracrine and juxacrine interactions minimally influenced PMN and/or MC viability and adhesion as well as cytokine expression (ie. IL-1 β , IL-8, IL-10)

Furthermore, no downstream effect on MC transmigration was observed when MC were treated with material-specific PMN conditioned medium either with or without endothelial cells present.

Conclusions: The incorporation of ECM-derived component gelatin to a PEG matrix resulted in an effected inflammation-modulating construct that mediated normal inflammatory response that quickly attenuated with more pro-healing MC phenotype. This minimalistic but yet robust material design bypass the complexity of employing biomolecules such as IL4 in regulating the host inflammatory response.

A Heterotypic Microfluidic Model of PDAC Microenvironment for Investigating Stroma-Tumor Interactions and Therapeutic Evaluations

Cole Drifka,^{ab} Kevin Eliceiri,^{abc} Agnes Loeffler,^{cd} Sharon Weber,^{cd} W. John Kao (PI, wjkao@wisc.edu)^{a-d}

^aDepartment of Biomedical Engineering, ^bLaboratory for Optical and Computational Instrumentation, ^cPaul P. Carbone Comprehensive Cancer Center, ^dSchool of Medicine and Public Health, University of Wisconsin, Madison, WI, USA

Introduction: Pancreatic ductal adenocarcinoma (PDAC) is nearly 100% fatal. The interplay between cancer cells, stromal cells, and the collagen-rich extracellular matrix (ECM) during progression to aggressive metastasis is critical but not fully understood.¹ Greatly limiting this understanding is the lack of a PDAC model that recapitulates key features of the *in vivo* stromal microenvironment while maintaining robust physical control with imaging and therapeutic accessibility. Additionally, traditional 2D culture formats may not accurately predict *in vivo* tumor responses due to neglected stromal contributions and may therefore limit the translation of new therapeutics. We have bioengineered a microfluidic model of the PDAC stroma-cancer axis incorporating clinically-isolated multicellularity, ECM components, and a spatially-defined 3D architecture.² The model's utility is supported by validating key features against clinically-evaluated human tissues, the ability to modulate ECM structure and monitor live cell-ECM interplay, and the potential to evaluate therapeutics in a microenvironment context.

Methods: Primary pancreatic stellate cells (PSCs) and cancer cells (PCCs) were isolated and characterized from clinically-evaluated PDAC tissue specimens. Microfluidic devices were fabricated via polydimethylsiloxane (PDMS) lithography. PSCs and PCCs, suspended in a collagen-based ECM, were patterned as 3D trilayers within devices. Void space created on each side of the trilayer was used to change media and administer therapeutic agents via capillary action. Second Harmonic Generation (SHG) imaging was used to visualize and quantify collagen structure and reorganization patterns in 111 pathology-reviewed human PDAC tissues and in different ECM formulations within the model. Microfluidic models were established, treated with increasing doses of paclitaxel for 48 hr, and assayed for cytotoxicity and culture compactness.

Results: Primary PSCs and PCCs pattern as a 3D trilayer due to laminar flow. PSC contraction of the ECM away from the PDMS sidewalls results in a compressed trilayer culture with void space flanking each side that can be used to exchange fluid via capillary action for *in situ* media changes or therapeutic administration (Fig 1).

Fig 1 (A,D) Empty device (B,E) PSC-PCC-PSC trilayer in 3D ECM (C,F) contracted trilayer with media +/- therapeutics in flanking void space.

Additionally, the trilayer emulates the spatial histological relationship of dense stromal components (PSCs and collagen) encompassing disseminating cancer cells *in vivo* (Fig 2A). After ECM contraction, the interface between PSCs and PCCs can be resolved and provides a unique opportunity to parse out cell-ECM interactions as a function of cell type (Fig 2C). Compared to normal pancreas, we show that collagen fibers in PDAC tissue are significantly longer (21.02 vs 18.56 μm , $p < 0.001$) and more aligned (0.36 vs 0.27, $p < 0.001$). In the model, *in vivo* collagen fiber lengthening and alignment can be represented by modulating the initial ECM formulation and allowing the intrinsic contractile behavior of PSCs to remodel the collagen network (Fig 2D). This establishes a platform to study the unclear role collagen architecture has on PDAC cell behaviors. Additionally, paclitaxel treatment reduces cell viability and culture compactness in a dose-dependent manner, suggesting that both cell and ECM responses to therapeutics can be analyzed (Fig 3).

Fig 2 (A,B) *In vivo*, PCCs are surrounded by a PSC-laden stroma with linear, aligned collagen fibers. In the model (C,D), PSCs contract and align the collagen around the central PCC region. Cells are green, collagen is orange.

Fig 3 Trilayer culture compactness after treatment with (A) vehicle control (B) 100 nM paclitaxel. (C) Quantified cell/ECM area as an indication of trilayer compactness. Data shows mean \pm SEM, * $p < 0.05$ vs. control for $n = 3$ devices. Scale bars = 100 μm .

Conclusions: We have developed and characterized a human tissue-based PDAC model to study underlying pathological mechanisms and to assess new therapeutic approaches, which are needed to improve PDAC prognosis. The use of patient-derived tissue components, ability to introduce therapeutics, and power to modulate and quantify cell and ECM changes support the model's value to PDAC translational research.

Enhanced migration of Mesenchymal stem cell spheroids towards glioma

Smruthi Suryaprakash¹ and Hon Fai Chan¹ and Kam W Leong^{2*}

¹Department of Biomedical Engineering, Duke University, USA

^{2*}Department of Biomedical Engineering, Duke University, ss515@duke.edu

INTRODUCTION

Glioblastoma is one of the most aggressive forms of brain cancer. Each year 18,000 people are diagnosed with glioblastomas with an average survival of 10 to 12 months. MSC are an attractive candidate for cell based therapy since they can be easily isolated, manipulated and have no immune rejection. MSC transduced with TRAIL are capable of migrating towards the tumor cells and kill the tumor cells due to bystander effect¹. However for cell based therapy migration, survival and retention are the major factors. MSC in spheroidal form has shown to have increased expression of CXCR4 which is critical for migration towards tumor cells². The spheroidal form also might help the cells to survive for longer and prevent it from getting washed out due to the extracellular matrix surrounding the cells and larger size respectively.

Hence MSC in spheroidal created using a microfluidic platform was used for cell based therapy to treat glioma

EXPERIMENTAL METHODS

Preparing the chip

Microfluidic device was prepared using soft lithography techniques. Silicon mold was patterned using SU-8 3025 to be of 200um in height. PDMS prepolymer and curing agent was then poured onto the silicon mold and cured. The PDMS mold was peeled and holes were punched in the inlet and the outlet. The device was bonded to a cover slip using oxygen plasma treatment. To make the second chip hydrophilic a two-step sol-gel coating procedure was followed.

Preparing the MSC spheroids

Cell culture medium supplemented with 0.3% pluronic F-127 and 10 million cells/ml was used as the inner phase. The oil phase used was HFE-7500 supplemented with Pico-Surf 1 surfactant. The outer aqueous phase comprised culture medium supplemented with Pluronic F-127 (2.5 wt%). The Flow rate of the inner phase was 4ul/min, middle phase was 13ul/min and outer phase 30ul/min.

RT-PCR for CXCR4

MSC single cells and MSC spheroids were cultured for 3days. mRNA was extracted and RT-PCR was performed using CXCR4 and GAPDH primers. A 2% agarose gel was used to run the cDNA.

MSC Migration assay

IBIDI cell culture insert was used to culture MSC/MSC spheroid and U87 on either side of a 500um gap

RESULTS AND DISCUSSION

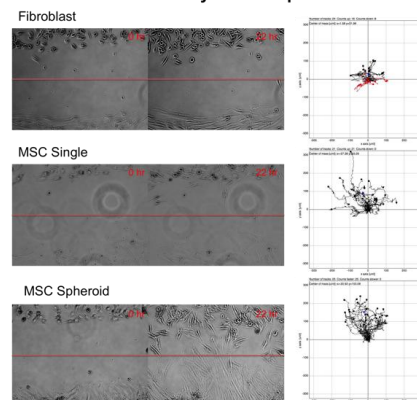

Rapid formation of MSC spheroids

Enhanced CXCR4 expression in MSC spheroids

Enhanced directionality of MSC spheroids

Using the microfluidic device the MSC spheroids were prepared in as fast as 4hrs. RT-PCR showed enhanced expression of CXCR4 which is crucial for MSC migration towards tumor cells. The migration assay demonstrated that MSC in spheroidal form moved greater distance and was more directional towards the tumor cell compared to single MSC cells.

CONCLUSION

MSC spheroids were prepared using a microfluidic device in as small as 4 hrs. These MSC spheroids showed higher expression of CXCR4 and enhanced migration towards tumor cells. Hence MSC in spheroidal form are an excellent candidate for treating glioblastomas. In the future these spheroids will be transduced with TRAIL and evaluated as a potential drug carrier for treating glioblastomas.

A Novel Soft Tissue Model for Biomaterial-Associated Infection and Inflammation – Bacteriological, Morphological and Molecular Observations

Sara Svensson^{1,2}, Margarita Trobos^{1,2}, Maria Hoffman^{1,2}, Birgitta Norlindh^{1,2}, Sarunas Petronis^{1,3}, Jukka Lausmaa^{1,3}, Felicia Suska^{1,2} and Peter Thomsen^{1,2}

¹BIOMATCELL VINN Excellence Center of Biomaterials and Cell Therapy, Sweden

²Department of Biomaterials, Sahlgrenska Academy at University of Gothenburg, Sweden

³SP Technical Research Institute of Sweden, Sweden, sara.svensson@biomaterials.gu.se

INTRODUCTION

Infection is one of the main risks for implant failure, resulting in severe patient suffering and high treatment costs. Biofilm-producing bacteria are a great concern and a “race for the surface” between bacteria and host tissue cells has been postulated¹. However, little is known about the initial events *in vivo* during biomaterial-associated infection and the role of specific surface characteristics. In the present study an infection model in soft tissues focusing on the initial events between host defence cells and bacteria on and adjacent to biomedical implants was developed. A primary aim was to analyse the biological events in three interconnected “sub-compartments”: the implant surface, the peri-implant exudate and the tissue. A secondary aim was to investigate the role of noble metal chemistry versus nanotopography *in vivo*.

EXPERIMENTAL METHODS

A biofilm-producing strain of *Staphylococcus epidermidis* (10^6 CFU) was inoculated to implant and sham (no biomaterial) sites in subcutaneous pockets in rats. Very smooth titanium disks (sTi), nanostructured Ti disks (nTi), noble metal coated (silver, gold and palladium) nanostructured Ti disks (nNoble) and sham sites were analysed with respect to number of viable bacteria; amount, viability and gene expression of host cells; as well as with different morphological techniques on the implant surfaces, the surrounding exudate and the tissue after 4 h, 24 h and 72 h. Control rats were inoculated with saline. Results were evaluated with Wilcoxon signed rank test, Mann-Whitney U test and paired samples t-test ($n=7-8$).

RESULTS AND DISCUSSION

The results showed a low and transient inflammatory response in both sham and implant sites without bacteria, as demonstrated by a peak of infiltrating inflammatory cells at 24 h, a low degree of cell death and early but transient gene expression levels of tumour necrosis factor- α (TNF- α), interleukin-6 (IL-6), IL-8, Toll-like receptor 2 (TLR2), TLR4 and elastase (ELA2). Administration of *S. epidermidis* to the sham and implant sites resulted in a significantly higher recruitment of inflammatory cells with a predominance of polymorphonuclear cells (PMN), higher and continuous cell death and an overall higher gene expression of TNF- α , IL-6, IL-8, TLR2 and ELA2. Very few viable *S. epidermidis* were detected at 4 h, but increased significantly to 24 h. Relatively lower levels (10^1-10^3 CFU) of *S. epidermidis* were detected on the implants compared with the exudates (10^2-10^4). At

all time points, *S. epidermidis* was predominantly located in the interface zone, both extra- and intracellularly (Figure 1). The results suggest that an efficient immune response was elicited at all sites, as judged by the extra recruitment and higher activity of inflammatory cells at infected sites, the PMN predominance and the distribution of inflammatory cells at the interface. Small differences were found between the different materials, but a trend towards an increased inflammatory response and a reduced amount of viable bacteria was seen for nNoble implants, demonstrating a role of the noble metal chemistry. However, the access to and the presence of bacteria on the implant surface may shift the race for the surface in favour of *S. epidermidis*, emphasizing the need for long-term studies

Figure 1. Tissue sections labelled by a coagulase-negative-specific FISH-probe (left) and stained with May-Grünwald Giemsa (right) showed *S. epidermidis* localised extra- and intracellularly of host defence cells in the interface zone between the implant and the tissue.

CONCLUSION

This experimental model allows detailed analysis of early events in inflammation and infection in relation to biomaterials *in vivo* and may lead to insights of host defence mechanisms in biomaterial-associated infections.

Pore Structure and Imaging of Collagen- and Elastin-based Scaffolds for Vascular Grafts

H. Frank*, J. Shepherd, S. Best, R. Cameron

Department of Materials Science and Metallurgy, University of Cambridge, United Kingdom

*hef30@cam.ac.uk

INTRODUCTION

Vascular grafts are needed to treat atherosclerosis, the single biggest cause of death in the developed world. Autografts such as the internal mammary artery or the saphenous vein are commonly used, but their main problem is with availability. Collagen- and elastin-based scaffolds used as vascular grafts are advantageous as they mimic the extracellular matrix of blood vessels (~30% collagen, ~7% elastin)¹. Previous studies have used SEM and histology to characterise collagen- and elastin-based scaffolds² but here confocal microscopy is laid out as an improvement to histology.

In this study, collagen- and elastin-based scaffolds have been created by freeze drying. They were visualised using SEM in order to determine the effects of elastin on the pore structure of the scaffold. Confocal microscopy was used as a new technique for clearly distinguishing between and elucidating the distribution of the two proteins.

EXPERIMENTAL METHODS

The experimental procedure used was detailed by Pawelec *et al.*³. Briefly, a 1 wt% slurry of protein in acetic acid was prepared. The protein was a mixture of collagen and elastin (ranging from 20:80 to 100:0 collagen:elastin). The slurry was degassed under vacuum and lyophilised in a mould made of stainless steel and PTFE. Scaffolds were then cross-linked using EDC and NHS.

SEM and confocal microscopy were used to image the interaction between collagen and elastin. Samples imaged using SEM were coated with gold while those observed using confocal microscopy had been stained with acriflavine, a non-specific fluorescent dye.

RESULTS AND DISCUSSION

Figure 1. SEM images of mixed collagen and elastin scaffolds. Left: collagen:elastin = 75:25. Right: collagen:elastin = 25:75.

The SEM images (figure 1) clearly show the pore structure of freeze dried collagen and elastin scaffolds. In both cases the pores are elongated, with sheets of collagen separating the pores. However, differences in the proportions of collagen and elastin cannot be seen clearly.

Figure 2. Confocal images of mixed collagen and elastin scaffolds. Left: collagen:elastin = 80:20. Right: collagen:elastin = 20:80. Green = collagen, red/yellow = elastin. Scale bars are 200 μm.

The images from figure 2 clearly show the differing concentrations of collagen and elastin in the two scaffolds, and can lead to a calculation of a quantitative value of collagen and elastin concentrations. The left hand image shows sheets of collagen in green, with large fibres of elastin distributed across the scaffold. This challenges a previous study which shows a more integrated structure of collagen and elastin². The right hand image confirms the even distribution of large elastin fibres across the scaffold.

CONCLUSION

The proportion of collagen and elastin within a freeze dried scaffold does not noticeably affect the pore structure of the scaffold, as shown by SEM. In all cases, collagen sheets are formed with differing amounts of elastin fibres on, depending on initial elastin concentration. These elastin fibres could affect mechanical or biological properties of the scaffolds.

A mixture of SEM and confocal microscopy should be used when determining the structure of mixed collagen and elastin scaffolds. SEM clearly shows the pore structure of scaffolds, while confocal microscopy gives an indication of the distribution of collagen and elastin across the scaffolds, along with a quantitative measure of the collagen and elastin concentrations. This will aid in creating scaffolds with a collagen/elastin concentration gradient which will better mimic the extra cellular matrix of blood vessels.

INTRODUCTION

Tissue engineering (TE) emerges as a promising approach in promoting tendon regeneration. However, unfavourable post-surgical adhesion formations restrict adequate tendon healing through the TE approach. Naproxen sodium (NPS), a non-steroidal anti-inflammatory drug (NSAID), has been demonstrated to prevent adhesions through inhibiting inflammatory response. In this work, polymer compositions (i.e. different poly-L-lactic acid (PLLA) to polycaprolactone (PCL) ratios) and percentage of water (H₂O) to hexafluoroisopropanol (HFIP) as co-solvent were varied to understand how these factors can influence the release of NPS from electrospun scaffolds.

EXPERIMENTAL METHODS

NPS was loaded into 8wt% PLLA/PCL blends with different polymer ratios and different HFIP/H₂O ratios. These varying formulations were electrospun into aligned scaffolds. Morphological assessment of these scaffolds was done through Scanning Electron Microscopy (SEM). *In vitro* drug release was carried out and the distribution of NPS within the electrospun fibers was determined by using X-ray photon spectrometry (XPS). *In vitro* cell culture studies were conducted by using L929 murine fibroblasts to assess the biocompatibility of NPS-loaded aligned scaffolds.

RESULTS AND DISCUSSION

PLLA/PCL-NPS were successfully electrospun into well-aligned fibers with beadless morphology. *In vitro* drug release profiles of the scaffolds with different PCL to PLLA ratios (Fig. 1A) and different amount of H₂O (Fig. 1B) were shown in Fig. 1. By adjusting the amount of H₂O as the co-solvent, NPS could be released sustainably for as long as two weeks.

Fig. 1: Cumulative NPS release of the scaffolds prepared from (A) different PCL to PLLA ratio and (B) different H₂O to HFIP ratio

In XPS data (Fig. 2), the presence of NPS was indicated by the Na 4s characteristic peak (binding energy = 1071 eV). More NPS was detected on the fiber surface when no water was added (90-10-0, solid line), while lower

NPS amount was detected on the fiber surface when 3 vol% of H₂O was used (dash-dot line), indicating that more NPS resided in the core of the fiber (Sch. 1). However, further increasing H₂O content resulted in having more NPS on the fiber surface, yielding a peak with an intermediate area that lies between 90-10-0 (no H₂O) and 90-10-3 (3 vol% H₂O).

Fig. 2: The XPS analysis of the scaffolds with and without NPS

Sch. 1: Possible NPS distribution within fibers with different H₂O contents

Live/Dead staining showed that L929 cells were able to proliferate healthily and arrange themselves according to the fibers alignment on day 7 of culturing (Fig. 3).

Fig. 3: Fluorescence microscopy images of L929 cultured samples over 7 days.

CONCLUSION

In this work, NPS was loaded into electrospun PLLA/PCL scaffolds with aligned, beadless and continuous fibrous morphology. By adjusting the H₂O content, a two-week sustained release could be achieved. *In vitro* cell studies showed that L929 cells could proliferate and align to the fiber orientation. These optimized PLLA/PCL scaffolds possess both sustained NPS releasing ability and desirable tendon TE characteristics, and could have good potential in achieving better tendon regeneration.

Analysis of cells proliferation after dynamic culture on cross-linked synthetic collagen peptide based microcarriers

M. La Marca and Suzan van Dongen

Fujifilm Manufacturing Europe, The Netherlands, margherita_la_marca@fujifilm.eu

INTRODUCTION

Nowadays, non-satisfying therapies for musculoskeletal injuries exist, above all for larger defect. Tissue engineering is a possible solution to restore the morphology and functions in bone disease¹.

During the last years different tissue engineering strategies including degradable porous scaffolds of natural or synthetic biomaterial, were proposed.

Interrogating the biological micro-world in a continuous and non-invasive manner is one of the most critical aspects which may limit the understanding of the biological complexity.

In this study synthetic collagen peptide (SCP) based microcarriers were prepared, , To mitigate the nutrient concentration gradients at the surface of the scaffolds, we used the spinner flasks. In this 3D, dynamic culture system, we investigate the proliferation and differentiation of C2C12 cell line.

EXPERIMENTAL METHODS

SCP microcarriers were prepared by an emulsification method and cross linked by DHT method. Cultispher G® was use as a reference.

Sterile spinner flasks were filled up with medium containing, microcarriers and C2C12 cells. The speed of the stirrer was set up and the cells were then cultured at 37°C, 5% CO₂ in a humidified incubator.

After day 1, 7, 14 and 21, SEM, dapi, live/dead and DNA content analysis were performed.

Data are expressed as mean \pm S.D., and statistical significance has been evaluated by Student's t-test or one-way ANOVA. Data were considered statistically significant when $p < 0.05$.

RESULTS AND DISCUSSION

SEM and dapi analysis were performed to verify the morphology of the cells, furthermore to have a quality results of cells proliferation.

Live/Dead assay showed that cells are viable up to 21 days.

DNA content analysis performed using the PicoGreen® assay, showed a linear increase of DNA content during the three weeks of the experiment. So we can assume a linear proliferation of the cells in our system. Moreover, we observed an improved proliferation on the SCP based microcarriers than in the commercial (shown in figure 1).

Figure 1 shows the DNA content results after day 1, 7, 14 and 21.

CONCLUSION

SCP based microcarriers show promising cell attachment and proliferation results and seem to be very suitable for cell culturing. On the basis of obtained results, we will further optimize the SCP microcarriers using the same dynamic system, in order to improve cell proliferation and differentiation.

Cell Response on the Ti-15Mo alloy Surface after Nanotubes Growth

Ana Paula Rosifini Alves Claro¹, André Luiz Reis Rangel¹, Nathan Trujillo², Ketul C. Popat²

¹ UNESP - Univ Estadual Paulista, Faculty of Engineering, Materials and Technology Department, Guaratinguetá Campus, São Paulo, Brazil

² Department of Mechanical Engineering, Colorado State University, Fort Collins, CO 80523, USA

INTRODUCTION

Titanium and its alloys have been widely used for biomedical applications due to their excellent properties and biocompatibility. However, these materials are considered bioinerts, i.e., they cannot bond chemically to the surrounding bone. Surface modification techniques have been studied to promote the chemical bond and better osseointegration [1-5].

EXPERIMENTAL METHODS

Ti-15Mo alloys were produced from sheets of commercially pure titanium and molybdenum in an arc-melting furnace under an argon atmosphere. The ingots were remelted and then homogenized under vacuum at 1000 °C for 86.4 ks. They were cold worked by swaging into bars (10 mm of diameter). Discs with 3 mm of thickness were cut for analysis.

Prior anodization, samples were grinded with emery papers and polished. TiO₂ nanotubes were obtained by anodizing method at room temperature in an electrolyte with 0.25 %NH₄F and glycerol at a constant anodic potential of 20 V. Annealing of nanotubes was performed at 450 °C for 1 hour. The morphology was observed by field emission scanning electron microscopy (FE-SEM; XL 30 FEG, Philips). Crystal structure was analysed by wide-angle X-ray diffraction. A contact angle goniometer was used to evaluate the wettability by sessile water-drop method.

Fibroblasts functionality was investigated by cellular adhesion, viability and morphology after 1, 4 and 7 days of culture. Cellular adhesion was investigated by fluorescence microscope imaging using calcein-AM live stain. Short-term cellular viability was investigated using MTT assay kit after 1, 4 and 7 days. Fibroblast morphology on Ti-15Mo alloy substrates was examined after 1, 4 and 7 days of culture using SEM.

RESULTS AND DISCUSSION

Figure 1 shows SEM micrographs of Ti15Mo after electrochemical anodic oxidation. Nanotubes highly ordered and vertically oriented were formed on surface alloy (Fig.1). Results indicate nanotube dimensions of approximately 60 nm in diameter and 160 nm in height. Surface exhibited super-hydrophilic behaviour after anodization.

Figure 1 – SEM images of the Ti-15Mo alloy surface morphologies after anodization: (a) top view ; (b) cross-section of TiO₂ nanotubes

MTT assay was used to evaluate the cell viability and results indicate that the cells are viable on nanotubular titania surfaces as well as on titanium alloy surfaces. The similarity between the absorbance values suggests that the cells are healthy and viable on all surfaces.

Fluorescence microscopy images of fibroblasts cells on Ti15Mo alloy before and after anodization are show in Fig.2a and Fig 2b, respectively. The images suggest that the cells are viable on these surfaces after 7 days of culture. SEM images (Fig. 3) show the morphology of cells on nanotubular surfaces after 7 days of culture.

Figure 2- Immunofluorescence images of the morphology of the fibroblasts cell on Ti15Mo alloy (a) and Ti15Mo (NT) groups (b) after 7 days of culture

Figure 3 – SEM observation of cells after 7 days of culture : (a) Ti-15Mo alloy; (b) Ti15Mo alloy after anodization

CONCLUSIONS

In this study, nanotubular formation was obtained on the Ti15Mo alloy surface by using anodization technique. The growth of TiO₂ nanotubes on the Ti-15Mo alloy surface lead to decrease of contact angle and a superhydrophilic behaviour was observed. Also a good interaction cell-material was verified after cell culture.

c.jerome@ulg.ac.be

INTRODUCTION

Shape memory polymers (SMPs) are smart materials presenting the remarkable property to switch from a temporary shape (stressed) to a permanent shape (relaxed) upon exposure to a stimulus, such as heat or light. SMPs raised a lot of interest, especially for biomedical applications, for the elaboration of suture wires and stents.^{1,2} In the last few years, biodegradable aliphatic polyesters, typically poly(ϵ -caprolactone) (PCL) and poly(lactide) (PLA) were widely studied for the synthesis of SMPs.^{3,4}

This communication aims at reporting a new concept for the synthesis of PCL-based SMPs. In order to meet the increasingly stringent requirements of biomedical applications, a metal-free process is proposed occurring at relatively low temperature, which can be compatible with the presence of a drug during implementation.⁵⁻⁷

EXPERIMENTAL METHODS

Shape memory properties were measured with a DMA Q800 (TA Instruments) using the tensile film clamp in controlled force mode. The sample was first equilibrated at 65°C for 5 min then a tensile stress ramp was applied to 0.6 MPa. The sample was then cooled down under stress at 3°C/min to 0°C and kept at 0°C for 5 min. The stress was then released and the sample was reheated at to 65°C. The process was repeated 4 times.

RESULTS AND DISCUSSION

According a Diels-Alder (DA) mechanism, two types of SMP, presenting reversible (furan) or non-reversible (anthracene) crosslinking, were synthesized in order to determine the influence of the crosslinking strategy on the shape memory properties. Typically, 4-arm star-shaped PCLs bearing either a diene (furan or anthracene) or a dienophile (maleimide) at their chain-ends were melt blended at 125°C before being cross-linked at 65°C. Shape memory properties were studied by Dynamical Mechanical Analysis (DMA) and the results are presented in Figure 1.

Figure 1: Dynamical mechanical analysis (DMA) of the PCL-based SMPs

When comparing the two curves, two main differences were observed between furan and anthracene strategies. Firstly, a higher strain for the furan-based is measured in addition of a steady increase in strain from cycle to cycle, which is not observed for the anthracene-based SMP. The first observation can be related to the crosslinking density, which is smaller for the furan-based SMP, due to the lower reactivity of furan with maleimide leading to a lower conversion yield and, in this way, of the crosslinking nodes density. The second observation can also be related to the occurrence of retro DA reactions under stress, leading creep of the material. From cycle to cycle, the sample is therefore less and less cross-linked, leading to larger ductility upon stress application, corresponding to a not pure elastic deformation. In case of the anthracene-based SMP, this phenomenon was not observed, corresponding to a pure elastic deformation. High fixity and recovery values were observed for each sample, about 99% and 98%, respectively). Moreover, upon cooling under constant stress, between 15°C and 0°C, a large increase of the sample strain was observed, due to the oriented crystallization of the PCL chains⁸, a behaviour that can promote so-called two-way shape memory property. Since anthracene-based SMP exhibit pure elastic deformation, two-way shape memory behaviour was successfully observed.

CONCLUSION

Owing to the different crosslinking strategies, reversible or not, the resulting SMPs exhibit marked differences in their shape memory properties. However, for each SMP, excellent recovery and fixity were observed as assessed by DMA. Moreover, the higher stability under stress of anthracene-based SMP allows considering its application for the elaboration of a material presenting remarkable two-way shape memory behaviour.

INTRODUCTION

Fibronectin (FN), a large glycoprotein found in body fluids and in the extracellular matrix, plays a key role in numerous cellular behaviours and particularly in cell adhesion¹. In recent work we were able to extract from pea plants a glycoprotein (called “green fibronectin” or gFN) with very high homology compared to plasma fibronectin (pFN). The gFN is purified by the method described by Pellenc et al.². It was also shown that the gFN has a higher percentage of glycosylation (70%) than pFN³ (5%). In view of its homology to pFN, it seemed appropriate to investigate its potential to elaborate cell and bacteria adhesive substrates as a substitute to pFN. Such strategies would enable to be free from the drawbacks associated with the use of human or animal plasma derived proteins. In this first study, we propose to graft the gFN to nitrogen plasma treated polystyrene surfaces (PSN₂) or via its sugar moieties.

EXPERIMENTAL METHODS

1 ml of a 20 µg/ml FN solution in PBS buffer (0.15 M, pH 7.4) was transferred to the plasma treated PSN₂ wells. The plates were then incubated at the desired adsorption temperature (37 °C) in a convection oven for the required adsorption time. We developed and optimized grafting of the FN via its sugar moieties to the aminated surfaces by reductive amination. The wells were sequentially washed with 3 rinses in PBS buffer. This step was followed by 3 rinses in 1% SDS aqueous solutions in the case of the desorption experiments. The amount of protein before and after the various rinses was determined using a BCA assay.

The amounts of grafted and adsorbed gFN were quantitatively compared to those for the pFN (the model protein) before and after SDS rinsing.

RESULTS AND DISCUSSION

The amount of adsorbed gFN was 0.85 ± 0.05 µg/cm² and more than 85% of the adsorbed protein was desorbed after three 1% SDS rinses. For pFN adsorption, the amount of adsorbed protein was 0.68 ± 0.02 µg/cm² of which 100 % was desorbed after 1% SDS rinsing. In the same conditions of temperature and protein time exposure to the surface, the amount of

proteins immobilized via our grafting method was 0.69 ± 0.03 µg/cm² and 0.58 ± 0.06 µg/cm² for gFN and pFN, respectively. The amounts remaining after 1% SDS rinses were 0.43 ± 0.03 µg/cm² and 0.19 ± 0.09 µg/cm² for gFN and pFN, respectively. The protein fractions remaining on the surface after three 1% SDS rinses were thus 68 ± 3 % and 38 ± 3 % for gFN and pFN, respectively. This result suggests that the amount of protein remaining on the surface was considerably higher for the gFN compared to that of the pFN protein. This result is consistent with a higher fraction of more tightly bound protein for the gFN compared to that of the pFN likely due a higher relative amount of sugar moieties on the gFN as described above.

CONCLUSION

These results are promising in that they validate our described grafting method approach for this “green” protein and likely for many other types of “green” proteins.

Peptide-Polysaccharide Based Injectable Hydrogel for Sustained Delivery of Active Agents

Cem Bayram^{1*}, Ekin Çelik² and Emir Baki Denkbaş³

^{1*} Chemistry Department, Aksaray University, Turkey, cembayram@gmail.com

² Bioengineering Department, Hacettepe University, Turkey

³ Chemistry Department, Hacettepe University, Turkey

INTRODUCTION

In recent years, low molecular weight building blocks and their ability to form self assembled gels and applications via noncovalent interactions have attracted a great interest. These molecular hydrogels have been reported as biocompatible and exhibit a protective environment for bioactive molecules such as enzymes and proteins¹.

However, there is a limitation in use of these hydrogel structures as matrix due to low mechanical properties. For example, frequently used Fmoc-peptides lose their stability and mechanical integrity at pH levels above 6.5. This situation makes them difficult to be used inside human body. A recent approach to enhance the mechanical properties of these structures is to mix them with polymeric additives and better fracture resistances have been observed than in cases when two mixing structures used alone. The conjugation of self-assembled gel structures of polysaccharides with low molecular weight molecules are also known as suitable and stable compositions for drug delivery and tissue culture applications².

EXPERIMENTAL METHODS

The lyophilized peptide (Fmoc-Phe-Phe-OH) were dissolved in 0.1M NaOH to obtain 20mM peptide solution. Then the mixture was separated into 1 mL aliquots, and GdL (glucono-d-lactone) was added to each specimen with, 20 mM concentration to start gelation. Meanwhile, another set of peptides were dissolved in 0.1 M NaOH containing 0.1% – 0.5% w/v alginate solutions and then gelated as mentioned above. The resulting gels were characterized morphologically, chemically and mechanically. Imaging of specimen were carried out with Scanning Electron Microscopy after freeze drying of the gels and chemical characterization was analyzed with Fourier Transform Infrared Spectroscopy. Rheological measurements were performed by rheometer system with cone-plate geometry (34 mm scale, 4°) at 25°C.

For sustained release studies, the gelation solutions were incorporated with varying concentrations (0.5%, 1.5% and 2.5%) of vancomycin. HCl. Release experiments were performed with simply injection of hydrogels into Phosphate Buffer Saline release media (pH:7.4)

RESULTS AND DISCUSSION

Stable transparent gels were obtained after standing overnight at room temperature. The SEM images revealed that the structure of resulting gel systems, – both Fmoc-Phe-Phe-OH only, and with alginate – resembles each other with slight differences. Matrices made from peptide only shows highly entangled fibers with approximately 30 nm diameter; whereas composite scaffolds have these nanofibers homogenously dispersed through alginate leaflet structures.

FTIR analyses exhibits the peaks around 3310 – 3290 cm⁻¹, 1650 – 1630 cm⁻¹ and 1540 – 1530 cm⁻¹ indicating the N-H stretching (amide A), >C=O stretching (amide I) and N-H bending (amide II), respectively. In addition to these peaks, carboxylic acid functionality can be observed in composite gels.

The rheological analysis of the gels were done with 0.1% deformation ratio at 0.01-10 Hz frequency with frequency- sweep scanning, The elastic modulus (G') of gels were calculated higher than viscous modulus (G'') with the data evaluated from rheometry analyses, which means that all systems are solid gels.

The most effective parameter on vancomycin release was found as alginate concentration.

CONCLUSION

A Fmoc-Phe-Phe-OH hydrogel was prepared by self assembly of peptides alone and in presence of alginate. Alginate incorporation improved the mechanical integrity and stability respect to peptide only gel structure. The sustained release time of vancomycin also was found to be prolonged by managing incorporated alginate amount. The resulting peptide-polysaccharide composite gel system is a promising material for injectable and biodegradable hydrogel.

Characterisation of Freeze-Dried Collagen-Fibrinogen Constructs

Jennifer Shepherd^{1*}, Charlotte Rasser¹, Serena Best¹, Ruth Cameron¹

¹Department of Materials Science and Metallurgy, University of Cambridge, UK, *jhr37@cam.ac.uk

INTRODUCTION

A promising route for tissue repair is via the implantation of a scaffold structure that enables infiltration and proliferation of a patient's own cells, leading to production of extra-cellular matrix and regeneration of native tissue characteristics. Collagen is a common material of choice, but a high degree of cross-linking is typically required in order to avoid rapid degradation *in vivo*. This degree of cross-linking can affect the bioactivity¹. The addition of another biologically relevant material within the system may impart additional biological cues to, for example promote a particular cell type or cell response. In a freeze-dried structure it is important to be able to characterise the effect of multi-composition on structure as well as understanding the distribution of the different materials within the structure.

This work considers the freeze-drying of 50:50 collagen: fibrinogen materials. Fibrinogen has been demonstrated to promote cell migration^{2,3} and thus appears a promising additive to a collagen based scaffold. Structures were imaged using SEM, micro-computed tomography and confocal microscopy.

EXPERIMENTAL METHODS

A 1wt% collagen slurry in 0.05M acetic acid (insoluble type I collagen derived from bovine dermis) was produced and acriflavine, a non-specific fluorescent dye (excited at 488 nm) added in trace amount. Fibrinogen (derived from human blood plasma and depleted of plasminogen) was dissolved to form a 1wt% solution in deionised water and a Fibrinogen - Alexa Fluor 647 conjugate added in a ratio 50:1 fibrinogen: fibrinogen conjugate. The collagen suspension and fibrinogen solution were then combined and gently mixed before being poured into silicone moulds.

Freeze-drying was carried out in an AdVantage Virtis Freeze-dryer using a freezing temperature of -30°C and primary drying temperature of 0°C. Confocal imaging could then be carried out dry without any post-lyophilisation processing. A Leica SP2 confocal system was used with excitation at 488 and 633 nm. SEM (JEOL JSM-5510) and Micro-computed Tomography (Skyscan 1172) were also considered in order to analyse pore structure in 2 and 3 dimensions.

RESULTS AND DISCUSSION

The use of two fluorescent stains with widely separated excitation and emission wavelengths enable fibrinogen and the acriflavine staining to be clearly detected independently (*Figure 1*). The conjugated fibrinogen (red on the images) appeared uniformly distributed and despite the relatively low ratio of conjugate to standard fibrinogen, provided thorough staining of the material.

Figure 1: Confocal images at low and high magnification demonstrating the distribution of the fibrinogen alexa-fluor conjugate through the structure

Figure 2: Pore structure imaged with (a) SEM and (b) a volume rendered model derived from micro-CT

Figure 3: Using a shrink wrap analysis in CT-Analyser (Bruker Micro-CT) interconnection diameters could be investigated.

A combination of SEM and micro-CT allowed for both a qualitative and quantitative analysis of the pore structure (*Figures 2 and 3*). Analysis showed the addition of fluorophores to have no significant effect on pore structure.

CONCLUSION

Addition of a non-specific fluorescent stain and the Fibrinogen - Alexa Fluor conjugate to the initial slurries, enabled confocal microscopy to be used as a means of analysing chemical distribution, without any post-lyophilisation processing. Although confocal imaging allowed some investigation of pore structure, SEM and micro-CT provided additional qualitative and quantitative information.

Nanosized grooves controlling neuronal cell-organization and axonal outgrowth for cochlear implant optimization

Alexey Klymov¹, Joost te Riet², John A Jansen¹ and X Frank Walboomers¹

¹ Department of Biomaterials, Radboud University Medical Center, Nijmegen, The Netherlands

² Department of Tumor Immunology, Radboud Institute for Molecular Life Sciences, Radboud University Medical Center, Nijmegen, The Netherlands

INTRODUCTION

The loss of hair cells ultimately leads to sensorineural deafness. This is due to the resulting lack of stimulation of up to 30000 neuronal cells (spiral ganglion cells, SGCs) of the auditory nerve. Preferentially these hearing deficits are treated by placement of cochlear implants (CI), circumventing the hair cells by direct SGCs stimulation [1]. While being able to return the ability to perceive abstract sound, the modern CI cannot return the patients high fidelity hearing. This is mainly due to the lack of direct interaction between the SGCs and the CI electrode, leading to a strong decrease in separation of electrical stimuli. While the attraction of SGCs to the electrode surface can be achieved by use of neurotrophins[2], the interaction between cells and electrode-surfaces could be optimized by utilization of surface topographies [3]. This may allow a more organized cell-electrode contact.

EXPERIMENTAL METHODS

A silicon master featuring five different grooved patterns (pitch sized between 150 nm and 1000 nm) and a smooth control, were used for replication of the surfaces into tissue culture plastic polystyrene by solvent casting (Figure 1). The substrates were used for culture of rat pheochromocytoma derived neuron-like PC12 cells. The cells were analyzed after 7 days of cell culture by light microscopy and scanning electron microscopy. Cell body orientation, axon orientation and axonal outgrowth have been assessed.

Figure 1: Multi-patterned culturing replicate. A) Silicon wafers with smooth and grooved surfaces (pitches between 150 nm and 1000 nm) were combined to one silicon master mold for solvent casting of polystyrene surfaces. B) The substrates were analyzed by SEM and AFM for quality control (600 nm pitch pattern shown).

RESULTS AND DISCUSSION

Axonal outgrowth was significantly stimulated by all grooved patterns compared to the smooth control (Figure 2). A threshold was found for cell-body alignment on grooves with a pitch size of 300 nm, while axons already aligned to grooves with a pitch size of

200 nm (Figure 3). The interaction of the axons has been found to be primarily based on contact with the ridge regions, rather than with the groove region on the substrates.

Figure 2: Differences in axon-outgrowth of neuronal cells as a response to differently patterned substrates.

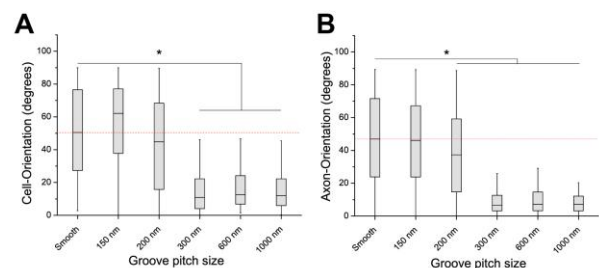

Figure 3: Cell-body and axon orientation on smooth and grooved topographies.

CONCLUSION

Nanogrooves can be used to manipulate neuronal cell behavior by increasing the axonal outgrowth and direct the alignment of cell bodies and axons. For optimization of CI electrodes a starting point can be the threshold of grooves having a 300 nm pitch, as this is the smallest pattern that could induce significant cell body and axon orientation.

The effectiveness of tetra sodium EDTA as an anti-biofilm agent for use in biomaterials

Steven L Percival^{1,2} and Peter Kite²

¹Institute of Ageing and Chronic Disease, University of Liverpool, Liverpool, UK

²Surface Science Research Centre, University of Liverpool, Liverpool, UK

INTRODUCTION

EDTA is regarded as a 'potentiator' of other antimicrobials¹. Consequently EDTA *per se* has not generally been recognised as an important antimicrobial in its own right. Conversely tetra sodium EDTA has been found to be a very effective antimicrobial on biofilms in catheters². In spite of this recent research there is a significant lack of available data on the effectiveness of TEDTA on biofilms. Biofilms are microcolonies of microorganisms encased in an extracellular polymeric matrix. Biofilms are reported to be associated with 80% of all known human infections and 65% of hospital acquired infections. It is well documented that microorganisms growing within the biofilm lack susceptibility to antimicrobials when compared to their planktonic counterparts. It is therefore imperative that any antimicrobial agent used, and developed for use on and within biomaterials, is effective on biofilms. The purpose of this study was to determine the minimum biofilm eradication concentration (MBEC) of tetra sodium ethylenediaminetetraacetic acid (TEDTA) on the clinical isolates *Staphylococcus lentus*, *Staphylococcus simulans*, *Staphylococcus aureus*, *Staphylococcus aureus* (MRSA), *Klebsiella ornitholytica*, *Escherichia coli* and *Acinetobacter baumannii* using the an MBEC biofilm model.

EXPERIMENTAL METHODS

- A starting suspension for each microorganism was prepared to a McFarland standard of 1.0 in Mueller-Hinton Broth. The starting suspension was diluted to obtain a working inoculum of 10⁷ cfu/ml.
- 150 µl of the working inoculum was placed in each test well in the designated column of the MBEC plate (University of Calgary, Calgary, Canada).
- Columns were set up to test a maximum of 8 isolates per plate, with one well for growth control and six EDTA concentrations in duplicate.
- Using a 96 well tissue culture plate, the challenge plate was prepared.
- The concentrations of TEDTA prepared and tested were 0, 5, 10, 20 and 40 mg/ml.
- The peg lids were transferred to the challenge plates and incubated at 35°C for 1, 3, 6, 12 and 24 hours.
- Pegs from the challenge plates were rinsed in saline for approximately 1 minute, transferred to recovery media plates and then sonicated in a

sonicating water bath on high for 5 minutes to dislodge the surviving biofilm.

- The challenge plate was used to determine minimum inhibitory concentration (MIC) values for TEDTA.
- The turbidity, determined on a plate reader, in the wells of the challenge plate was used to determine the MIC for the planktonic bacteria shed from the biofilm during the challenge incubation.
- The MBEC for each TEDTA concentration and time was obtained by reading the turbidity or re-growth on the recovery plate.
- A 3 log drop was defined as being the MBC (Minimum Bactericidal Concentration) of tetra sodium EDTA.

RESULTS AND DISCUSSION

For *Staphylococcus aureus* maximal log reductions of 2.67 were seen in 5 and 10 mg/ml of TEDTA at 24 hours. With *S. simulans* the maximal reduction in colony forming units was reached at 2 hours at a concentration of 5 mg/ml (2.38 log reduction). *S. aureus* was reduced by 3 logs after 6 hours. *S. lentus* was reduced by >3 logs after 6 hours for all the concentrations of TEDTA investigated. With *A. baumannii* the MBC was reached at 3 hours with 40 mg/ml of TEDTA. For *E.coli* a 3 log reduction was achieved after only 1 hour for all concentrations of TEDTA investigated. For *K. ornitholytica* all TEDTA concentrations resulted in a 3 log reduction after 3 hours.

CONCLUSION

More work is needed to elucidate the importance of these findings and the potential role of TEDTA as an antimicrobial agent for use in both clinical and environmental situations.

Composite scaffolds from gelatin and elastin-like block polypeptides for tissue engineering

Duc H. T. Le¹, Tatsuya Okubo¹, Ayae Sugawara-Narutaki²

¹Department of Chemical System Engineering, The University of Tokyo, Japan

²Department of Crystalline Materials Science, Nagoya University, Japan, voltrapp@chemsys.t.u-tokyo.ac.jp

INTRODUCTION

Severe burn injuries, which cause large and deep damage to the skin dermis, are a major health problem due to their resulting physical and psychological traumas. Collagen, with its favourable physical and biological functions, shows promising use as dermal substitutes for severe burn treatments. However, successful wound healing without skin contraction still remains a challenge due to insufficient elasticity of the materials.^[1] Elastin, despite its small proportion in skin dermis, plays an important role in skin elasticity. This is because elastin assembles into elastic fibers interwoven among collagen bundles to convey elasticity to the whole structure.^[1]

Recently, we have constructed a novel elastin-like polypeptide (ELP) by mimicking the localization of hydrophobic domains in native elastin molecule.^[2] The polypeptide, named **GPG**, contains a proline-rich (VPGXG)₂₅ (X: V or F) sandwiched by two glycine-rich (VGGVG)₅ (Figure 1). **GPG** is able to assemble into beaded nanofibers with flexibility and well dispersibility in water by temperature trigger or in 10–30% (v/v) trifluoroethanol (TFE) aqueous solutions. These obtained nanofibers can be used to mimic the elastin structure in skin dermis. In this study, scaffolds composed of **GPG** fibers and gelatin, a hydrolyzed form of collagen, are fabricated by electrospinning method to resemble the composite fibrous structures in skin dermis, where elasticity is effectively tuned by a small amount of elastin fibers.

MKL-(VGGVG)₅-LWLGSGL-[(VPGVG)₂VPGFG(VPGVG)₂]₅-KL-(VGGVG)₅-LWLEHHHHHH

Figure 1. The amino acid sequence of **GPG**.

EXPERIMENTAL METHODS

A suspension of **GPG** fibers formed in 30% (v/v) TFE was mixed with a gelatin solution (30% TFE) to produce a homogeneous mixture of **GPG** fibers and gelatin. The concentration of gelatin was 12.5 wt%. The proportions of **GPG** fibers toward gelatin were 0, 0.5, and 1.0 wt%. The mixtures were loaded into syringes and electrospun in the optimized conditions as follows: voltage supply 25 kV, air gap distance 13 cm, feed rate 0.5 mL/h. Electrospun scaffolds were cross-linked by glutaraldehyde vapour in 16 h. Cross-linked matrices were immersed in glycine solution to remove unreacted glutaraldehyde, and then washed repeatedly by water. For the tensile test, all samples were cut into a dumbbell-shape and soaked in phosphate buffer saline prior to the measurement.

RESULTS AND DISCUSSION

Figure 1a–c shows SEM images of the as-spun gelatin and **GPG**/gelatin composite fibers. Formation of gelatin fibers with an average diameter of about 100 nm

was observed in Figure 1a. Blending of gelatin with small amounts of **GPG** fibers did not alter the morphologies of the electrospun fibers (Figure 1b, c). The elastic moduli of cross-linked scaffolds are shown in Figure 1d. The **GPG**/gelatin composite shows a decrease in elastic modulus when 1.0 wt% of **GPG** fibers were added into gelatin. The modulus of 1.0 wt% **GPG**/gelatin matrix is 1.20 ± 0.50 MPa. As a control experiment, elastic modulus of a composite sample composed of 1.0 wt% (VPGXG)₂₅, the middle block component of **GPG**, and gelatin was also examined. The elastic modulus of the control sample is 3.17 ± 0.82 MPa, which shows no decrease compared to one of the gelatin scaffolds. Noteworthy, (VPGXG)₂₅ only assembled into nanoparticles but not fibers in 30% TFE. The result suggests that the assembled structures of **GPG** may affect the elastic modulus of the composite materials. Studies of cell attachment and proliferation on the constructed scaffolds are in progress.

Figure 1. SEM images of as-spun fibers of (a) gelatin, (b,c) **GPG**/gelatin composite scaffolds with **GPG**/gelatin ratio: (b) 0.5 wt%, (c) 1.0 wt%. (d) Elastic moduli of cross-linked scaffolds.

CONCLUSION

GPG/gelatin composite scaffolds were successfully constructed by electrospinning method. The elastic modulus of **GPG**/gelatin scaffolds decreases at 1.0 wt% addition of **GPG** fibers. Works to adjust elastic moduli of the composite scaffolds close to one of skin dermis (0.08 MPa)^[1] are on-going.

Pelvic Floor Repair Materials Releasing Vitamin C to Promote Extracellular Matrix Production

Naside Mangir^{1,2}, Anthony J Bullock¹, Sabiniano Roman¹, Nadir Osman^{1,2}, Christopher Chapple², Sheila MacNeil¹

¹Department of Materials Science Engineering, KROTO Research Institute, University of Sheffield, United Kingdom

²Royal Hallamshire Hospital, Urology Clinic, Sheffield, United Kingdom, n.mangir@sheffield.ac.uk

INTRODUCTION

Non-absorbable synthetic meshes (polypropylene) currently used in surgical treatment of Stress Urinary Incontinence (SUI) and Pelvic Organ Prolapse (POP) are associated with serious complications such as exposure and erosion¹.

We hypothesize that slowly degrading synthetic matrices, which stimulates cell infiltration and extracellular matrix (ECM) production, may overcome these complications leading to a better integration into patient's native tissues. The aim of this study was to develop a pelvic floor repair material from poly-lactic acid (PLA) scaffold releasing vitamin C which was assessed for fibroblast attachment and proliferation, ECM production and mechanical properties.

EXPERIMENTAL METHODS

The technique of emulsion electrospinning was used to construct a core-shell morphology of vitamin C and PLA for achieving continuous release of the hydrophilic bioactive factor from the hydrophobic polymer. The electrospun PLA fibres contained Ascorbic Acid (AA), the naturally occurring active form, or Ascorbate-2-Phosphate (A2P), the synthetic long acting form, or distilled water (Vehicle). The surfactant Span80® was used to obtain a stable water in oil emulsion with a water/oil phase ratio of 1:40. The release of both drugs was measured by spectrophotometric methods. Then, a total of 500,000 human dermal fibroblasts were seeded on 1 cm² sized scaffolds and cultured for 2 weeks. Cell attachment and viability were evaluated by Resazurin assay and DAPI staining. Total collagen production was assessed using Sirius red staining. Mechanical properties (ultimate tensile strength, strain and Young's Modulus) of scaffolds were evaluated in dry and wet states using BOSE electroforce tensiometer.

RESULTS AND DISCUSSION

No significant differences were observed between emulsion electrospun scaffolds and pure PLA scaffolds in terms of fibre diameter and pore size. The successful release of both AA and A2P was demonstrated with a burst release of 20-25%. Both AA and A2P containing scaffolds and Vehicle scaffolds were significantly more hydrophilic (Figure 1) and stronger in both dry and wet states compared to pure PLA scaffolds. We observed a positive correlation between the water uptake and the

strength of the scaffolds (Pearson's $r=0.66$; $p<0.005$). Fibroblasts showed higher metabolic activity and produced more total collagen on scaffolds containing either AA or A2P compared to cells grown on control PLA scaffolds (Figure 2).

Figure 1. Diagram showing water uptake (percent increase in weight after incubation in PBS compared to dry state) of scaffolds (*: $p<0.05$)

These results showed that incorporation of a surfactant and other bioactive factors can significantly improve the hydrophilicity and mechanical properties of PLA scaffolds as well as the cellular response to them. This study is the first to compare the effect of AA and A2P in 3D on collagen production and mechanical properties of biomaterials. These findings are in line with previous studies showing increased collagen production of fibroblasts in 2D and 3D culture conditions upon stimulation with various forms vitamin C.

CONCLUSION

One strategy in developing a pelvic floor repair material for treatment of SUI and POP can be to incorporate bioactive factors for stimulating cell infiltration and ECM production from host tissues leading to a good integration of the material into the native tissues.

Figure 2. Metabolic activity (left) and collagen production of fibroblasts grown on scaffolds (right) [$**p<0.005$ and $*p<0.05$ compared to Vehicle scaffolds; numbers after letters show grams of AA or A2P per gram of PLA]

Synthetic collagen peptide based microspheres/ hydrogel hybrid system for bone growth factor delivery

L. de Miguel^{1*}, G. van Osch² and S.G.J.M. Kluijtmans¹

¹Fujifilm Life Sciences, P.O. Box 90156 Tilburg, Netherlands

²Departments of Orthopaedics and Otorhinolaryngology, Erasmus Medical Center, Rotterdam, Netherlands
laura_de_miguel@fujifilm.eu

INTRODUCTION

Bone fractures and other orthopaedic related injuries constitute a major health problem nowadays, with more than 500,000 bone graft procedures being performed annually¹. For bone regeneration purposes, bone morphogenetic proteins (BMP) have attracted much attention in the past years.

BMP-2 is one of the most powerful osteoinductive factors for bone regeneration in ectopic and orthotopic sites, including critical size defects. It is involved in the recruitment of endogenous mesenchymal stem cells from adjacent tissues and in their stimulation towards osteogenic differentiation, resulting in bone tissue formation. BMP-2 is clinically used in association with a collagen scaffold for spinal fusion surgery and tibial fracture healing. However, both its supraphysiological doses needed to be efficacious and its animal origin results in side effects. Increased stability and controlled release of BMP-2 have shown to enhance bone formation². Therefore, many efforts have been directed to the use of carriers that could provide a controlled release and protect the BMP from the rapid degradation by proteolytic enzymes. Hybrid systems have shown to be a useful approach to achieve better controlled protein release⁴.

Synthetic collagen peptide (SCP) is a new animal-free material, which is fully bio-degradable and bio-absorbable.

The final aim of this work is to design a hybrid system consisting of BMP-2 loaded-SCP microspheres included into a hydrogel for controlled BMP-2 release.

EXPERIMENTAL METHODS

SCP was produced at Fujifilm by recombination techniques. SCP microspheres were prepared by an emulsification process and further crosslinked by different methods. SCP microspheres were characterized in terms of size and morphology by diffraction particle size analysis and scanning electron

microscopy. The degree of crosslinking was quantified by the 2, 4, 6-trinitrobenzenesulfonic acid (TNBS) assay. A model protein, FITC-lysozyme and BMP-2 were loaded onto the microspheres by diffusional loading at different doses and protein release studied in PBS in presence and absence of collagenases. These microspheres were further included into a hydrogel and protein release studies were performed.

RESULTS AND DISCUSSION

Microspheres had a size of ~50 µm and a spherical morphology with a rough surface. The degree and type of crosslinker of the SCP microspheres were shown to influence protein retention and release. Their inclusion onto a hydrogel contributed to a better controlled protein release.

CONCLUSION

SCP microspheres could be easily obtained by emulsification techniques and stabilized by further crosslinking. The ability of the hybrid SCP microspheres/hydrogel system to control protein release was shown SCP microspheres are therefore considered as promising candidates for the delivery of growth factors in bone regeneration applications.

³School of Engineering, Nazarbayev University, Kazakhstan

INTRODUCTION

Chronic wound represents a complex environment that requires multipurpose approach. The healing process consists of several phases. The prolonged inflammation stage, indicative of chronic wounds, damages the surrounding healthy cells and tissues. This phase is associated with uncontrolled secretion of pro-inflammatory cytokines from macrophages, neutrophils and T-cells, and decrease of growth factors required for re-epithelialization and formation of granulation tissue. As a consequent result, the wound is prevented from the tissue repair and closure.

In order to remove inflammatory cytokines, macrophages, necrotic tissue, and bacteria we decided to increase adsorbing properties of the wound dressing. For this purpose activated carbon (AC) was chosen as the main adsorbing agent. Today's market is full of activated charcoal dressings, where a thick layer of charcoal is used. While, in this novel dressing we propose reduction of AC particles through their even distribution in the polymer. For this purpose, agarose (AGR) was selected as a promising biomaterial for wound healing applications. It does not require additional crosslinking agents and forms a gel at the room temperature. The transparent nature of this polysaccharide can allow monitoring of the wound state. Absence of toxicity and inertness of agarose may prevent unnecessary reactions at the wound site. Its slow degradation rate is beneficial for the end product properties such as longer shelf life.

Three various gels (hydrogels, cryogels, and double cryogels) with or without incorporated AC particles were prepared for comparison of physical and mechanical properties and to identify the best option.

EXPERIMENTAL METHODS

To prepare agarose cryogels, agarose powder was dissolved in distilled water which was brought to boil. AGR solutions of 0.5%, 1%, 1.5%, 2% (w/v) were poured into glass tubes and placed in cryobath at -12°C for two hours. Then, tubes were extracted and left at room temperature to thaw. To prepare AGR solution with incorporated AC particles, AC was added to AGR powder and the above steps were repeated.

AGR hydrogels with or without AC were used as control. To prepare hydrogels, AGR solution after boiling was placed at the room temperature to form a gel.

The inner structure of gels was analyzed by confocal microscope. Gels were assessed for sorption capacity, porosity, flowrate and permeability. Adsorption

capacity of AC within agarose gels was tested using crystal violet as a model small molecule.

RESULTS AND DISCUSSION

Assessment of gels demonstrated successfully formed cryogels and hydrogels. In comparison to hydrogels, cryogels possessed larger pores, evenly distributed AC particles in pore walls, high moisture, and better physical-mechanical properties. Larger pores can allow absorption of necrotic tissue and bacteria from the wound. Adsorption by AGR-AC cryogels was stably increasing and did not reach equilibrium in contrast to AGR-AC hydrogels.

ELISA analysis showed that AC particles effectively remove TNF-alpha, IL-6, and IL-8. The adsorption profile was proportional to the size of molecules. IL-8 as a smaller cytokine was absorbed more efficiently than TNF, although there was not a significant difference.

Figure 1. Adsorption of small model molecule –crystal violet by agarose and agarose-activated carbon cryogels, hydrogels, and double cryogels.

CONCLUSION

The obtained results indicate that AGR-AC cryogel is a potential wound dressing material that is not prone to bacterial spoilage, provides moist environment, has high sorption capacity, large pores, and is able to remove inflammatory cytokines from the wound exudate to facilitate wound healing process. We hypothesize that removal of inflammatory cytokines, bacteria, and necrotic tissue will assist chronic wounds to escape from the inflammation phase and proceed to regeneration of tissues.

The Effect of Amphiphilic and Anionic β -sheet Peptides on Blood Clotting

Ziv Azoulay¹ and Hanna Rapaort^{1,2*}

¹ Avram and Stella Goldstein-Goren Department of Biotechnology Engineering, Ben-Gurion University of the Negev, Beer - Sheva, Israel

^{2*} Ilse Katz Institute for Nano-Science and Technology (IKI), Ben-Gurion University of the Negev, Beer - Sheva, Israel, hannarap@bgu.ac.il

INTRODUCTION

In the past decade there has been an increasing interest in developing blood coagulation inducers. β -sheet amphiphilic zwitterionic peptides were recently reported to accelerate bleeding arrest in induced in-vivo bleeding models².

In this study, we characterized the influence of an amphiphilic and anionic β -sheet peptide on blood clotting and bleeding arrest. In-vitro rheological, spectral and microscopic assays were utilized to assess the peptide's effect on swine blood plasma coagulation.

EXPERIMENTAL METHODS

Peptides: The amphiphilic and anionic β -sheet peptide Pro-Asp-(Phe-Asp)₅-Pro and its scrambled analog Asp-(Phe)2-Pro-(Asp)2-Pro-Phe-Asp-(Phe)2-(Asp)2, denoted P-FD-5 and Sc-PFD respectively were custom synthesized and supplied as lyophilized powders.

Thromboestograph (TEG): Peptide aqueous solutions were mixed with freshly re-calcified platelets poor swine plasma (PPP) in a standard TEG cup (360 μ L) to a final concentration of 10 mM Ca²⁺ and 0.17 % w/v (1 mM) peptide. The slope of the curve and the level of the plateau are a measure of the coagulation kinetics and the strength of the clot, respectively.

Circular dichroism (CD): Spectra of P-FD-5 peptide, purified human fibrinogen and purified human thrombin solutions were taken separately and after mixing combinations of 1:3400 (molar ratio) of each protein to peptide. The CD signals of the mixtures were compared to the calculated sum of the individual ones to indicate whether interactions between the peptide and the proteins led to conformational changes.

Confocal microscopy: Human fibrinogen (1-10% fluorescently labelled) was first mixed with human thrombin and CaCl₂ as described elsewhere¹ and latter mixed with peptide solutions or injected beside P-FD-5 hydrogel³ on a confocal plate. Samples were left to interact for 1 h at 37° C and saturated humidity.

RESULTS AND DISCUSSION

According to TEG measurements P-FD-5 inhibited the coagulation kinetics and weakened the clot strength (compare curves a and c, Figure 1). This effect could have been attributed to reduce in calcium concentrations interacting with the peptides; However, increase in Ca²⁺ concentrations did not alleviate the effect (not shown). Based on the smaller effects of Sc-PFD on the coagulation (curve b Figure 1) it could be deduced that the inhibitory effect of the P-FD-5 peptide is both related to the amino acids composition, i.e. the anionic charge, and to the β -sheet conformation.

CD analysis revealed a distinct conformational change for P-FD-5 in the presence of thrombin suggesting enzyme inhibition by the peptide (Figure 2). This effect wasn't seen for P-FD-5 and fibrinogen mixtures (not shown).

At elevated P-FD-5 concentration (4% w/v) the peptide which forms a hydrogel was found to have little effect on fibrin fibres formation at its proximity as could be deduced by the confocal images (Figure 3).

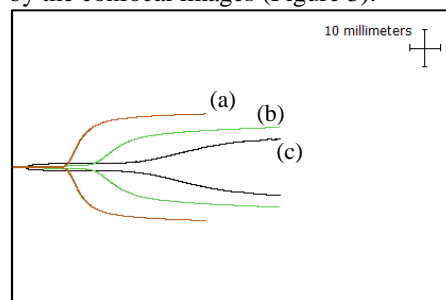

Figure 1: Representative TEG curves tracking the coagulation in swine's recalcified PPP, supplemented with: (a) Tris buffer as a control, 0.17% w/v (1mM) Sc-PFD (b) and P-FD-5 (c). Y axes correlative to storage modulus G'

Figure 2: CD spectra of P-FD-5 0.3 mM (diamonds), Thrombin, 1 U/ml (triangles) and their mixture in DIW (+, same concentrations) and a curve of the calculated sum of the peptide and the protein (x).

Figure 3: Confocal microscopy images indicative of fibrin fibres formation at the proximity of 4% w/v P-FD-5 hydrogel (right) and in absence of the hydrogel (left).

CONCLUSION

In summary, the amphiphilic and anionic β -sheet peptide P-FD-5 inhibits plasma clotting when soluble, and appears to have little effect when in gel state on fibrin fibres formation.

Processing and Mechanical Properties of Biodegradable β TCP-15Fe15Mg Composites

Sanjaya K. Swain, Irena Gotman, Elazar Y. Gutmanas

Department of Materials Science and Engineering, Technion, Haifa, 32000, Israel, swains@technion.ac.il

INTRODUCTION

Due to their similarity to bone mineral, calcium phosphate (CaP) ceramics are considered materials of choice for bioresorbable (β -tricalcium phosphate, TCP) and non-resorbable (hydroxyapatite, HA) bone graft substitutes. The brittle nature of these ceramics, however, limits their use to low load bearing applications. To improve mechanical behavior, CaPs are combined with biodegradable polymers (PLA, PGA, PCL). Typical CaP-polymer composites are produced by hot pressing and contain low volume fractions ($< 20\%$) of the ceramic phase¹. As a result, the strength of such composites is close to that of the polymer matrix. Significantly higher strength values combined with measurable ductility were reported for β TCP-PLA nanocomposites that comprised large ($\geq 60\%$) volume fraction of the CaP phase². To achieve even better mechanical properties, the PLA component in the reported work was substituted with a biodegradable Mg-Fe alloy, all while retaining the high volume fraction of β TCP. Both Mg and Fe based alloys are increasingly studied as potential materials for temporary medical implants³. Still, the corrosion of Mg in the physiological environment is too rapid for most implant applications whereas that of Fe is considered too slow⁴. Combining Fe and Mg in a nanocomposite is expected to result in an acceptable degradation rate, in between Mg and Fe.

MATERIALS AND METHODS

β TCP nanopowder was prepared by chemical precipitation followed by calcination at 750°C . 50Fe50Mg (vol.%) nanocomposite blend was prepared by attrition milling of Fe ($\sim 2\ \mu\text{m}$) and Mg ($< 44\ \mu\text{m}$) powders for 4 h, in dry hexane under Ar at 20:1 stainless steel balls-to-powder ratio. 30 vol.% of the prepared 50Fe50Mg powder was blended with 70 vol.% of β TCP powder and milled for additional 4 h to yield β TCP-15Fe15Mg composition. Dense β TCP-15Fe15Mg disks 10 mm in diameter were produced by high pressure consolidation in a rigid die at 2.5 GPa, at T_{room} . Some specimens were annealed at 400°C for 4 h. The density of consolidated specimens was measured and mechanical properties tested in an Instron machine. The microstructure and phase composition of the composites were characterized employing x-ray diffraction (XRD) and scanning electron microscopy (SEM/EDS).

RESULTS AND DISCUSSION

The density of all high pressure consolidated specimens was above 98 % of the theoretical. XRD patterns of dense β TCP-15Fe15Mg specimens are shown in Fig. 1. Only the peaks of β -TCP and Fe are present, the absence of the Mg peaks suggesting amorphization (at least partial) of Mg during attrition milling. After annealing at 400°C , a small peak of Mg appears in the pattern suggesting crystallization of the Mg component.

Fig.1: XRD patterns of as-consolidated and annealed (400°C , 4 h) β TCP-15Fe15Mg composites.

SEM image in Fig. 2(A) demonstrates uniform phase distribution in β TCP-15Fe15Mg composite; the absence of pores confirms that the material is near fully dense.

Fig.2: Mechanical properties (A) and SEM images of the fracture surface (B) of β TCP-15Fe15Mg specimen annealed at 400°C for 4 h.

Fig. 2(B) presents the strength of β TCP-15Fe15Mg specimens compared to β TCP-30PLA nanocomposite. In bending, β TCP-15Fe15Mg is almost 3 times stronger than β TCP-30PLA and approaches the bending strength of compact bone. Such a significant increase of bending strength is achieved owing to the much higher strength of the metallic phase compared to the PLA polymer. Annealing at 400°C did not affect bending strength of β TCP-15Fe15Mg but resulted in an increase of the compressive strength.

CONCLUSION

β TCP-15Fe15Mg composites possess attractive mechanical properties and can be considered as candidate materials for load bearing orthopedic applications. Further work will concentrate on degradation studies and fabrication of porous 3D scaffolds.

Economical Production of Medium Chain Length Polyhydroxyalkanoates

Yiingos Psaras

Faculty of Science and Technology, University of Westminster, United Kingdom, y.psaras@my.westminster.ac.uk

INTRODUCTION

The plastics industry is being increasingly criticized concerning the nature of its products. Although used in an extensive variety of products, one third of all plastics serve the function of packaging and are inevitably discarded². Being non-biodegradable, their disposal raises the issue of pollution and toxic hazard to wildlife, the environment and humans. The economical burden of processing landfill waste and the finite amount of petroleum require that traditional plastics be replaced.

Polyhydroxyalkanoates (PHAs) are produced as intracellular storage compounds by bacteria under nutrient limiting-induced growth stress¹. Their wide range of properties makes these polymers suitable replacements for traditional oil-derived plastics; the polymers present additional features that extend their applications into the biomedical field. Conversely, high production costs hurdle their large-scale industrial and biomedical application³.

The objective of this study was to address the issue by investigating the production of polymer by *Pseudomonas mendocina* via the utilization of cheap sources for carbon and nitrogen; biodiesel waste, glucose and corn steep liquor were used and compared with sodium octanoate.

EXPERIMENTAL METHODS

Production:

PHAs were produced at shaken flask level using a two-stage seed culture of *P. mendocina* (no. 10542, strain CH20). First seed cultures, prepared in nutrient broth (10% by volume of the second seed culture), cultured for 24 hours were used to inoculate the second stage mineral salt media (MSM) seed culture (10% by volume of the final production media), which was cultured until the optical density reached 1.6 or the incubation time reached 24 hours. This was then used to inoculate the final production media cultured for 48 hours. All media were autoclaved separately and flasks were inoculated simultaneously with the same inoculum under sterile conditions and incubated at 200 rpm and 30°C. Experiments were carried out in triplicate. Growth profile curves were constructed by measuring the optical density at 450nm, pH and nitrogen concentration of the production media in samples retrieved every three hours. For the estimation of nitrogen, 0.2ml of phenol nitroprusside (pH 12) and 0.3ml alkaline hypochlorite were added to 0.5 ml of culture sample supernatant (centrifuged at 15600 relative centrifugal force (rcf) for 10 min and diluted a hundredfold), followed by incubation in the absence of direct light for 45 minutes at room temperature and spectrophotometric measurement at 635nm.

Extraction

Harvested cultures were freeze-dried at -47°C and 0.32mbar. Sodium hypochlorite and chloroform were used in a 5:22.5 ratio for every 0.3g of dry cells. The mixture was incubated at 30°C and 200rpm for 2 hours followed by centrifugation at 6260 rcf for 18 minutes, condensation on a rotary distillator at 37°C, filtration and precipitation in approximately 10 volumes of ice-cold 50% absolute ethanol-50% absolute methanol.

Characterization

Carbon-13 and Proton Nuclear Magnetic Resonance (NMR), Differential Scanning Calorimetry (DSC) and Dynamic Mechanical Analysis (DMA) were carried out for the polymer produced with sodium octanoate. Fourier Transform Infrared Spectroscopy (FTIR) was carried out for all polymers.

RESULTS AND DISCUSSION

Utilization of sodium octanoate in the production media produced a medium chain length PHA (MCL-PHA), identified as poly(3-hydroxyoctanoate), to a yield of 14.2%. This polymer had glass transition temperature of -34°C, melting temperature of 52°C and a Young's modulus value of 3.63MPa. By comparison, utilization of biodiesel waste gave a yield of 2.1% and the mixture of corn steep liquor and glucose gave a yield of 11.3%. These polymers were confirmed to have been MCL-PHAs but were not further characterized.

We report the use of simple, low-cost production at shaken flask level in contrast to fed batch and stirred fermentation, which are known to confer higher yield, as reported in previous studies.

CONCLUSION

Economic production of MCL-PHAs can be achieved with the use of cheap sources. Moreover, it is evident that yields achieved with cheap sources can rival those produced with the use of laboratory reagents, as seen on utilization of glucose and corn steep liquor, which approached the yield achieved with sodium octanoate.

A New Method to Rapidly Retrieve Encapsulated Cells from Alginate Hydrogels using Pyrophosphate

David C. Bassett* and Pawel Sikorski

Department of Physics, Norwegian University of Science and Technology, Norway

*david.bassett@ntnu.no

INTRODUCTION

Alginate hydrogels have a long and successful application in pharmacy, medicine and biomedical sciences¹ and are routinely used to encapsulate various types of cells to provide a synthetic extracellular matrix (ECM), provide immunoprotection, or transport cells to the point of injury^{2,3}. In our laboratory, we routinely encapsulate mammalian cells in alginate microbeads for 3D *in vitro* cell culture studies. In order to study the cells post encapsulation, it is often necessary to remove the cells from the alginate. Typically this is achieved using a calcium chelator such as citrate ions or Ethylenediaminetetraacetic acid (EDTA) and while effective at removing crosslinking Ca^{2+} , ourselves⁴ and others⁵ have observed high toxicity when using these reagents, which is detrimental to studies of this nature. Therefore we sought to test alternative chemical treatments in an attempt to improve the outcome of such experiments. Here we present our initial findings towards the development of a new protocol which is both rapid and cell compatible. This highly promising approach would appear to have great utility in extracting viable cells from alginate.

EXPERIMENTAL METHODS

Alginate microbeads were prepared as previously described⁶. Briefly, aqueous sodium alginate (2%, Protanal LF 2005, FMC Biopolymer) was extruded through a narrow needle (0.35 mm) into a bath of calcium chloride (50 mM) under an electrostatic accelerating voltage of 7 kV. The alginate was prepared with or without cells (MC3T3-E4 pre osteoblasts, 1×10^6 cells mL^{-1}). A known mass of alginate beads were de-gelled by the addition of 100 mM solutions of EDTA, sodium citrate and sodium pyrophosphate (PPI) at a range of pHs adjusted by the addition of NaOH or HCl. De-gelling was monitored visually and with the aid of a light microscope. Food colouring was added to cell-free alginate to aid observation that was found to not interfere with de-gelling. Cells were retrieved by centrifugation and washed in cell media prior to infiltration with toluidine blue and counting using an automated cell counter (Countess®, Life Technologies).

RESULTS AND DISCUSSION

Electrostatically generated microbeads were well formed spheres and had a narrow size distribution. ($\varnothing = 405 \pm 18 \mu\text{m}$). Phytic acid, EDTA, citrate and PPI were evaluated for their ability to chelate Ca^{2+} ions and de-gel Ca-alginate hydrogels. Phytic acid showed no de-gelling activity, even after prolonged periods of exposure and high concentrations. EDTA and sodium citrate were effective Ca chelators and performed well, however PPI appeared to react very rapidly with the Ca-

alginate (Figure 1). The rate of de-gelling was found to be dependant on pH: rates at pH 8-10 were significantly faster than rates at pH 6-7 for PPI. At pH 8, 1 mL volume of alginate beads could be completely de-gelled in approx. 2 ½ minutes. EDTA and citrate achieved similar and much slower rates in the range of pHs tested and were less affected by pH, although significant differences were found between them at the extremes of pH 6 and pH 10. Cell integrity following de-gelling using the Ca chelators at pH 8 and 100 mM concentration was measured by toluidine blue infiltration. Cell viability of $83 \pm 2\%$ was recorded for cells recovered from alginate using PPI, compared to $61 \pm 8\%$ and $64 \pm 10\%$ using EDTA and citrate respectively.

Figure 1: Rates of alginate microbead de-gelling as a function of pH for the indicated chelators. Sig. differences: * $P < 0.05$ 1 way ANOVA with Holm-Sidak test. \$ $P < 0.02$ Mann-Whitney t-test. N=6.

CONCLUSION

PPI would appear to be an effective reagent for the purpose of retrieving encapsulated cells from alginate hydrogels. Both the rate of de-gelling and viability of retrieved cells were enhanced compared to conventionally used reagents. A possible limitation of this technique is that PPI will tend to crystallise with Ca, though in our experiments this only occurred at prolonged times (hours).

Stable Electrospun Hyaluronan Matrices: Production and In Vitro Characterization for the Evaluation as Skin Substitute

Annalisa La Gatta¹, Marcella Cammarota¹, Antonella D'Agostino¹, Agata Papa¹, Stefano Guido², Chiara Schiraldi¹

¹Department of Experimental Medicine, Second University of Naples, Italy, annalisa.lagatta@unina2.it

²Department of Chemical Engineering, University Federico II of Naples, Italy

INTRODUCTION

Glycosaminoglicans, as native constituents of human tissues, are widely employed for tissue engineering purposes including the fabrication of skin substitutes for wound healing (1). The use of GAGs has been recently combined with electrospinning process in order to produce nanofibrous, highly porous matrices mimicking not only the composition but also the architecture of the extracellular matrix (ECM). In particular hyaluronan (HA) and chondroitin sulfate (CS) have been electrospun, usually in combination with collagen or gelatin and proposed as active analogs of native ECM. The presence of proteins in the matrix was reported to be necessary in order to achieve proper stability in physiological environment (2,3). Here, novel stable membranes were produced by HA electrospinning and subsequent crosslinking. No other macromolecules than HA were introduced in the final networks. Developed materials were characterized to assess their potential as skin substitutes.

EXPERIMENTAL METHODS

HA (M_w equal to 1400kDa, M_w/M_n equal to 1,4) was dissolved in DMF/water (1/1v/v) at 0.9% w/v. Newtonian viscosity of the solution, measured at 40°C was equal to 10.4 ± 0.2 Pa's. The solution was electrospun by using a blowing-assisted electrospinning apparatus.

Electrospun HA was crosslinked using 1-Ethyl-3- (3-dimethylaminopropyl) carbodiimide (EDC), EDC/1-Hydroxybenzotriazole (HOBt) or EDC/HOBt in the presence of Lysinemethyl ester in heterogeneous conditions. Morphology of the unmodified matrix, the same after reaction and after reaction and swelling in aqueous medium was observed by SEM. Swelling degree of crosslinked materials was measured by means of gravimetric measurements. Stability was evaluated in Phosphate buffered saline and in DMEM by quantitative determination of HA soluble fraction (carbazole assay). The most stable material was tested for biological response using human keratinocyte (HaCaT)/human dermal fibroblasts (HDF) co-culture in

a time-lapse experiment over 96h. Morphology of adherent cells was observed by SEM.

RESULTS AND DISCUSSION

SEM observation of electrospun HA revealed the attainment of nanofibers with a high interconnected porosity and pore dimension considered useful as a barrier against infection. After chemical modification by treatment in heterogeneous conditions with EDC, EDC/HOBt or EDC/HOBt in the presence of Lysine methyl ester, materials proved insoluble in aqueous medium and, as indicated by SEM analyses, the nanometric porous architecture was preserved during crosslinking. Swelling studies demonstrated membranes high water uptake capacity suggesting their appropriateness to maintain a moist environment at wound interface. Matrices stabilized by ester bonds completely dissolved in phosphate buffer saline solution (pH 7.4) within three weeks while, when diamine was used, the nano-matrices remained stable over two months, also in DMEM. Results showed that the chemistry here applied prompted the formation of tunable degrading nano(fibers)scaffold. Materials elicited a rather good biological response.

CONCLUSION

In conclusion, nanofibrous HA based matrices exhibiting outstanding stability were produced; characterization highlighted features suggesting membranes as interesting materials in skin repair.

Collagen and PNIPAM Hydrogels: An Injectable Solution to Repair the Knee

Amanda Barnes¹, J Lapworth², Mark Coles³, Stephen Rimmer² and Paul Genever¹
amanda.barnes@york.ac.uk

¹Biomedical Tissue Research Group, University of York, UK, ²Department of Chemistry, University of Sheffield, UK
³Centre for Immunology and Infection, University of York, UK

INTRODUCTION

Cartilage defects in the knee are commonly treated by surgical interventions such as micro-fracture and autologous chondrocyte implantation (ACI), to regenerate the damaged tissue. Although the newly formed cartilage may histologically resemble native cartilage, it lacks the mechanical properties. Treatments utilising biomaterials alongside micro-fracture or ACI could improve the quality of the regenerated cartilage. Furthermore the use of a thermo-responsive hydrogel will permit non-invasive surgery, as the biomaterials could be delivered via injection. Both collagen I and poly(N-isopropylacrylamide) (PNIPAM) hydrogels undergo gelation at physiological temperatures and are biocompatible. Individually as scaffolds they can be less than ideal for tissue engineering, collagen gels are mechanically weak, whilst PNIPAM gels are prone to syneresis during gelation and can be non-cell adhesive. Combining these two materials can overcome these limitations and exploit the biocompatibility of collagen and the mechanical strength of PNIPAM within one scaffold.

EXPERIMENTAL METHODS

Poly(NIPAM-co-styrene)-graft-poly(N-vinylpyrrolidone) (NSN) was synthesised as previously described [1]. Whilst collagen I was extracted from rat-tail tendon and solubilised in acetic acid. Hybrid gels were created by mixing NSN and collagen I at 4°C and subsequently gelling by incubation at 37°C. To combine the hybrid gels with mesenchymal stromal cells (MSCs), a cell pellet was directly suspended in the hydrogel liquid at 4°C prior to gelation.

RESULTS AND DISCUSSION

To assess the varying material properties of the hydrogels SEM imaging, rheological and syneresis measurements were performed. Collagen content was maintained at 0.3 wt% within the hybrid gels, whilst NSN was varied between 0.25 – 5 wt%. At concentrations below the minimum gelation concentration of NSN (approximately 2 wt%), collagen dominated the overall properties of the hydrogel, where the reverse was observed in gels with NSN concentrations of 2.5 wt% upwards. Acellular collagen gels did not exhibit syneresis after gelation, whilst gels of 5 wt% NSN shrank down to 30% of their original volume. Syneresis in blends of collagen and NSN reduced with decreasing concentrations of NSN. The highest mechanical properties observed from the gels upon application of shear force, was observed in the NSN only gels, where the shear moduli increased with increasing NSN concentration. Collagen only gels had a

low shear modulus of 0.16 kPa, addition of up to 5 wt% of NSN hydrogel increased this to 11.3 kPa.

The microstructure of the hydrogels also varied with NSN concentration, revealing the differences in the hydrogel properties. Collagen only gels contained a homogenous network of collagen fibrils. Inclusion of NSN, resulted in gels with increased porosity and the appearance of NSN globules coating the fibrils. The collagen fibrils were less visible as the NSN concentration was increased. It is this interaction between the two hydrogel components that is believed to result in the variable mechanical properties and syneresis behaviour.

Figure 1. Internal structure of collagen-NSN hybrid gels

Mesenchymal stromal cells (MSCs) encapsulated within the hybrid gels were found viable and uniformly distributed throughout the gels after 7 days of culture.

CONCLUSION

By varying the composition of collagen and NSN in the blends a series of hydrogels was produced, which have variable mechanical properties and microstructures. The hydrogels are easily fabricated and uniformly encapsulate MSCs. To progress this work, the chondrogenic potential of MSCs and chondrocytes within the different blends will be examined.

INTRODUCTION

The formation of bacteria biofilm on the surface of the medical products, nowadays, is a major clinical issue. Highly adaptive ability of bacteria to colonize the surface of biomaterials causes a lot of infections. This study evaluates samples of the AISI 316 LVM with special nanocomposite silver-including carbon coatings prepared by hybrid RF/MS PACVD (Radio Frequency/Magnetron Sputtering Plasma Assisted Chemical Vapour Deposition) deposition technique in order to improve the physicochemical and biological properties of biomaterials, adding new features, such as antibacterial properties.

The aim of the present work was to evaluate antimicrobial efficacy and biocompatibility of gradient a-C:H/Ti coatings in relation to the physicochemical properties of the surface and chemical composition of coating.

EXPERIMENTAL METHODS

For this purpose, samples were tested in live/dead test using two cell strains: human endothelial cells (Ea.hy 926) and osteoblasts-like cells (Saos-2). For testing bactericidal activity of the coatings, an exponential growth phase of *E. coli* strain DH5 α was used as a model microorganism. In order to evaluate the surface condition and estimate its physicochemical properties in connection with biological results, the structure and morphology were investigated using scanning electron microscopy (SEM), surface characteristics were determined using atomic force microscopy (AFM) and chemical composition of coatings were tested using X-Ray photoelectron spectroscopy (XPS). The mechanism of reactions was analysed also in reference to mechanical properties (hardness, modulus, adhesion) which were evaluated by means of the nanoindentation

technique and revealed very good mechanical characteristic of silver doped carbon coating

RESULTS AND DISCUSSION

Examined coatings showed an uniformity of silver ions distribution in the amorphous DLC matrix, good biocompatibility in contact with mammalian cells and the increased level of bactericidal properties. Additionally, if we take into consideration very good mechanical parameters of these Ag including gradient a-C:H/Ti coatings, they constitute a very good material for biomedical application, e.g. orthopaedics or dental.

CONCLUSION

Summarizing, a carbon coatings being manufactured by the RF/MS RFPACVD method modified by Ag ion enables to obtain biomaterial which limits the growth of bacteria and, at the same time, has a limited impact to the human cells.

C.V.Coombs@brighton.ac.uk

INTRODUCTION

Mesenchymal stem cells (MSC) have been widely used in tissue regeneration due to their multipotent ability, immunomodulatory functions and capacity to secrete a range of bioactive molecules¹. Consequently MSCs have been used therapeutically for: cardiovascular², inflammatory bowel and liver disease³ and type one³ and two diabetes^{4,5}.

Exercise has been reported as a stimulus for stem cell proliferation, migration and incorporation into damaged tissue⁶ and therefore has a potential role in promoting tissue regeneration. However, a systematic investigation of exercise-induced perturbations of blood-derived fractions on mesenchymal stem cells has not been conducted.

Therefore the aim of the current investigation is to provide baseline data to inform future studies in this area of research. It will assess the impact of serum, plasma, and platelet-rich plasma derived from a variety of exercise modalities, exposure to altitude and administration of recombinant human erythropoietin (rHuEpo) on the behaviour of MSCs *in vitro*.

EXPERIMENTAL METHODS

Pre- and post-exercise blood-derived fractions were isolated from recreationally active males who completed eccentric or concentric exercise protocols in a randomised cross-over design. On a separate occasion blood derived fractions were isolated from 24 well-trained athletes (19 males, 5 females) exposed to altitude for periods ranging from 2-4 weeks (n=10) and microdose rHuEpo injections ranging from 20 to 40 IU·kg⁻¹ body mass for 7 weeks before, during and 3 weeks after administration. Repeated sprint ability and maximal oxygen uptake ($\dot{V}O_{2max}$) were measured pre and post administration (n=14).

RESULTS

Preliminary data has shown that eccentric exercise, altitude and rHuEpo have an effect on a number of exercise variables. It is predicted that they will impact upon the behaviour of MSC *in vitro*.

CONCLUSION

Results obtained from this investigation have the potential to provide mechanistic evidence to construct interventions aimed at exploiting MSCs to promote tissue regeneration and repair.

Towards a 3-Dimensional Model of Neural Tissue with Integrated Recording Sites

H. Lancashire*, C. Pendegrass, A. Vanhoostenberghe and G. Blunn

Institute of Orthopaedics and Musculoskeletal Science, University College London, UK

*henry.lancashire.10@ucl.ac.uk

INTRODUCTION

In vitro systems are typically limited to 2D, particularly for recording from neural cells¹. New techniques emerging include spike arrays for recording from *ex vivo* culture², and 3D electrode arrays for recording from primary neuronal cultures¹.

The aim of this study is to develop a layered collagen/silicone construct, in which the silicone layer has windows to allow interconnection of the collagen in 3D, and has an embedded microelectrode array for *in vitro* neuronal recording. We present proof of concept experiments demonstrating the construction of cellular and acellular constructs using an example mouse fibroblast cell line.

EXPERIMENTAL METHODS

Recording electrodes were manufactured as sheets using a Nd:YAG laser cutter. Poly(4-styrene sulfonic acid) (Aldrich) was spin coated onto glass slides. A 30 μm layer of PDMS (Sylgard 184, Dow Corning) was spin coated and partially cured. 316L Stainless Steel (12.5 μm thick, Advent Research Materials, UK) was placed over the PDMS and patterned using the laser cutter. A second layer of PDMS was spin coated, fully cured, and windows and electrode pads were opened using the same laser cutter. **Collagen gels** were formed using protocols previously described³. L929 cells (mouse fibroblasts from subcutaneous adipose tissue, ECACC, UK) were dispersed in the gels uniformly. Cells were cultured in DMEM + 10% FBS. After 7 days *in vitro* (DIV) constructs were fixed with 10% formal saline. **Constructs** were formed by layering recording electrode sheets between collagen gels. Layered constructs were plastically compressed³. **Four treatment groups** were considered: Acellular Collagen; 0.5 million cells/mL; 1 million cells/mL; and Control electrode sheets without collagen. **Impedance Spectroscopy** of electrodes ($n=9$) was measured before construct formation, and after 7 DIV, in 0.9% saline using a Wayne Kerr 6500B Impedance Analyser (0 A bias current, 200 mV p-p). Absolute impedance, $|Z|$, and phase angle, θ , were measured from 20 Hz to 10 kHz. **Statistical significance** was determined at the $p \leq 0.05$ level using non-parametric statistical tests. Values are expressed as mean \pm standard deviation.

RESULTS AND DISCUSSION

Cellular and acellular constructs were successfully formed with feature sizes down to 100 μm (track widths). Of $N=36$ electrodes 1 failed (<3% failure) during manufacture. Cells remained viable throughout the culture period. Fig. 1 shows plots of mean electrode impedance. After 7DIV 1 kHz electrode impedance fell

in the control group from $2.0 \pm 0.2 \text{ k}\Omega$ to $1.4 \pm 0.2 \text{ k}\Omega$ (p

Fig. 1: Plots of mean electrode impedance. Significant differences in 1kHz impedance are marked (*).

< 0.001), this may be a spurious change due to air bubble formation following immersion in saline. Electrode impedance did not significantly change after 7DIV for constructs with acellular and cellular collagen gels ($p \geq 0.198$). After 7DIV 1 kHz electrode impedances were not significantly different between groups ($p = 0.272$), mean impedance was $1.4 \pm 0.4 \text{ k}\Omega$.

Continuation of this research includes: increasing electrode sheet transparency; electrophysiology of cells *in vitro*; and further minaturisation to increase electrode number and allow the use of modified tissue culture well plates. New designs (not yet tested) have reduced interelectrode distance from 5 mm to 500 μm and electrode diameter from 1 mm to 60 μm .

CONCLUSION

This work demonstrates a 3D tissue model with integrated recording sites. Over 7DIV cell number does not significantly alter 1 kHz electrode impedance.

Indirect Prototyped Polyurethane Urea Scaffolds for Cardiac Tissue Engineering

Roberto Hernandez-Cordova¹, Donna A Mathew², Alberto Ceballos-Villanueva¹, Hugo J Carrillo-Escalante¹,
Araida Hidalgo-Bastida^{2*}, Fernando Hernandez-Sanchez¹

¹Centro de Investigacion Cientifica de Yucatan (CICY), Merida, Mexico

²Manchester Metropolitan University, Manchester, UK, *a.hidalgo@mmu.ac.uk

INTRODUCTION

Multi-layered scaffolds with honeycomb-like micro-architecture could provide suitable scaffolds for cardiac tissue engineering. Such scaffolds require a completely interconnected micro-structure and an elastomeric-like behaviour to match the characteristics of the native tissue. Our aim was to fabricate these by indirect prototyping, using a porogen of polyvinyl alcohol (PVA) and injecting a poly-urethane urea (PUU).

EXPERIMENTAL METHODS

PUU was synthesized by two step method¹ from polycaprolactone-diol ($M_n \sim 2,000$), 4,4'-Methylenebis(cyclohexyl isocyanate) (HMDI) and 1,4-butanediol (BDA) as chain extender (Sigma Aldrich). Sn-octate was used as catalyser and N,N-Dimethylformamide (DMF) as solvent to carry the synthesis. The Replicator®3D printer, and a 1.7 mm PVA filament (MakerBot Industries) were used to fabricate a 3D porogen using a wood pile (grid) fibre arrangement. CAD model was obtained using OpenSCAD. We controlled the PVA fibre diameter and spaces between fibres through fabrication parameter to achieve different pore size on scaffold at the end of the process. A solution 25% p/V of PUU dissolved in DMF at 100°C during 3 hours was used to inject in porogen by a nitrogen gas injecting system. Specimens (5x10 mm, HxØ) were cut and placed in vacuum at 60 °C during 24 hours to allow solvent evaporation. Dried specimens were placed in distilled water during three days with two water change daily to dissolve PVA and then dried at 60°C overnight. SEM was used to assess micro-architecture. Elastic modulus at compression mode was determined in dried and wet (70% ethanol) samples. Biocompatibility was assessed by culturing human cardiomyocytes (Promocell, Germany) in 2D and 3D.

RESULTS AND DISCUSSION

PVA porogens of different filament cross-sectional area (300µm, 400µm and 500µm) were fabricated and used to obtain PUU scaffolds labelled as PUUS300, PUUS400 and PUUS500 (300µm, 400µm and 500µm equivalent pore diameter). Honeycomb-like micro-architecture (Fig. 1C) presents tubular channels which are controlled by dissolved PVA filaments. Pores are completely interconnected, which allow incursion of cells in all internal scaffold micro-architecture during cell culture. PUU scaffolds possess an elastomeric behaviour under compressive stress (Fig 1D) with elastic modulus of 11.16 kPa, 10.55 kPa and 16.03 kPa, PUU300, PUU400 and PUU500 respectively; similar to natural cardiac tissue (20-500 kPa)². We assessed scaffolds mechanical behaviour in wet condition to approximate scaffolds performance during cell culture.

Softening of scaffolds is showed as a decrease in elastic modulus, a notable advantage in this material³. Higher modulus in PUUS500 is due to higher distance between PVA filaments (Fig. 1A, B) producing a thicker wall in scaffolds. Furthermore, scaffolds demonstrated to be biocompatible with human cardiomyocytes *in vitro*.

Fig. 1. A) and B) PVA porogen of 300µm and 500µm cross-sectional area. C) PUUS300 showing micro-architecture. D) Stress-Strain curve of PUU scaffolds.

Fig. 2. Modulus of PUU scaffolds in compressive mode for 300µm, 400µm and 500µm pore size.

CONCLUSION

Indirect prototyped method can be a reliable processing approach for PUU scaffolds, resulting in structures with mechanical behaviour and micro-architecture similar to cardiac tissue, showing its potential for this application.

RF Magnetron Sputtering of Multicomponent Ion Doped Phosphate Glasses

Bryan Stuart¹, M. Gimeno-Fabra², D. Grant³, I. Ahmed⁴ and J. Segal⁵

¹Department of Mechanical, Materials and Manufacturing Engineering, University of Nottingham, England, epxbs4@nottingham.ac.uk

INTRODUCTION

Phosphate glasses have the ability to fully resorb in aqueous solution by reacting to form hydroxyl groups and leached ionic by-products. For biomedical applications these glasses have been used for tissue scaffolds and to produce glass fibres for biodegradable polymer composites. Currently their applications in this field are expanding to coatings and bone fixation devices (1).

This research utilises RF magnetron sputtering to create thin films of ion doped phosphate glass. We focus on understanding the relationship between the nature of sputtering target and the generated substrate's composition for a given set of sputtering parameters.

The phosphate network former combined with metal network modifying ions creates a complex quaternary oxide, consisting of varying strength covalent and ionic bonds, similar to the network depicted in Fig. 1. When bombarded with charged argon particles, atoms are preferentially ejected from the glass structure (2); a relationship termed "sputtering yield".

The purpose of this research is to understand this phenomenon by the use multicomponent oxide targets. The as-produced thin films are resorbable and potentially bioactive, with applications as coatings for implant devices, acting as slow release doping agents for improved osseointegration.

Figure 1. Tertiary phosphate glass structure (3).

EXPERIMENTAL METHODS

Quaternary phosphate glass targets, produced by melt-quenching have been applied using RF magnetron sputtering on commercially pure titanium discs and borosilicate cover slides. The phosphate glass coated titanium discs have been studied using SEM/EDX for deposition rate and compositional analysis.

RESULTS AND DISCUSSION

We have found that P40 coatings at 60 watts are deposited amorphous at $\approx 3.17 \text{ nm min}^{-1}$ (Fig.2 sample after coating for 4 hours). At higher powers of 120 watts, temperature increases and crystallisation occurs of both the target and sputtered coating. Preferential sputtering is related to the bonding strength of the oxide constituents, therefore as the network connectivity increases, deposition rate is reduced and sputtering yield is in favour of the network modifying ions. Network modifier ions are prone to preferential sputtering in comparison to the covalently bonded network forming the phosphate backbone. Furthermore, the sputtering of network modifying ions is related to reactivity, atomic mass and the oxide binding energy.

Figure 2. Cross sectional SEM of an applied ion doped phosphate glass by RF magnetron sputtering.

CONCLUSION

Thin film quaternary phosphate glass targets can be applied via RF magnetron sputtering to form coatings at low deposition rates between $1\text{--}5 \text{ nm min}^{-1}$. With careful consideration of the target's composition and the sputtering parameters, accurate predictions of the composition and thickness of the resulting thin films can be drawn.

Manufacture of Bioresorbable Fibre Reinforced Composites for Fracture Fixation Devices

Fernando Barrera Betanzos, Miquel Gimeno-Fabra, Joel Segal, David Grant and Ifty Ahmed

Department of Materials, Mechanics and Structures, Faculty of Engineering, University of Nottingham, UK
emxfb@nottingham.ac.uk

INTRODUCTION

Femoral diaphyseal fractures are one of the most common long bone fractures affecting the lower extremities. Due to the high vascularity and soft tissue volume associated with the femur, traumas within this region often require surgical intervention¹. Intramedullary (IM) nailing represents the best option to reduce and stabilise bone fragments in virtue of its inherent advantages over similar fixation devices, including minor tissue tethering, and reduced infection risk¹. In spite of these benefits, current IM nails remain metal-based devices, thus can potentially elicit a series of detrimental conditions such as inflammatory cascades and bone atrophy secondary to stress shielding, coupled with the possible need for removal after bone healing¹. Therefore, the prospect fabrication of an implant from materials with bone matching properties, capable of providing immediate fracture stabilisation while gradually transferring the load to the healing tissue, and eventually resorbing *in vivo*, becomes really attractive. Accordingly, this study focus on the manufacture of bioresorbable composites = from phosphate glass fibres (PGF) and polylactic acid (PLA)^{2,3}.

EXPERIMENTAL METHODS

Continuous glass fibres were produced using an in-house melt-draw transverse fibre spinning facility. The glass with theoretical composition of $45\text{P}_2\text{O}_5\text{-}16\text{CaO-}13\text{Na}_2\text{O-}24\text{MgO-}2\text{Fe}_2\text{O}_3$ (mol%) was synthesised from reagent grade precursors, batched and melted in a platinum crucible at 1150 °C.

A series of unidirectional (UD) composites with three volume fractions (~0.8, ~0.15, ~0.25) were fabricated by compression moulding at 180 °C for 10 minutes of a stack encompassing alternate layers of UD fibre mats and PLA films made by pressing batches of PLA pellets (NatureWorks 3251 D). A pure PLA plate was also produced by the same process for control purposes.

The plates were then cut into small pieces ($4 \times 1.5 \times 0.2$) cm³ for flexural properties measurement (n=9) using a Hounsfield Series S testing machine with a cross-head speed of 1 mm min⁻¹, and a 5 kN load cell in accordance with BS EN ISO 14125:1998. The results reported here are the mean value coupled with the standard error.

RESULTS AND DISCUSSION

Initial results confirm the reinforcing effect of PGF in PLA mechanical properties. Blank PLA samples had a flexural modulus and strength of 2.78 ± 0.06 GPa and 68.1 ± 1.02 MPa respectively. In the case of the 0.25 Vf specimen, the average strength values exceed 200 MPa, being superior or, at the least comparable to those previously reported (Fig. 1)³. Nevertheless, it should be

noted that the composite's flexural modulus (11.33 ± 0.57 GPa) is lower than the predicted using the rule of mixtures (16.65 GPa), requiring fibre contents in the order of 0.5 Vf to reach the upper limit of cortical bone modulus. Since the flexural modulus is highly sensible to the laminate stacking sequence, it can be anticipated that change in such parameter by piling up thinner laminae, will certainly improve the composite properties.

Figure 1. Flexural properties comparison of proposed composite systems and common biomaterials for fixation devices³.

CONCLUSION

Effective bioresorbable implants can be fabricated by compression moulding of PLA and PGF. Further efforts will focus on the close control of fibre orientation and laminating sequence, as we have demonstrated that these parameters are essential to optimise the final mechanical properties of the composite without compromising *in vivo* performance.

Development of a Soft Tissue *in vitro* Model for Ameloblastoma

T. Eriksson¹, S. Fedele¹, R. Day², V. Salih³

¹Eastman Dental Institute, University College London, UK

²Applied Biomedical Engineering, University College London, UK,

³Plymouth University Peninsula School of Medicine & Dentistry, UK; t.eriksson.11@ucl.ac.uk

INTRODUCTION

Ameloblastoma is a rare odontogenic tumour with great infiltrative capacity. It accounts for around 1% of oral tumours and occurs mainly in the jaw bones. Surgery is the main treatment option, however recurrent tumours occasionally occur¹. These recurrences sometimes invade the soft tissue surrounding the jaw bone. Recurrences in the gingivae are most common, but tumours growing into the sinonasal passages, eyes and brain have also been reported². Soft tissue spread of the tumour is difficult to stop, as no non-invasive therapies are currently available³. By creating an *in vitro* three-dimensional model of the tumour using tissue-engineering techniques, we aim to assess the interactions of the tumour cells with the surrounding stroma and the invasion mechanisms the tumour cells use to infiltrate the soft tissue. The model can also be used to test anti-infiltrative agents to stop the growth of the tumour. Here, we present work towards developing an *in vitro* model able to support the inclusion of ameloblastoma tumour cells.

EXPERIMENTAL METHODS

Gingival fibroblast cells (GF) were added to pH neutralised collagen type I gels to create a three-dimensional model. In order to mimic the tissue stroma and ground substance, growth factor-reduced Matrigel (BD Biosciences) was added to half of the gels (2:1 collagen to Matrigel). Plastic compression was then performed to improve the mechanical properties of the scaffold⁴. The optimum cell density was determined by seeding increasing cell concentrations in the gels and measuring contraction over time. Gels were cultured for 14 days and assessed for cell viability with Live/Dead confocal staining using 2uM calcein AM and 4uM EthD-1 (Life Technologies) in PBS. Samples were examined with haematoxylin and eosin staining on formalin-fixed paraffin-embedded sections and transmission electron microscopy (TEM) on resin-embedded samples. Several methods to incorporate cells from the AM-1 cell line into the scaffold were also explored.

RESULTS AND DISCUSSION

Fibroblasts were shown to exert major contractile forces on the scaffolds (fig.1). For further studies a cell concentration which results in minimal contraction, but does not compromise scaffold remodelling will be used. Fibroblasts remain alive and proliferate in both scaffolds during the two-week culture period (fig. 2). The cells were shown to remodel the scaffold and produce extracellular factors seen as large vesicles through TEM.

Further characterisation of the two scaffold types will be carried out using SEM to assess differences in scaffold appearance.

Figure 1: Cell induced collagen gel contraction. Increasing the cell density (displayed per ml of collagen gel) caused increased contraction in compressed gels.

Figure 2: Live/Dead staining of fibroblasts A) Matrigel and collagen; B) collagen-only scaffold on day 14. Green = live cells.

CONCLUSION

These models form the basis for a soft tissue scaffold into which an ameloblastoma tumour model made with the AM-1 cell line will be incorporated. The ability of the scaffold to maintain AM-1 cells will initially be assessed with single-cell culture in decellularised collagen scaffolds. Once incorporated, the ameloblastoma cells in the 3D co-culture scaffold will be analysed both for interactions with the scaffold itself and with fibroblasts, protein production and infiltrative potential. This will allow for identification of any pathways the tumour cells use for tissue destruction. This may lead to development of non-invasive therapies.

Porous Electrospun PCL Fibres for Osteo-Differentiation

Selene Alcantara-Barrera¹, Zandra Flores², Ricardo Vera-Graziano¹, Alfredo Maciel- Cerda¹, L. Araida Hidalgo-Bastida^{2*}

¹ Centro de Biomateriales, Universidad Nacional Autonoma de Mexico, Mexico

² Manchester Metropolitan University, Manchester, UK, *a.hidalgo@mmu.ac.uk

INTRODUCTION

Electrospinning has been used with different natural and synthetic polymers, to produce nanofibres as scaffolds for regenerative medicine. Polycaprolactone (PCL), a FDA approved semi-crystalline biodegradable polymer, presents good mechanical properties, compatible with both strong and soft tissues. However, the PCL hydrophobicity inhibits cell attachment and growth. Our aim in this work was to fabricate porous PCL nanofibres with glucose on the surface, to decrease their hydrophobicity and to promote osteo-differentiation.

EXPERIMENTAL METHODS

Solutions of PCL (Aldrich®) 12% wt were prepared dissolving in chloroform and in the solvents system dichloromethane: N,N-dimethylformamide (80:20). The solutions were electrospun with the following parameters: flow rate 1.0 ml/h, voltage 8 kV, distance (syringe tip-collector) 25 cm. For solutions of PCL with glucose (Sigma-Aldrich®), glucose content was 10% wt respect to PCL, with the solvent system THF: DMF: H₂O (86.5:4.5:9). The scaffolds were analysed by SEM with a JEOL field emission JSM-7600F microscope using a backscattered electrons detector (LABE). The mechanical tests were conducted according to the ASTM D1708-96 norm, using a universal testing machine Instron 5500R at 10 mm/min and 25 °C. The glucose solution in water was prepared with a concentration of 10% wt. Cellular adhesion was evaluated by seeding mesenchymal stem cells (Promocell, Germany) and quantified via Alamar blue and Live/Dead stain (Life Technologies, UK).

RESULTS AND DISCUSSION

The fibre diameter and relative porosity of the scaffolds are shown in Table 1. It was observed that the fibres generated from chloroform solution exhibited larger diameters, 0.5-1.0 µm pores along the fibres (Fig. 1 A).

Fig. 1. SEM micrographs of PCL fibres showing A)Porous fibres:chloroform, B)Non-porous fibres: dichloromethane / N,N dimethylformamide.

The scaffolds obtained with the DCM: DMF (80:20) resulted in thinner fibres without pores (Fig. 1 B). In order to modify the hydrophobicity of these scaffolds, a glucose solution was sprinkled on the surface of both materials, and subsequently compared with PCL. Finally, the solution of PCL containing glucose generates a scaffold constituted by rough fibres with diameter slightly bigger than in the case of DCM: DMF system (Table 1).

The mechanical behaviour of the electrospun scaffolds indicated that porous fibres exhibited a lower tensile value compared to the non-porous fibres; although the porous fibres presented a higher Young modulus than the non-porous scaffolds (Table 1). Fibre's porosity and glucose presence also affected the cellular response (data not shown), although further studies need to be conducted.

SCAFFOLD	FIBRE DIAMETERS (µm)	RELATIVE POROSITY (%)	TENSION (MPa)	YOUNG MODULUS (MPa)
PCL/CF	5.36 ± 0.633	22.79	1.23	11.16
PCL/DC M-DMF	0.91 ± 0.146	29.44	3.48	5.36
(PCL/CF) + gluc	5.36 ± 0.633	< 10	1.23	11.16
(PCL/DC M-DMF) + gluc	0.91 ± 0.146	7.73	3.48	5.36
PCL-gluc/THF-DMF-H ₂ O	1.37 ± 0.41	22.37	NA	NA

Table 1. Fibre diameter, relative porosity and mechanical properties of the electrospun scaffolds.

CONCLUSIONS

The solvent system used in solution is crucial in the final electrospun scaffold morphology, and contributes to the microstructure and porosity of the fibres. This ultimately has an effect on mechanical properties and cellular response, both for biocompatibility and osteo-differentiation.

Atomic Layer Deposition of Silver on High Aspect Ratio Structures for Medical Implants

Zahra Golrokhi

Department of Materials Science and Engineering, University of Liverpool, Liverpool L69 3GH, UK

E-mail: golrokhi@liv.ac.uk

INTRODUCTION

Silver nanoparticles are one of the interesting research topics in recent years. There has been growing interest toward silver nanoparticles use as antimicrobial coatings. Silver nanoparticles release a low level of silver ions to supply defence against bacteria. In this study, we present the synthesis of silver nanoparticles via liquid injection atomic layer deposition (ALD) with precise thickness control by using the saturated growth rate at relatively low substrate temperatures (<130°C).

The characteristic to ALD is a saturated film growth rate which allows conformality and uniformity on high aspect ratio structures [1, 2].

EXPERIMENTAL METHODS

Silver thin films were deposited in the Aixtron AIX 200FE which is a liquid injection ALD designed for various oxide materials on different types of substrates. The flow of the Argon as a carrier gas is controlled by a mass flow controller. The 0.1M silver precursor ((hexafluoroacetylacetonato)silver(I)(1,5cyclooctadiene)) [Ag(hfac)(COD)] was dissolved in anhydrous toluene in a nitrogen glove box. The substrates were Si (100) wafer and soda lime glass (75 × 25 mm²) at the same time for each growth experiment. Silver thin films were deposited at growth temperature of 125-128°C.

Elemental compositions of the surface, morphology and crystal structures of the films were analyzed by XPS, AFM and XRD respectively.

RESULTS AND DISCUSSION

Figure 1 shows the effect of [Ag(hfac)(COD)] dose by varying the dose between 0 and 6s at a growth temperature of 125°C with 2s propanol doses as a co-reactant. The growth rate rapidly increased between 0-2s doses to 0.013 nm/cycle and then saturated above 3s. This confirms that [Ag(hfac)(COD)] is a self-limiting precursor for ALD growth which provides large area uniformity, and the thickness uniformity on high aspect ratio structures.

Figure1. Growth rate as a function of [Ag(hfac)(COD)] dose for propanol (2s) based ALD at 125°C on Silicon.

Figure 2 shows scanning electron microscope images deposited from (hfac) Ag (1,5-COD) as a function of doses on silicon. As the silver dose is increased from 1s to 6s, the silver NPs on the surface reached saturation and consistency.

Figure2. SEM micrographs at different silver doses on silicon substrate at 125°C.

CONCLUSION

Silver NPs were deposited by liquid injection atomic layer deposition technique using pulses of ((hexafluoroacetylacetonato)silver(I)(1,5cyclooctadiene)) [Ag(hfac)(COD)] dissolved in 0.1M toluene solution and pulses of propan-1-ol as a co-reactant.

There has been a significant resurgence of interest in silver NPs due to its diagnostic and antibacterial applications. Current research aimed to develop antibacterial coatings for bio-compatible medical implants with atomic layer deposition technique. However, several related facts were not investigated in detail, and the work is to be continued.

INTRODUCTION

Bioresorbable phosphate-based glasses have been investigated for varying tissue engineering applications¹. The degradation rate of these glasses can be tailored by doping with varying metal ions such as Mg, Fe, Ti, and B². In this study, boron was added at varying quantities in place of phosphate. The effect of boron addition on the glass thermal properties, chemical durability and cytocompatibility was investigated.

EXPERIMENTAL METHODS

Glasses with three different compositions were produced, denoted as P48B12, P45B15 and P40B20. The thermal processing window T_{pw} (i.e. onset of crystallisation temperature T_{con} minus glass transition temperature T_g) of the glasses was investigated via Differential Thermal Analysis. The chemical durability was characterised in phosphate buffer saline at 37°C for 60 days. The cytocompatibility of the glasses was studied by culturing the human osteosarcoma cell line (MG63) directly onto the glass surface for 14 days.

RESULTS AND DISCUSSION

The thermal properties of the glasses in Table 1 revealed that T_{con} and T_c values decreased with the addition of B₂O₃, whilst only slight increases were observed for the T_g values. The thermal processing window (T_{pw}) was observed to decrease with increasing boron content, thus increased glass crystallisation tendency and reduced thermal stability³.

Table 1: thermal properties of glasses with B₂O₃ variation.

Glass code	$T_g/^\circ\text{C}$	$T_{con}/^\circ\text{C}$	$T_{pw}/^\circ\text{C}$	$T_c/^\circ\text{C}$
P48B12	545	800	255	860
P45B15	550	780	230	825
P40B20	555	750	195	770

The degradation study revealed the dissolution rate of P48B12 glass at $3.64 \times 10^{-5} \text{ kg cm}^{-2} \text{ hr}^{-1}$, which increased to $4.23 \times 10^{-5} \text{ kg cm}^{-2} \text{ hr}^{-1}$ for P45B15 and then have a further increase to $5.92 \times 10^{-5} \text{ kg cm}^{-2} \text{ hr}^{-1}$ for P40B20 (Figure 1). The decrease of chemical durability with boron addition was suggested to be due to the P₂O₅ content being replaced by B₂O₃, boron units BO₃ and BO₄ introduced into glass system while BO₃ units were not as resistance as BO₄ units⁴. For all three glasses, the metabolic activity of MG63 cell line (Figure 2) was seen to increase throughout the 14 days culture period. The metabolic activity of cells on P48B12 glasses and

P40B20 glasses were significantly close to tissue culture plastic (TCP).

Figure 1: Weight loss vs time for glass compositions investigated.

Figure 2: Metabolic activity of MG63 cells, (Alamar Blue assay).

CONCLUSIONS

Thermal stability and chemical durability of borophosphate glass decreased with the addition of boron in place of phosphate. Cell culture studies suggested all glasses produced had good cytocompatibility with the MG63 cell line.
